Proseptasine is *p*-benzyl-amino-benzene-sulphonamide, a white tasteless substance made up in tablets of 0.5 grm. for oral administration.

Dosage.—From January to June 1937 we gave two tablets three times daily (3 grm.) for four days.

From July to December 1937 we gave four tablets three times daily (6 grm.) for four days.

The drug was administered to all emergency cases and as early as possible.

Experimental conditions

During the period under test (1937) the conditions have been as constant as is possible in a teaching institution. 1930 to 1935 has been spent in standardizing administration and technique and we consider that since 1935 we have been able to work under conditions that were constant and under control.

1. The hospital technique is controlled by the medical superintendent.
2. The medical staff and the major part of the responsible nursing staff is permanent.
3. Statistics for 3 years have been kept by a group of trained medical officers.
4. No additional treatment has been given during the period in which proseptasine has been administered.
5. The diagnosis of the cause of morbidity has been arrived at after a routine examination.

Causative organisms in general infection

It has not been possible to investigate the bacteriology of the genital tract in the cases admitted during 1937. Nor have we any information regarding the organisms causing genital infection in India. Such information is badly needed and is forming the subject of an inquiry now commencing at this hospital.

Taylor and Wright (1930), examining the bacteriology of the vagina in 1,123 women prior to delivery, found the following:—

	Per cent
Non-hæmolytic streptococci ..	37.8
Hæmolytic streptococci ..	2.7
Pseudo-hæmolytic streptococci ..	1.3
Staphylococci ..	58.8

Margaret Thomas (1930) investigating a group of 800 cases found the following organisms :—

	Per cent
Streptococci ..	39.3
Streptococci and others ..	13.7
Staphylococci ..	16.9

Margaret Thomas's cases were taken from the wards of an isolation hospital, and the proportion of streptococci would naturally be higher than in cases taken from the ordinary maternity wards of a hospital.

King (1930) reporting 236 cases of puerperal infection gave the following figures :—

	Per cent
Streptococcus ..	37.7
<i>Streptococcus viridans</i> ..	6.3
Staphylococcus ..	10.6

3. Obstetric shock is usually present.

4. Multiple vaginal examinations or attempts at delivery have been practised.

5. The case is usually terminated by means of an obstetrical operation.

The morbidity rate has, since 1935, decreased by approximately 5 per cent per annum and it is necessary to consider any factors that may have caused this reduction, having regard to our belief in 1935 that our technique was so standardized that we considered it unlikely to effect the morbidity rate, unless something new was introduced.

During the first 6 months of 1936, 10 c.cm. of concentrated anti-scarlatina serum were administered intramuscularly to all emergency cases admitted. The morbidity rate showed no improvement over the cases admitted during the

Commentary

There is a reduction of morbidity due to genital sepsis from 22.16 per cent (1935) and 16.94 per cent (1936) to 11.45 per cent in 1937 during which time proseptasine was given prophylactically. This reduction has occurred chiefly in the abnormal cases, which are of particular interest, and form a clinical group with the following characteristics :—

1. The membranes are ruptured and infection is potential or apparent.

2. The patient has been in labour from a few hours to a few days.

second six months of the year and to which no serum was given. It was concluded that anti-scarlatina serum (10 c.cm.) was of no prophylactic value.

Since 1936 we have paid greater attention to vaginal lacerations as a cause of genital sepsis. Median episiotomy has also been more extensively practised since 1935. These additions in technique could easily account for the 5 per cent decrease in morbidity for 1936. We do not presume that the additional 5 per cent decrease in morbidity during 1937 was also due to the

ON THE NECESSITY OF TEACHING THE FREQUENCY OF RHEUMATIC INFECTION IN YOUNG INDIANS

By H. STOTT, M.D., F.R.C.P., D.P.H.

LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology, and Physician, King George's Hospital, and Dean of the Medical Faculty, Lucknow University, Lucknow

1. *Historical note.*—Only of recent years has the fact of the occurrence of rheumatic infection amongst Indians become widely recognized. Indeed there are still some who do not recognize the existence of rheumatic fever in India at all, whilst perhaps the majority of medical practitioners in India would affirm that rheumatic infection occurs only rarely. It is mainly by the experience and teaching of the professors and lecturers of the medical colleges of India that this obscurity is now being dispelled.

As long ago as 1886, Norman Chevers in his classical *Commentary on the Diseases of India* remarked on the rarity of acute rheumatism in Bengal. 'The experience of a working life time', he writes, 'has taught me that acute rheumatism is rare in Lower Bengal'. He

(Continued from previous page)

adds to the technique, as we feel that owing to the composition of the staff there was no increase in efficiency in 1937 as compared with 1935. We conclude that the 1937 improvement was due to the prophylactic administration of prosectasine. It is worthy of mention that both the medical and nursing staffs were impressed with the smooth clinical course run by many abnormal cases in which our clinical experience led us to expect complications.

Toxicity.—No ill effects have been observed as a result of the administration of prosectasine. We have administered up to 250 tablets (125 grm.) without signs of toxic symptoms.

Dosage.—The manufacturers recommended 2 tablets (1 grm.) three times daily. We were frankly sceptical as to the possibility of this amount being adequate to produce efficient bactericidal action in the blood. Double the dose produced no improvement in results, and we suggest that much larger doses are indicated.

Although a reduction of 5 per cent is not very striking, we feel that it is encouraging enough to advocate further investigation with very much increased dosage.

quotes Malcolmson as having made a similar observation as regards Madras in 1835, 'The common acute rheumatism of Europe is very little known in India', but Morehead of Bombay remarked with greater vision that 'Acute articular rheumatism is not so common in India as in colder climates, yet it is by no means rare'.

Rogers (1910) wrote concerning 'the extreme rarity of rheumatic and scarlet fever in India, and specially in Bengal' and 'the great rarity of true acute rheumatic fever in India...'

Megaw (1910) wrote 'on the causation of heart disease in Europeans in India' and investigated two series of heart cases amongst Europeans and Anglo-Indians at the Presidency General Hospital, Calcutta. The first series consisted of 144 cases from 1906 to 1908 and contains 37 cases which were clearly rheumatic, of which 12 contracted their disease in India (4 in the hills and 8 in the plains) whilst 21 were contracted in Europe and 4 were doubtful. One case of chorea was admitted. The second series included 43 cases which Megaw personally investigated in 1909, of which 14 were clearly rheumatic and of which 4 only (one with chorea) were contracted in the plains of India. 'It seems safe to conclude that rheumatism of the type with which endocarditis is associated does definitely occur in the plains of India, but that it is much less common than in colder climates'.

Sir Leonard Rogers (1919) wrote 'Tropical countries differ in a remarkable way from temperate in the almost complete absence of rheumatic fever. Rheumatic fever does occur in hill stations in the Himalayas with European temperatures, but is scarcely ever seen in the hot plains. As a result of the absence of both rheumatic fever and scarlet fever heart diseases differ widely in their incidence. Other affections due mainly to syphilitic atheroma are very common, and organic diseases of the mitral valves proportionately rarer'.

Dr. Basu (1925), Teacher of Medicine, Calcutta Medical School, analysed 446 hospital and private patients examined by him from July 1919 to March 1925 and found (a) that 8 per cent of his total 446 cases, (b) that 57 per cent of his 28 cases of acute endocarditis, and (c) that 47 per cent of his 35 cases of chronic endocarditis were of rheumatic origin. On examining the details of his figures, these percentages certainly do not appear over-estimated. Dr. Basu added that mitral disease is rare, because rheumatic fever is rare in Bengal.

J. T. Clarke (1930), after an exhaustive study of available records, suggested that the disease is practically non-existent in the 'true' tropics. He confines his observations to the strict geographical tropics, and though he quotes the evidence of Calvert and Sutherland to the effect that they had seen rheumatic fever, chorea and nodules in Indian children, which conditions they regarded as rare, he disqualifies this evidence on the grounds of geographical limits. He further quotes Rogers as stating that out of 4,800

post mortems in Calcutta only one showed rheumatic carditis.

Sir Leonard Rogers wrote (Rogers and Megaw, 1930):

Deaths from circulatory diseases in the Indian series are just one half of those in the London one. The essential cause of this great difference is the remarkable absence of rheumatic fever and its sequelæ amongst Bengalis. In 4,800 Calcutta post mortems over 37 years only one death was returned as due to rheumatic endocarditis, and that was in an Anglo-Indian who had probably visited a cold climate; there was also only one case of possible rheumatic pericarditis. Moreover, among several thousand specimens in the Calcutta pathological museum accumulated during eighty years, there is only one described as rheumatic endocarditis in an Indian subject and that may well have been of pneumococcal or septic origin, as during twenty years' post-mortem experience the writer found all his endocarditis cases to be due to that class of organism. It may therefore be held that reliable evidence of the occurrence of rheumatic endocarditis in Bengal is still lacking. My collaborator, J. W. D. Megaw, agrees that rheumatic endocarditis is much less common than in Europe, but is by no means rare in Lucknow and not infrequent even in some places where the winter season is not really cold.

In 1923, I became interested in this question, soon after being appointed as physician to King George's Medical College Hospital. During the following years a large number of cases of mitral stenosis amongst young Indians, mostly with congestive heart failure, were admitted to the medical wards. It was the cause of this not uncommon mitral stenosis which first aroused my interest. In personal discussion with responsible teachers from medical colleges of all provinces of India and with Indian practitioners and civil surgeons of long experience, I found uniform agreement that undoubtedly definite clinical cases of acute and subacute rheumatic infection did occur in Indian children and young adults, and that the cause of mitral stenosis in India, as in England, was preceding rheumatic infection. Lieut.-Colonel Sandes, I.M.S., Professor of Medicine and Physician to Medical College Hospitals, Calcutta, told me he frequently recognized acute and subacute rheumatic infection in young Indians in his wards in Calcutta.

In 1930 one series of observations was published in this journal under the title of 'On rheumatic infection as a cause of mitral stenosis amongst young Indians'. In that article, I concluded, from my personal experience, in the following words:—

(1) Congestive heart failure following mitral stenosis is quite common in young Indians between 12 and 18 years of age in the United Provinces.

(2) Acute articular rheumatic fever does affect young Indian adults.

(3) Some acute rheumatic fever cases are observed to progress to peri- and endocarditis.

(4) Subacute (carditis) was more difficult to recognize in Indian children even than in European children, for such children were not often brought to doctors and doctors have not been so far fully taught of its occurrence.

(5) Irreparable advanced mitral disease and congestive failure in young Indian adults is an index in India, as in England, of preceding unrecognized subacute

(6) Other possible causes of the common mitral stenosis in young Indian adults could be eliminated, e.g., (1) congenital abnormality, (2) degenerative diseases, and (3) other infections (streptococcal, pneumococcal, scarlet fever, influenzal, syphilis, etc.).

(7) The impression that those who had considered the typical of rheumatic fever (i.e., in cold damp climates) that rheumatic infection would not exist in warm climates such as India cannot be upheld.

Professor Hughes and Yusuf (1930) of the K. E. Medical College, Lahore, wrote 'Heart affections are met with much less often in tropical and in sub-tropical countries than in temperate regions, the difference being largely accounted for by the rarity of rheumatic fever in the former'. (Both these remarks may, in 1937, be considered open to revision.—H. S.) 'This fever probably varies in incidence and type in different parts of the tropics. In the textbooks of tropical medicine it receives little or no attention'. Hughes then describes 35 heart cases, 31 of which were treated in the Medical College Hospital, Lahore, between 1st October, 1929 and 30th April, 1930, being 5.6 per cent of the total admissions to those medical wards, all except one being a Punjabi Indian. Nineteen of the 31 cases had mitral stenosis. The Wassermann reaction was negative in all except two cases, with aortic regurgitation. In five mitral cases, subacute multiple arthritis existed and 13 gave a history of painful swollen joints. Gonorrhœa, syphilis and other specific causes were excluded as far as possible. Hughes concludes:

In the Punjab, heart lesions, especially of the mitral valve, often bear an ætiological relationship to a disease in certain respects resembling rheumatic fever of temperate climates. This disease shows some or no heart signs with a strong tendency to relapse. Sometimes successive attacks of arthritis are followed by mitral lesion. Some patients complain of rheumatic attacks for years before they come under observation. Unhealthy tonsils occur. The joints swell and become tender, sometimes abruptly, with some fever (102° or 103°) and subside quickly after two or three days. More often the joints swell and subside slowly. Usually there is little fever. The ankles, knees and wrists are most often affected, usually with some stiffness. Response to salicylates was not marked. No cases of rheumatic nodules or of chorea were seen. In short, the mitral disease of these patients seems to be an infection generally subacute or chronic which like rheumatic fever affects the heart or the joints or both together. Whether it is actually a variety of rheumatic fever it is difficult to say, but it is obviously an analogous condition. Possibly it also caused the aortic disease in three cases in which the mitral valve also was affected.

In 1931 Professor Hughes and Yusuf became more definite. Referring to the 1930 series they then wrote:

Attention was drawn to the fact that in the Punjab rheumatism is an important cause of valvular heart disease, especially of mitral stenosis. Although most frequent in pubescent and young adults it resembles the rheumatic fever of children in temperate climates. Acute arthritis is seldom seen, the disease usually taking a subacute or chronic course with a strong relapse tendency. In some cases with typical heart lesions the history indicates little or no involvement of the joints and in these the cardiac condition is

generally either discovered in routine examination or escapes detection until compensation fails. The joints most frequently attacked are the ankles, knees, wrists, elbows and small joints of the hands and feet but almost any joint may be affected. In the more acute cases especially, the disease first appears in one or two joints and spreads to others a day or so later. We have not seen rheumatic nodules or chorea in any patient, but tonsillitis is sometimes present.

Professor Hughes further now reports the occasional occurrence of uncomplicated aortic regurgitation of rheumatic origin. The two patients were 18 and 21 years old, with well-marked aortic incompetence who gave typical histories of rheumatism but showed no mitral lesion. They were admitted for lobar pneumonia and for malaria, respectively, and the aortic lesion was found only on routine examination. There were no complaints of cardiac trouble; blood pressure 115/40 and 132/50. Wassermann reaction was negative in both cases. The occurrence in India of uncomplicated aortic regurgitation of rheumatic origin was thus substantiated.

Lieut.-Colonel Hodge (1932), now Professor of Medicine, Medical College, Calcutta, reported fourteen selected cases of rheumatic fever from Bengal :

In Bengal the incidence of rheumatic fever is generally accepted. The writer has seen a number of unmistakable cases of rheumatic fever in Chittagong, Chinsura and Darjeeling and Jalpaiguri. Twelve cases are quoted—12 being in children 5 of whom showed chorea and 2 pre-choreic symptoms.

In 1932-33 some ten letters appeared in the correspondence columns of the *British Medical Journal* on 'Acute rheumatic infection in the tropics' (Clarke, Hughes, Keates, Mackinon, 1932), (Clarke, Ross, Dutton, 1933).

The evidence of those against its occurrence carried little weight. Three quotations are appended : (1) 'Twenty-five years of civil surgery in the Punjab has convinced me that rheumatic infection is practically non-existent amongst the indigenous population. If rheumatic fever were at all prevalent, surely one would see cases of mitral disease. I have never seen a case of primary disease of the mitral valve. In 600 post mortems at Amritsar I never saw any evidence of inflammation of the mitral valve'. (2) Rheumatic fever is a disease of temperate climates, and even if I am incorrect in saying that none occurs in the tropics, it is so rare there that I have no doubt that some special difference between temperate climate countries and the tropics will ultimately give the clue which should help to elucidate the cause of this disease'. (3) 'A transfer to the tropics seems to be the best though unfortunately an expensive treatment for rheumatic fever'.

On the other hand, this correspondence produced letters of weight from Lieut.-Colonel Hughes, Professor of Medicine, Medical College, Lahore, and from Lieut.-Colonel Dutton,

Principal and Professor of Medicine, Medical College, Patna.

Lieut.-Colonel Hughes wrote :

There is no doubt whatever that (1) at present rheumatic fever whilst not prevalent is by no means uncommon amongst the indigenous population of the Punjab, and (2) that mitral disease is a frequent result of rheumatic infection. I have heard from a colleague of two patients with rheumatic chorea in the same Indian family who both suffered from mitral disease as well. One died of cardiac failure. At the Medical College, Lahore, mitral disease occurred seven times (3.5 per cent) in 200 consecutive post mortems.

Lieut.-Colonel Dutton (1933) wrote :

Experience of my ward cases showed that typical acute rheumatism, rheumatic endocarditis and chorea were quite numerous during the cold weather and reacted to appropriate anti-rheumatic treatment. Many children were admitted with typical rheumatic endocarditis which developed into mitral stenosis, proved later by post mortem. A considerable number of chorea cases were admitted and cured by anti-rheumatic treatment only. There is no doubt whatever in my mind that acute rheumatism with endocarditis is almost as common in India during the cold weather in those provinces which have really cold weather as it is in any temperate climate.

From Vizagapatam, Madras, Kutumbiah (1935) and from Calcutta Banerjea (1935) have published their series of cases of rheumatic heart disease.

Gunewardene (1935) wrote in his *Heart Disease in the Tropics* : 'There is overwhelming clinical evidence that rheumatic fever and its complications are certainly met with in the tropics. In a paper read before the Ceylon Branch of the B. M. A. recently Dr. Cyril Fernando gave notes of 40 cases of rheumatic fever in Ceylon showing convincing evidence that all the usual sequelæ of rheumatic fever are met with in the tropics'.

In 1936 from Miraj in the Bombay Deccan, i.e., well within the true tropics, Dr. Carruthers (1936) of the American Presbyterian Hospital published an excellent study of rheumatic heart disease in Bombay Deccan.

Dr. Carruthers reported his experience at Miraj, Bombay Deccan, and concluded that :

1. Rheumatic fever, as shown by the presence of rheumatic heart disease, although not as prevalent as in other parts of the world, nevertheless is a common condition (in Indians) in the Bombay Deccan.
2. The percentage of heart disease that is rheumatic in origin is greater than in other parts of the world.
3. There would seem to be a slight but definite tendency to a later age of onset in rheumatic heart disease in the Deccan (see table).
4. The percentage of rheumatic heart disease without clinical evidence of rheumatic fever is no greater in the Deccan than elsewhere.

Carruthers' 100 heart cases were admitted over the two years 1933-35 forming 5.08 per cent of the total 1,967 medical admissions. Forty-seven per cent of the heart cases were of rheumatic origin, forming 2.44 per cent of the medical admissions.

In Kutumbiah's Vizagapatam series 43.2 per cent and in Banerjea's Calcutta series 33.2 per cent resulted from rheumatic disease.

The age of onset is shown in the following table compared with Cabot's (1926) English figures :

	Bombay Deccan	England
Below 10 years ..	8 or 17.02 per cent	45 or 18.8 per cent
" 20 " ..	21 or 44.68 "	125 or 52.3 "
" 30 " ..	31 or 68.68 "	172 or 72.1 "

Of the 47 Deccan cases, 36 were males and 11 females. The table shows a slight but definite tendency to a later age of onset in India*. Of the Deccan cases, 74 per cent gave a definite history of joint pains and 25 per cent showed these in hospital. There were no choreas. Thirteen or 27 per cent died in hospital, and 7 had autopsies, six showing mitral sclerosis.

Finally in 1937 a note on the prevalence of acute rheumatic infection and of rheumatic endocarditis in India was required for the Office International d'Hygiene Publique to be held in Paris in October 1937, to which end the Public Health Commissioner with the Government of India sought information from the provincial directors of public health and from the annual provincial hospital returns. I had the privilege of reading their replies, which may be thus summarized : Official public health opinion holds that acute rheumatic fever and acute rheumatic endocarditis do exist all over India, but the official opinion is still, with few exceptions, that the prevalence of rheumatic fever is 'rare' or 'very rare'. The medical returns from civil hospitals under 'acute rheumatism' are utterly unreliable since fibrositis, myalgias, arthritis, and many joint conditions, both acute and chronic, are all almost invariably dumped indiscriminately under this head.

2. *Incidence.*—The comparative prevalence of rheumatic fever between India as a whole and other countries, e.g., England, and between the different provinces and areas of India in the present absence of sufficient diagnosis and of accurate statistics is naturally difficult to determine. Statistics for admission to the hospitals of medical colleges and schools and statistics of post mortems done in such teaching institutions would provide the most reliable figures available. Allowance however must be made for 'tropical diseases' which swell the 'total' medical admissions for all causes, and the 'total' post mortems performed in India and which do not of course influence European statistics. The rheumatic fever admission rate and the post-mortem rate in India would be greatly reduced as compared with those of non-tropical countries.

About one-tenth of the total medical admissions and about one-third of total post mortems performed in medical college hospitals are for 'tropical diseases'. Even with this allowance,

the figures indicating the true rheumatic fever prevalence rate would be higher in India than those returned because it is only comparatively recently that the not uncommon prevalence of rheumatic fever in India is being recognized, and also because subacute rheumatic infection in Indian children is so difficult of diagnosis. After all it is only comparatively recently in England that the diagnosis and frequency of early rheumatic infection has been clarified.

3. *The stenosis rate or the mitral rate as an index of rheumatic infection.*—The admission rate for acute rheumatic fever or for acute rheumatic carditis (endo- or peri-, or both) only is often regarded as an index of the prevalence of rheumatic infection. But a more reliable index and one easier to obtain is the hospital admission rate for mitral stenosis or for primary mitral disease (stenosis and regurgitation) or for heart failure from mitral disease specially under 30 or 40 years of age. From such primary-mitral-disease figures all cases secondary to aortic disease and degenerative arteriosclerotic lesions, or to myocardial degeneration are of course excluded. At least 95 per cent of all cases of mitral stenosis and probably also of primary mitral disease under 30 or 40 years are due to preceding rheumatic infection. Mitral stenosis or primary mitral disease as an index of preceding acute rheumatic infection is just as reliable an index, or even more so, than is the spleen rate as an index of preceding acute malaria. Such a standard might be well known as the 'stenosis' or mitral rate of rheumatic infection. Such a 'stenosis' rate would include cases due not only to acute but also to subacute and to chronic preceding rheumatic infection.

The post-mortem diagnosis of mitral stenosis, or of mitral valve disease, under 30 or 40 years of age, at the various medical schools of India is reliable, and the proportion of mitral stenosis cases furnishes some rough guide as to the frequency and distribution of acute rheumatic infection. From such statistics those due to tropical diseases have to be excluded when dealing with countries in which tropical diseases are not endemic.

4. *The post-mortem incidence of acute rheumatic infection and of mitral disease post mortems at Indian Medical Colleges.*—In 1925, I collected and analysed the statistics of 10,937 post mortems performed up to that date in the medical colleges of India (Calcutta, Patna, Lucknow, Lahore, Bombay and Madras), with Rangoon and Colombo as representatives of the Near East, also of 4,130 post mortems from the medical colleges of Hong Kong, Singapore and Java as representatives of the Far East, and compared them with 4,378 post mortems from Guy's and St. Mary's Hospital, London, whilst Dr. Ophuls, Professor of Pathology at Stanford University, San Francisco, U. S. A., was good enough to provide me with a comparative series of 3,912 post mortems to indicate the American

* This difference would not satisfy any statistician.—
Editor, I. M. G.

figures. From the Indian and 'Far East' American figures all tropical diseases, i.e., diseases not occurring in England, were excluded, so that some rough comparison becomes possible as to the incidence of rheumatic and of primary mitral diseases amongst these 19,659 post mortems.

The following table indicates that rough comparison but obviously too great importance should not be attached to such figures. They can only serve as some basis for further investigation and discussion.

frequency. (3) Whereas most cases dying in hospital are post-mortemed in London, only 'unclaimed' bodies can be post-mortemed in most medical colleges in India. However, these figures are the most accurate at present available.

If the percentage frequency of rheumatic and of mitral disease combined is worked out on the post mortems performed for deaths from circulatory system disease (which probably gives a true figure) the percentage for India and for London is precisely similar (*vide* Table II).

TABLE I

Post-mortem diagnosis	IN THE MEDICAL COLLEGES OF				TOTALS
	India, Rangoon and Colombo	Hong Kong, Singapore and Java	London: Guy's and St. Mary's	San Francisco, U. S. A.	
1. Rheumatic endocarditis	60	0	119	1	180
2. Mitral disease	145	25	43	56	269
3. (1 + 2)	205	25	162	57	449
4. Total post mortems less 'tropical' ..	8,568	3,027	4,378	3,786	19,759
5. Percentage of 3 to 4	2	0.8	4	2	2.2

So far as the figures go, it would appear that post mortems are done for rheumatic endocarditis and for mitral disease combined twice as frequently in London as in India and San Francisco, and four times as frequently as in Hong Kong, Singapore, and Java. There are however obvious fallacies: (1) Although tropical diseases are excluded from the Indian series, yet undoubtedly such diseases do influence the

Moreover, if the figures for India and for London be further analysed (*see* table III), the interesting inference can be drawn that in India possibly preference is given to diagnosis of 'mitral disease' rather than to one which more definitely indicates the probable causative factor.

The American figures of post mortems for circulatory disease include a very large number

TABLE II

Post-mortem diagnosis	IN THE MEDICAL COLLEGES OF				TOTALS
	India, Rangoon and Colombo	Hong Kong, Singapore and Java	London: Guy's and St. Mary's	San Francisco, U. S. A.	
1. Rheumatic endocarditis	60	0	119	1	180
2. Mitral disease	145	25	43	56	269
3. (1 + 2)	205	25	162	57	449
4. Total post mortems 'circulatory diseases' ..	807	49	631	1,255	2,742
5. Percentage of 3 to 4	25	50	25	2	14

post-mortem figures, e.g., many cases are diagnosed post mortem as anæmia (which is not excluded) and many of these are probably due to ancylostomiasis and to malaria. (2) The post-mortem figures are previous to 1925; since then in India the knowledge of the prevalence of rheumatic fever has increased and this knowledge may to some extent influence the diagnosis

due to arteriosclerosis, atheroma and other degenerative cardiovascular diseases, so that a comparison becomes difficult.

It is of some interest to examine the relative frequency of rheumatic and mitral post mortems at the different Indian medical colleges. These are set out below (table IV), but here again too much reliance should not be placed on

TABLE III

Post-mortem diagnosis	INDIA, RANGOON AND COLOMBO		LONDON: GUY'S AND ST. MARY'S	
	Actuals	Percentage of circulatory post mortems	Actuals	Percentage of circulatory post mortems

2. Mitral disease	145	18	43	7

deductions drawn from them. Further investigation is required.

As judged by these post-mortem figures, the order of frequency of post mortems for combined rheumatic endocarditis and mitral disease is

low-lying areas near the sea coast or rivers, especially where liable to floods, and during heavy rains, *e.g.*, in the hills during the monsoons when rain falls and the diurnal range of temperature is maximal. Damp clayey soils for

TABLE IV

Post-mortem diagnosis	IN THE MEDICAL COLLEGES OF								TOTALS
	Calcutta	Patna	Lucknow	Lahore	Bombay	Madras	Rangoon	Colombo

(1) Lahore, (2) Lucknow, (3) Colombo, (4) Bombay, (5) Rangoon, (6) Madras, and (7) Calcutta. If the Guy's and St. Mary's London figures (25 per cent + 4 per cent) were added they would be placed fourth or fifth after Colombo or Bombay.

5. *The importance of rheumatic infection.*—This lies not in the initial attack, nor in the relapses, but in the gradual progressive fibrosis of the mitral valve which so often follows and which kills the young Indian patient in his late teens or early twenties. Three questions of practical importance arise: What are the ætiological factors? Why are more cases of rheumatic infection not diagnosed? What steps are required to improve the diagnosis?

6. *Ætiological factors in acute rheumatic infection.*—The available figures are not yet sufficiently scientific nor numerous in India to decide with reference to such ætiological factors as sex, caste or area of frequency. There seems little doubt however that as in Europe the incidence falls far more heavily on the poor and especially on those ill-nourished and debilitated by previous disease and infection. Moreover, the incidence may be expected to be greater (as elsewhere throughout the world) in cold and damp seasons, areas and dwellings, *e.g.*, in

obvious reasons also predispose. Dry hot areas (*e.g.*, near the Sind desert) may be expected to furnish a low incidence. More direct predisposing conditions are pharyngeal catarrhs, recurrent tonsillitis and exposure to chill by permitting the causative germ of rheumatic infection to enter the system through this portal. Adequate preventive measures are thus indicated: good dry warm housing, climates, soils and clothing, good food and physique, a healthy nasopharynx and a sufficient income. On theoretical grounds some believed that rheumatic infection would be rare in the tropics because heat and its attendant perspiration are preventive and curative. A well-recognized ætiological factor is damp cold *plus* a draught which produces a 'chill'. Dry cold is not a usual precursor unless there be a chill of exceptional severity. But in India sudden chills after free perspiration are very common. A great draught in conditions of great humid heat and great perspiration, but with little fall in general atmospheric temperature, will produce an individual chill as readily as a lesser draught with lesser heat and perspiration with a considerable general climatic fall in temperature.

7. *Why are more cases of rheumatic infection not diagnosed?*—Some reasons why more

cases are not diagnosed in Indian children are : (1) The existence and prevalence of rheumatic fever in India have only recently been generally recognized, and in fact is even now questioned and at times denied by some outside medical teaching colleges and schools. Even now, most authorities speak of it as 'rare' or 'very rare'. (2) The general unwillingness of Indian families to bring their children or young adults to hospital and to leave them in hospital without relatives, and that for an apparently trivial illness which in its subacute form displays only moderate fever with limb or joint pain and not those with striking and dramatic symptoms which are typical of some diseases with which Indian families are readily familiar, *e.g.*, cholera, tetanus, rabies, etc. Parents are not alive to the serious cardiac conditions which may not infrequently arise. (3) The want of special accommodation and of special physicians for children's diseases in India, *e.g.*, the comparative absence of children's beds, of children's wards, of children's hospitals, and of special out-patients for children with physicians specializing only in children's diseases, not only in the hospitals attached to medical colleges and schools (where they are essential) but also in time in all civil, Dufferin and private hospitals. (4) The diagnostic difficulty. Moderate fever for a week or two even with severe joint, limb or heart pain is not recognized as serious in a country where severe fever often with severe febrile pains is of daily occurrence. (5) The want of better teaching by children's specialists in Indian medical colleges and schools, both undergraduate and post-graduate. Hence, the present generation of medical men, whether of degree or licentiate standard, is not as fully trained as they should be in the diseases of children.

8. *Steps required to improve diagnosis* may be mainly summed up within the two words, education and provision, *e.g.*—(1) Information to medical officers in Government service, by circulars from the administrative medical officers and through their post-graduate classes, and to private practitioners, by articles to the medical press and by papers read before medical associations and societies. (2) Special attention by the school medical service and medical inspection of school children. (3) Teaching by specialists in the diseases of children to all medical students in their curriculum as now laid down by the Medical Council of India. (4) A definite quota of questions on children's diseases in all parts of the appropriate qualifying examination papers and *viva voce*, *e.g.*, in medicine, pathology, hygiene, obstetrics and surgery. (5) Instruction to nurses, preparing for the Nursing Certificate examinations of the provincial State Medical Boards. (6) The general public information concerning the occurrence and prevalence of rheumatic infection and of its sequelæ, through the public health services, the Red Cross, women and child welfare centres, with their health visitors and midwives, with

lectures to the educated public and especially to mothers through such agencies. (7) By providing special children's hospitals, wards, beds and out-patients in all medical colleges and medical school hospitals and as soon as possible in all hospitals and dispensaries. (8) A revised and more accurate nomenclature in diagnosis and the annual hospital returns, *e.g.*, not 'acute rheumatism', which might reasonably include acute lumbago or acute sciatica, but 'acute rheumatic' infection, to include acute rheumatic fever (polysynovitis), acute rheumatic carditis (peri- and endo-), rheumatic chorea, and nodules and chronic rheumatic mitral disease.

Summary

1. Recent views concerning the occurrence of acute and chronic mitral rheumatic infection in India are reviewed.

2. The experience of teaching physicians attached to medical college hospitals that such infection most certainly occurs in all its forms and is not uncommon is noted.

3. In comparing the incidence of rheumatic infection in India and Europe, and throughout India, the most reliable standards would be (a) the hospital admission, (b) post-mortem rates of the Indian medical colleges and schools, and (c) the clinical experience of their attached physicians.

4. Allowance must however be made for tropical diseases which affect the Indian as compared with European admission and post-mortem rates.

5. A stenosis rate or mitral rate is suggested as a more reliable index for the incidence of rheumatic infection than an admission rate for acute rheumatic polyserositis or carditis.

6. Amongst 10,937 post mortems from the medical college hospitals of India the incidence for acute and chronic mitral endocarditis combined was 2.2 per cent of the total post mortems and 14 per cent of the post mortems for total circulatory diseases.

7. If the post-mortem rate for rheumatic mitral (7 per cent) disease and for primary mitral disease (cause unspecified) (18 per cent) be added together the same figure is reached for India as in London post mortems (18 per cent for rheumatic and 7 per cent for unspecified). It would therefore appear in India that primary mitral disease (of young adults) is not so far recognized as being mainly due to rheumatic infection.

8. The relative order for acute rheumatic infection and for mitral disease as judged by those 1925 figures at the Indian medical colleges is (1) Lahore, (2) Lucknow, (3) Colombo, (4) Bombay, (5) Rangoon, (6) Madras, and (7) Calcutta. But future investigation will make large differences in these figures.

9. The importance and ætiology of rheumatic infection is briefly referred to.

POST-ARSPHENAMINE BLOOD DYSCRASIAS

By R. V. RAJAM, M.B., M.S. (Mad.), M.R.C.P. (E.)
Veneral Specialist, Government General Hospital,
Madras
and

R. BALACHANDRAN TAMPI, M.B., B.S.

Blood dyscrasias as a result of modern anti-syphilitic treatment are relatively rare and grave complications. The literature on the subject is scanty. Folley and Moore claim to have described the first case in the American literature. McCarthy, Loveman and Wilson have recorded seventy cases in their special study on the subject. In general, blood dyscrasias following the administration of arsphenamines are characterized by the symptomatic and pathological expression of depressed bone-marrow function, the type of reaction depending upon the type of injury and the particular elements affected. Piney's (1931) hæmatological studies have confirmed the fact that a condition resembling agranulocytosis produced by benzol poisoning is rarely caused

(Continued from previous page)

10. Some steps required to improve the recognition of the prevalence of rheumatic infection are detailed.

by salvarsan and similar substances. The following figures are quoted by Moore (1933) to show the relative frequency with which each preparation of arsenic produces this group of toxic reaction :—

Arsphenamine	..	10 cases
Neo-arsphenamine	..	43 "
Sulpharsphenamine	..	14 "
Silver-arsphenamine	..	1 "

Aubertin, Blanestein and Lehmann have observed two cases of agranulocytosis in syphilitic patients after treatment with acetylarsan. These patients according to their report had also severe anæmia. No cases have been so far reported with tryparsamide. Though the above figures show that the neo-arsphenamine group produces the greatest number of blood reactions, it is considered by the Council of Pharmacy and Chemistry of the American Medical Association that sulpharsphenamine is the worst of the offending agents.

Clinically four different types of reactions are described :—

1. Symptomatic purpura.
2. Thrombocytopenic purpura.
3. Agranulocytosis.
4. Aplastic anæmia.

There may occur a combination of these syndromes. The frequency of each type is shown by the following figures in the reported cases :—

Thrombocytopenia	..	12 cases
Thrombocytopenia with agranulocytosis	..	7 "
Agranulocytosis	..	15 "
Aplastic anæmia	..	36 "

This depends upon the degree of damage to the thromboplastic, leucoblastic and erythroblastic tissues, respectively. In the severe type of aplastic anæmia the hæmopoietic activity of the bone marrow is completely suppressed and all the formed elements are thereby involved.

The clinical picture of thrombocytopenia is essentially one of purpuric hæmorrhages from the skin, mucous membrane and viscera. Blood platelets are markedly diminished. The other elements are usually not affected. Recovery is said to be the rule.

In the other type of cases with granulocytopenia, fever, and soreness of the throat, with or without necrosing ulcerations of the bucco-pharyngeal tissues, are the usual signs. A blood count reveals the marked fall of leucocytes caused by an absolute granulocytopenia. Very low figures down to 136 per c.mm. are reported. Other septic complications may set in with lethal termination. In cases associated with platelet deficiency purpuric hæmorrhages and visceral hæmorrhages may complicate the picture. Usually the anæmia associated with this group of disorder is slight and non-progressive. The gravest of all the types is aplastic anæmia. Progressive anæmia is evident from the onset in addition to thrombocytopenia and agranulocytic symptoms. The course is downhill. Blood shows a progressive and often rapid

reduction of all the elements. The aplastic nature of hamopoiesis is well demonstrated by examination of bone-marrow smears.

It has been generally observed that blood changes occur late in the course of treatment. Moore is of opinion that excessive dosage plays no apparent rôle. The prognosis is rather grave in all this group of reactions. Aplastic anæmia is attended with the highest mortality (80.5 per cent) while death due to thrombocytopenia has not been recorded so far. It is surmised that the probability of survival is in direct proportion to the extent of damage to the bone marrow.

Regarding the mechanism of production of blood dyscrasias by arsphenamines, it is thought that the benzene radical is the toxic factor. The latter is supposed to exert a direct inhibitory action on the bone marrow, which may explain the leucoblastic and erythroblastic reactions. The acute onset of thrombocytopenia, however, has led to the suggestion that the platelets are directly destroyed while in the peripheral circulation. Another explanation that may be considered plausible in this connection is that perhaps similar to benzol, arsphenamines exert toxic action first on the megakaryocytes much earlier than on the leucoblastic and erythroblastic elements. That these complications are due to the drug administered are also shown by the fact that sometimes regeneration of the different tissues and elements occurs on the withdrawal of the toxic agents.

Why is it that in only a few patients the bone marrow succumbs and shows hypoplastic or aplastic manifestations, though all under treatment are exposed to the same type of poison? This has led to the suggestion of a constitutional predisposition as the determining factor. In the opinion of Voegtlin quoted by Hamilton no explanation of these cases other than a peculiar idiosyncrasy can as yet be given. Still another view shared by Whitby and Britton (1935) is of a congenital deficiency of bone marrow in such cases.

With this short review, as a preamble, three cases are reported for discussion. The following three cases occurred in the venereal department of the General Hospital, Madras, from 1931 to 1937. These are the only three cases that have been observed so far:—

Number of cases of syphilis treated in the department from 1931 to 1937 .. 18,620

and
Number of injections of arsenicals given during the same period .. 64,101

Case 1.—A male, aged 22, attended the venereal out-patient department, on 22nd July, 1933, for late secondary syphilis. Blood Kahn and Wassermann reaction were both strongly positive. Weekly injections of neo-salvarsan and hypoloid bismuth were started. He had a total of 0.95 gm. of neo-salvarsan and 3 c.cm. of hypoloid bismuth. He took the last injection on 7th August. On 9th August, he was admitted as an in-patient in the venereal department for bleeding per rectum, epistaxis and bleeding from the

gums. His general condition was fair. Both the conjunctivæ were congested. There were no purpuric spots on any part of the body. The motions were tarry. Urine—normal.

Blood count showed the following:—

Red blood cells	..	4,650,000 per c.mm.
White " "	..	8,125 "
Differential count:—		
Polymorphonuclears	..	64.0 per cent
Lymphocytes	..	24.6 "
Mononuclears	..	8.6 "
Eosinophils	..	2.8 "

Blood platelets—14,762 per c.mm. He was given calcium thiosulphate 10 c.cm. of 10 per-cent solution intravenously and $\frac{1}{2}$ c.cm. of 1 in 1,000 adrenaline daily. Bleeding from the gums stopped after two days. He was given also 20 c.cm. of horse serum intravenously and 20 c.cm. intramuscularly. He was discharged on 24th August at his request. No further arsenical injections were given to him. The platelet counts on successive days were as follows:—

10-8-1933	..	12,500 per c.mm.
11-8-1933	..	20,000 "
12-8-1933	..	20,000 "
13-8-1933	..	20,000 "
14-8-1933	..	20,000 "
16-8-1933	..	50,000 "

Case 2.—A male, aged 25, attended the venereal out-patient department, on 25th April, 1937, for multiple penile sores which he developed five days after exposure to infection. Dark-ground examination was repeatedly negative for the *Spirochaeta pallida*. Both Wassermann reaction and Kahn of the blood were repeatedly negative, even after 0.3 gm. neo-salvarsan provocative injection. He was given gradually increasing doses of Dmeleos vaccine intravenously, starting from 1 c.cm. There was no improvement of the condition. Later Fouadin was tried and he had 51 c.cm. in all, again with no improvement. In spite of the negative dark-ground and serology, anti-syphilitic treatment was started on 28th June. He had a total of 12 injections (36 c.cm.) of acetylarsan twice weekly and four weekly injections (4 c.cm.) of bismostab. The ulcers were healing under this regime of treatment. The last injection was given on 10th August.

On 16th August he sought admission on the medical side for fever and bleeding from the gums—eight days' duration. Condition on admission—temperature 103.8°F., pulse 110 and respiration 28 per minute. Chart 1 shows the course of the temperature. Blood

CHART 1

Name—Ramchandra. Age—25.

pressure 110/58. There was nothing abnormal in the other systems. The temperature showed a steady rise up to 105°F. on 23rd August. Bleeding from the gums

became worse, the general condition became progressively low and on 23rd he expired. There were no lung signs or throat ulceration. The following table shows the blood changes and treatment adopted:—

received a total of 3 gm. of neo-salvarsan and 4 c.cm. of bismostab. The sore was responding well. The last injection was given on 6th September. He was suddenly taken ill on 11th September with

TABLE

Date	Red blood cells in 10 ⁶ per c.mm.	WHITE BLOOD CELLS	Blood platelets per c.mm.	Treatment
		Total and differential count		
19-8-37	3.1	Marked leucopœnia. Relative lymphocytosis. Few immature granular leucocytes.	56,250	
21-8-37	2.21	1,000 { Poly. .. 14 per cent Lympho. .. 86 "	..	Campolon 2 c.cm. intramuscularly. Adrenaline 1 in 1,000, b.d. Calcium chloride 3 grains intravenously. 1 c.cm. 5 per cent sodium nucleinate.
22-8-37	2.24	800 { Poly. .. 13.3 " Lympho. .. 86.7 "	72,000	Cold sponging. Nucleic acid, campolon and adrenaline as before. 10 c.cm. 10 per cent sodium thio-sulphate intravenously.
23-8-37	1.9	1,000 { Poly. .. 8 " Lympho. .. 92 "	..	Treatment as before and 10 c.cm. pentose nucleotide (Evans) intramuscularly.

Other laboratory reports.—The hæmoglobin was 50 per cent and the reticulocyte 0.3 per cent; there was no blood in the fæces, and the urine was normal, and the van den Bergh negative.

Bone-marrow smear.—The sternum was trephined and smears were made from the marrow. Marked absence of leucoblastic elements. Very few myelocytes and lymphocytes. No evidence of any active regeneration of erythropoietic elements. Blood transfusion was not done in this case. No post mortem was done.

Case 3.—A male, aged 46, attended the venereal out-patient department on 2nd August, 1937, with a primary syphilitic sore of 20 days' duration. Blood Wassermann reaction strongly positive. There was nothing of significance in the previous history. He had 0.45 gm. neo-salvarsan intravenously once in five days and weekly injections of 1 c.cm. of bismostab. He

intense malaise, shivering attacks, bleeding from the gums and severe headache. On admission he was looking definitely ill and presented a puffy face. Temperature 103.6°F., pulse 100, and respiration 30 per minute. Tongue was coated and throat congested. There was no ulceration of the throat. Moderate bleeding from the gums which were markedly swollen and inflamed. Examination of the other systems revealed nothing abnormal. Chart 2 shows the course of the temperature. Blood pressure—70/54. Bleeding and prostration were progressive. Later, he developed pneumonic signs and expired on the 14th September. There was neither throat lesion nor hæmorrhages from other parts of the body than the gums, palate and conjunctivæ, throughout the course of the illness. Blood examinations and the treatment adopted are summarized in the following table:—

TABLE

Date	Red blood cells in 10 ⁶ per c.mm.	Total	WHITE BLOOD CELLS	Blood platelets per c.mm.	Treatment
			Differential count		
11-9-37	3.6	2,500 per c.mm.	Poly. .. 7.6 per cent Lympho. 86 " Mono. .. 3 " Eosino. .. 6 "	..	
12-9-37	3.07	1,250	Poly. .. 4 per cent Lympho. 92 " Mono. .. 1 " Eosino. .. 3 "	32,000	2 c.cm. hæmoplastin intramuscularly. 5 c.cm. 10 per cent calcium chloride intravenously. Manetol (Bayer) 1 tube 4 hourly. Nuclein 1 ampoule b.d.
13-9-37	..	1,300	Poly. .. 5 per cent Lympho. 94 " Eosino. .. 1 "	28,000	7 c.cm. calcium chloride intravenously. Manetol 1 ampoule 4 hourly. Nuclein 1 ampoule t.d.
14-9-37	1.95	1,200	Poly. .. 3 per cent Lympho. 97 "	20,000	Manetol and nuclein continued. Stimulants, glucose and brandy. Coramine 2 c.cm. 4 hourly. Continuous oxygen.

Other laboratory reports.—The blood smear showed anisocytosis, the blood culture and agglutination for *B. typhosus*, and para A, B and C were all negative.

The bleeding time was 2 minutes 30 seconds and the coagulation time 3 minutes 10 seconds.

Blood transfusion was not performed in this case either. A post-mortem examination was done and the following is an extract from the notes:—Sub-conjunctival hæmorrhage, sub-pericardial and sub-peritoneal petechiæ, sub-mucous hæmorrhages of the tongue and palate, and patches of ecchymosis on face and chest. Hæmorrhage into the left suprarenal glands. Entire stomach showed numerous sub-mucous patches of ecchymosis. The same was found in the intestine. Consolidation of the lower part of the upper lobe of the left lung—hypostatic pneumonia.

CHART 2

Name—Kasinathan.
Age—46.

Section of the cervical lymph glands.—The normal architecture of the node is lost. The cells are more or less uniformly distributed throughout the section. Marked proliferation of the lymphocytes, many of which show mitosis and active division. No myelocytes.

Section of femur.—Pale red marrow confined to the upper end; the rest showing atrophy and fatty transformation. Only very few cellular elements.

Section of lumbar vertebra (1st).—Very little pale red marrow is seen.

Basophils	..	0.5 "
Undetermined cells	..	2 "

Discussion

It is evident from the history of the above cases that their clinical conditions were due to the arsphenamine treatment employed. The recovery in case 1 confirms the observation of other workers, that usually thrombocytopenic cases run a benign course and respond well to ordinary therapeutic measures. The platelet

count in this case is much lower than that enumerated in any case so far. Though the patient was on his way to recovery it cannot be stated that complete regeneration of the platelets had occurred. When he was discharged the count was only 50,000 per c.mm. which is far below the normal. It is also to be noted that the symptoms in this case started two days after the last injection.

Case 2 is still more interesting in that it represents a typical secondary aplastic anaemia with all the blood elements employed. It is a moot point whether the severe type of aplastic anaemia caused in this case was the result of Fouadin or acetylarsan or a combination of both.

In case 3, neo-salvarsan was the drug employed. Agranulocytosis was the most prominent feature. Only the bone-marrow examination has thrown light on the aplastic condition of the hæmopoietic system. Possibly if he had survived some time more a better clinical picture of aplastic anaemia might have developed. In cases 2 and 3 there were no throat lesions which are usually associated with such low neutrophil counts. The tremendous amount of marrow damage is shown by the marrow count after death in case 3. The futile attempts at treatment are also shown by the two fatal cases. It cannot be said whether blood transfusion might have done any good.

Unfortunately we have no particular sign of warning for the early detection of this group of disorders. Attention may be drawn to a case only after doing a blood count. Undue bleeding from the gums during the arsenical treatment however offers us a clue in some cases. Moore and Kiedell advise a total and differential leucocytic count at frequent intervals during treatment. 'Leucopenia associated with a reduction of the percentage of the polymorphonuclear neutrophils and of large mononuclear transitional cells, or the appearance of many fragile or abnormal leucocytes, should be regarded as a serious omen' (Moore, 1933). It is perhaps also worth while to do a preliminary blood examination in debilitated patients and in the occasional group of cases where spreading and sloughing of the sore take place in spite of anti-syphilitic treatment.

The treatment of these secondary blood dyscrasias is far from being satisfactory, especially in the well-established cases of aplastic anaemia. The utter uselessness of the many therapeutic measures and the resulting high mortality of this severe type of blood disorder only show the helplessness of the clinician or the syphilologist when he is faced with such a condition. The earliest evidence of damage to the hæmopoietic system calls forth prompt withdrawal of further arsenic medication. Adrenaline is used in platelet deficiency; calcium, thiosulphate and liver preparations may be used as a

(Continued at foot of opposite page)

* The complete absence of normoblasts is very unusual; so also is the high lymphocyte count.—EDITOR, I. M. G.

(Continued from previous page)

routine. Bleeding may be stopped by symptomatic measures. Regeneration of the leucoblastic tissues is now attempted by using pentosenucliotide and similar preparations. While some are of opinion that blood transfusion is the sheet-anchor in the treatment of aplastic anæmia, many unsuccessful reports have made it lose its value in others hands. Repeated blood transfusion may, however, tide over a crisis and give time for other measures to be adopted in the regeneration of the hæmopoietic system.

It is generally suggested that no further arsenical injections are to be given in the recovered cases. Recurrence is said to be invariably fatal.

Summary

1. A brief résumé of 'depressed bone-marrow function' due to arsphenamines is attempted.

2. Some of the theories on the mechanism of production of this group of disorders are discussed.

3. Three cases are reported, two of them fatal, showing hypoplastic or even aplastic changes.

4. The interesting and special features of the cases are discussed.

5. A brief paragraph is devoted to the different lines of treatment adopted.

6. As in cases of post-arsenical encephalitis there is a large element of unpredictability and inevitability about this group of blood disorders.

We are indebted to Lieut.-Colonel G. R. McRobert, I.M.S., and Dr. D. Govinda Reddi for the notes of case 2, who was under their observation and treatment. Our thanks are due to the staff of the pathology department of the Medical College for the post-mortem notes on case 3.

evolved the following simple method of using only strips of newar and a Balkan frame which appears to us to be simpler for most Indian hospitals, especially the smaller ones, than the method depicted by Boehler (1935). The photographs are, we consider, sufficient to illustrate the method.

Fig. 5.—Showing the patient with arms flexed and illustrating the shoulder braces.

Fig. 6.—Skiagram showing good reduction obtained by this method in a fracture of the first lumbar vertebra.

Warning. This method will not obviate operative interference if there is a dislocation of the lumbar vertebrae such that the lower articular processes of one vertebra are wedged in front of the upper articular processes of the vertebra next below. It is therefore imperative to take a lateral skiagram.

PREMEDICATION IN SODIUM EVIPAN ANÆSTHESIA—A STUDY OF 535 CASES

By E. S. CHELLAPPA, M.B., B.S. (Madras)
 Willis P. Pierce Memorial Hospital, Madura
 (Formerly Anæsthetist, K. E. M. Hospital,
 Secunderabad)

A REPORT on thirty patients operated upon under sodium evipan anæsthesia by the present writer (1934) appeared in this journal. In none of these cases was any premedication used, because it was held at that time by the manufacturers to be contra-indicated. Since then, the writer has had the opportunity of observing the effects of sodium evipan in over 500 cases, and an attempt is made in this article to assess the comparative values of sodium evipan with and without premedication. While indicating its great usefulness in minor operations, and in a lesser degree in major operations, a record was made in the last article of three complete failures, in spite of maximum dosage, out of a total of thirty cases. It was also recorded that 10 patients had to be given either morphia or eukodal injections after the operation because they became very boisterous. Further experience of 45 more cases confirmed the reality of these two defects. In an attempt mainly to overcome these difficulties as suggested in an article by Nichol (1935) we started premedication with eukodal (Merck), a codeine derivative, and hyoscine hydrobromide. Nichol himself and others had used omnopon, a morphia derivative, in the place of eukodal. The 535 cases under review include 350 patients operated upon without premedication and 185 with premedication. After the first 75 cases, which were all done without premedication, the cases selected for premedication were generally those major and minor operations where a fair relaxation and certainty of effect were important. Moreover, those patients were also selected who, on account of their heavy build or for other reasons, were likely to be more resistant to evipan. These 185 cases therefore are a good test of the effect of sodium evipan.

Technique and dosage.—About one hour before the operation, a patient of average build and health is given $\frac{1}{4}$ gr. of eukodal and 1/150 gr. of hyoscine subcutaneously, and the patient left in a quiet dark place. The patient is drowsy or asleep when he is taken to the theatre, and the injection started in a convenient vein. Each gramme of the white powder is dissolved in 10 c.cm. of sterile distilled water supplied with it. The patient is asked to count slowly, as the injection is given at the speed of 1 c.cm. for 15 to 20 seconds. Most patients stop counting after 2 or 3 c.cm. have been injected, and become unconscious. If the patient holds the breath, or if the breathing is slow or shallow after the first few c.cm. as often happens, it should cause no alarm, but further pushing in of the solution is delayed till the

breathing is better and is then continued. This respiratory phenomenon is less marked after correct premedication than without any. The dosage is judged by the weight, age and general health of the patient, by the relaxation of the jaw, and also to some extent by the time he takes to stop counting during injection. When the patient has become insensitive to pin-pricks, no more solution need be injected. If tremors of the limbs occur or the patient becomes stiff when the knife is used, it means that the dose has been just below optimum. The average dose needed is about 8 c.cm. Strong, sturdy, and heavy adults often need the full dose of 10 c.cm., while feeble old people, diabetics and those debilitated by disease may go under with 4 or 5 c.cm. only. Alcoholics and neurotic patients require a higher dosage than the average. The same technique is adopted when no premedication is used, but the dose required to get the patient under is always higher and the effect not always certain either, as will be shown later.

Precautions.—Successful results with sodium evipan depend in a great degree on proper dosage and timing of premedication. The dose of hyoscine is kept fixed at 1/150 gr. while the dose of eukodal is varied from 1/6 gr. to 1/3 gr. according to the weight of the individual, $\frac{1}{4}$ gr. being the average. Only very heavy individuals, prepared for an operation needing fair relaxation, require the maximum of 1/3 gr. The operation should never be started earlier than 45 minutes after premedication. With these precautions there is little risk of respiratory depression. Even though in a few cases the breathing may be somewhat slow or shallow after the injection of evipan, as soon as the operation is started it corrects itself. In such cases, the blood may be rather dark when the first incision is made, but turns brighter quickly as the breathing becomes deeper. Among the 535 cases under review not one patient has died of respiratory failure or of any other cause attributable to sodium evipan. There have been a very few cases where the respiration stopped for a few seconds, but they were easily revived by an injection of icoral or coramine and by artificial respiration. The head should be turned to one side during the injection of evipan to prevent the tongue falling backwards.

Advantages of premedication.—The most important advantage is that it greatly diminishes the risk of failure to get the patient satisfactorily under, as the following figures will show.

'Complete success' denotes good relaxation at the start of operation. Under 'satisfactory' are included those cases, where, though full relaxation was not obtained after injection and the patient might have reacted to the first skin incision, the operation could be carried on without delay or inconvenience, sometimes with a few whiffs of an inhalation anæsthetic.

'Failures' are those cases which, even after the full dose of 10 c.cm., moved and struggled so that the operation could be proceeded with

	Total	Complete success	Satisfactory	Failures	Percentage of failure
Number of cases with pre-medication.	185	140	38	7	3.8
Number of cases without pre-medication.	350	232	66	52	15.0

only after the patient was got under a chloroform-ether mixture. Thus, the percentage of failure with premedication is only 3.8 per cent as against 15 per cent without premedication. The seven failures with premedication were encountered with very heavy robust adults, with alcoholics, or with highly neurotic patients.

The other important advantage is that while fully 30 per cent of cases without premedication become boisterous after operation, the number of such cases is negligible when premedication is used. The tendency to post-operative restlessness is greater when an operation is started with the patient not fully under. Post-operative vomiting is rarely met with in evipan anæsthesia.

In addition to these two advantages of premedication, the respiration is more even during the injection of evipan, the disturbing muscular twitches and jerks are avoided, and the available duration of anæsthesia is increased by a few minutes. The anæsthesia can easily be continued with a few whiffs of chloroform-ether mixture or pure ether if the patient shows signs of coming out before the operation is over.

Suitability of evipan for different operations.—Its greatest sphere of usefulness lies in minor surgery. For opening of abscesses, removal of small superficial tumours, dilatation and curetting of the uterus, repair of injuries, hydrocele, etc., it is extremely convenient and safe to use. In addition, it can be used with advantage in selected major operations like exploratory laparotomy, appendicectomy ectopic gestation, etc., lasting not more than half an hour. In these cases the sodium evipan can be supplemented if necessary when its effect is wearing out by a mixture of chloroform-ether. For patients acutely ill, evipan is safer to use than any other general anæsthetic. Diabetes, nephritis and diseases of the lung are indications rather than contra-indications for the use of evipan.

For major operations of long duration involving much shock, evipan is not indicated. For

CONTROL OF *STEGOMYIA FASCIATA* (*ÆDES ÆGYPTI*) MOSQUITOES IN INDIAN COUNTRY CRAFT BY A MOSQUITO-PROOF METAL CAP (BENNETT PATTERN) FOR DRINKING-WATER RECEPTACLES

By F. D. BANA, M.B., M.R.C.S., D.P.H., D.T.M. & H., J.P.
Administrative Medical Officer, Bombay Port Trust

FOLLOWING on Colonel Covell's and Dr. Mhatre's recommendations in their malaria and ædes surveys of Bombay, 1928 and 1933, to lessen the breeding of *Stegomyia fasciata* mosquito in the country craft in the docks and bunders of Bombay, measures have been taken by the Bombay Port Trust from time to time to minimize this nuisance. This article attempts to relate the measures taken, with a brief description and a sketch of a mosquito-proof cap devised and fitted to drinking-water barrels and receptacles in the country craft, with which it is hoped to reduce the incidence of breeding of this potential carrier of yellow fever in the

(Continued from previous page)

such, avertin, whose action is almost specific in preventing shock, is to be preferred.

In three cases of Cæsarean section for which we used sodium evipan, we found the babies asphyxiated and revived them with some trouble. We are definitely of the opinion that it should not be used for Cæsarean section.

Sodium evipan is also not convenient for tonsillectomy and operations generally on the throat and nose, because sneezing and cough may be troublesome. Moreover, the vascularity of the parts is increased and there is more hæmorrhage than usual. It is unsuitable for operations about the anus and rectum, such as hæmorrhoids and fistulæ in ano, because the dilatation of the anal sphincter causes much shock. A low spinal analgesia with the patient in a sitting position gives unrivalled relaxation of the sphincter for these cases.

Summary and conclusion.—Premedication should be carried out as a routine before sodium evipan. Exceptions are operations of a very minor nature like the opening of an abscess, and also patients who are extremely ill, when premedication is not necessary. The advantages of premedication are explained and the dosage and technique of administration of sodium evipan described in detail. Its suitability for various operations is also discussed.

For kind permission to publish this report I am grateful to Lieut.-Colonel R. F. D. MacGregor, I.M.S., Chief Medical Officer of the K. E. M. Hospital, Secunderabad, where this study was made.

Port of Bombay. The danger of the spread of this disease to India is increased by the speeding up of modern travel, and especially by aerial transport bringing its endemic centres in Africa nearer to India. Once the virus of yellow fever is introduced the disease may be spread like wild-fire by the *stegomyia* prevailing in Bombay. In the words of the Sanitary Commissioner with the Government of India: 'Should yellow fever happen to be introduced into India, the disease would be so appalling that it might well cripple the country for a generation, as all factors which make for a rapid spread of the disease are present'.

Native craft trading in or with Bombay come from the western coast line of India including Sindh, Kathiawar, Gujarat, Bassein in the north to Ratnagiri, Goa and Cochin in the south. The *stegomyia* mosquito is found breeding in these country craft, mostly in the wooden drinking-water barrels or boxes, or other open water receptacles. A preliminary survey made in 1935 has revealed that out of 898 country craft examined, during the stated period, fully 458 or 51 per cent or every alternate craft was found harbouring the mosquito or its development form in various stages (Bana, 1936). It was therefore decided to take steps to minimize this breeding by selecting a special gang of workmen from the malaria preventive staff of Bombay Port Trust called 'the country-craft gang', to examine regularly from the shore side as many of these country craft as possible and to empty out infested water, giving a free supply of water in replacement. This has been carried out for the last three years by firm persuasion and educating the owners as to the danger of mosquito breeding, and the co-operation of the master, *tindal* or crew of the craft has been obtained. These were at first hostile, but later co-operated in minimizing the nuisance and danger to themselves and others working in the Docks. Thus, during the year 1935-36 about

Wooden barrel with mosquito-proof cover and tap.
Scale 3/4 inch to a foot.

19,453 country craft were examined in the Alexandra, Prince's, and Victoria Docks and in Malet, Carnae, Sassoon and Darukhana bunders, of which 5,688 were found breeding and 5,551 were emptied out. The percentage of breeding

by this voluntary working was reduced to 28.7 per cent from 51 per cent. As the Port Trust had no legal powers to enforce this inspection the Government of Bombay were approached and they were pleased to give powers under the Indian Ports Act to legalize their action, in December 1936. The results of the working for 1936-37 are still better, inasmuch as the ratio

backed by powers obtained, shows what co-operation and education can do in matters of sanitation and habits of the people, most of whom are ignorant and hardly able to read or write. The dual control of the mosquitoes in the native craft in the Port of Bombay with the regular land campaign on the Port Trust Estates has lessened the incidence of this pest

Mosquito-proof cap with plug.

Plan at top of cork.

of those found breeding to those examined was brought down to 19.3 per cent, the actual numbers of country craft examined being 22,789 of which 4,338 were found breeding and 4,335 emptied out and given free supply (3 only defaulting before the powers were given). This happy result of voluntary inspection, later

and it is gratifying to note that there are less complaints from staff, shipping, general public and other services. During the monsoon, however, extra sources of breeding have to be contended with, *i.e.*, open areas, roof gutters, etc., for which extra men and material are required.

BERTIELLA STUDERI, A NATURAL TAPE-WORM PARASITE OF MONKEYS, IN A HINDU CHILD

By SUDHIR CHANDRA ROY, B.Sc., M.B., D.T.M.
P. O. Kurigram, District Rangpur

THE patient, a Hindu Brahmin male child, aged eight years, fairly well nourished, has been passing segments of a worm in his stools for the last ten months. At first the child passed these segments with almost every motion but at present he passes them only occasionally.

(Continued from previous page)

Having achieved some success in keeping down the incidence of the stegomyia breeding in country craft by regular inspections, it was further decided to devise a way by which the mosquito could be prevented access to the drinking-water receptacles. Provision of a perforated metal cap or filter which can be fitted to the man-hole of the barrel was suggested and such a cap has been devised. Its dimensions are $5\frac{1}{2}$ inches square with a depth of 3 inches. It has a screw-down lid or edge which can be fitted to the opening of the water barrel or box. Into it fits a wooden cover or cork with a handle and chain serving to keep dust and dirt out when fixed. The cap serves as a filter to gross impurities, such as fibre, dust, grain, seeds, and vermin such as rats, cockroaches, ants, flies, etc., besides keeping off mosquitoes. It has a perforated mesh of holes $1/16$ inch in size. The water of a barrel fitted with one shows not only no mosquito larvæ, but is clearer and cleaner, containing less debris. The barrel has to be fitted with a draw-off tap at the bottom. This cap can be made in sizes and fitted to ordinary wooden water receptacles, either barrels or boxes, at present in use by the country craft. The suggestion for fitting new metal cisterns was considered difficult to put into practice, on account of the cost which would be heavy for the owner of this class of country boats who use cheap wooden receptacles and to which he has been used for very many years, and this *via media* for preventing the stegomyia breeding in the craft was therefore devised. It is anticipated that the experiment of fitting these caps to the water receptacles will effectively prevent the breeding of mosquitoes in the native craft and eliminate the existing nuisance and menace to health.

I have to thank Sir G. Wiles, K.C.S.I., I.C.S., chairman, Bombay Port Trust, and Mr. G. E. Bennett, chief engineer and acting chairman, for rendering all help, and the latter for designing the cap, after whom it is named.

Bana, F. D. (1936). A practical way of dealing with *Aedes aegypti* (*Stegomyia fasciata*) mosquito breeding in country craft. *Indian Med. Gaz.*, Vol. LXXI, p. 79. (Correspondence—p. 306.)

The only complaint is occasional griping round the umbilicus. The tongue is slightly coated and liver just palpable. The child had an attack of dysentery about one year back.

The child lives in Barisal but came here only three months ago.

Stool examination reports

Naked-eye appearance.—Semi-solid, greyish, slightly offensive stool with live segments of a tape-worm present in it.

Reaction.—Acid.

Microscopic examination.—Some undigested food residue and vegetable cells, and a fair number of bacteria present.

Cysts of—(a) *Entamoeba histolytica* present—few only. (b) *Entamoeba coli* present—fair number.

Eggs of—(a) *Trichuris trichiura* present—very few only. (b) *Ascaris lumbricoides* present—numerous.

Segments.—These were identified as *Bertiella studeri*, a natural tape-worm of monkeys.

My thanks are due to my teachers, Dr. P. A. Maplestone, for identification of this tape-worm, and to Dr. B. M. Das Gupta for the report on the stool.

According to Maplestone and Riddle (1936) only eleven instances of this tape-worm in human beings have been hitherto reported so that this makes the twelfth.

THE HYDROGEN-ION CONCENTRATION OF CHOLERA STOOLS

By C. L. PASRICHA

MAJOR, I.M.S.

D. N. CHATTERJEE,

and

K. S. MALIK

(From the Cholera Bacteriological Enquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)

As far as we are aware there is no record in the literature of any determinations of the hydrogen-ion concentration of the characteristic 'rice-water' cholera stools. In the present report the results of a single examination of the stools of 150 patients during the acute stage of the disease are given and in addition the daily reactions of the stools in a series of thirty cholera patients.

The stool was collected by a sterile catheter into a test-tube and the hydrogen-ion concentration estimated soon after the collection of the sample. The determination was completed within 30 minutes of the collection. A Hellige comparator with a non-fading standard colour disc and 13 mm. rectangular troughs was used for the estimation of the pH values. The indicators employed were methyl red (pH 4.4 to 6.0), brom-thymol blue (pH 6.0 to 7.6), phenol red (pH 6.8 to 8.4) and thymol blue (pH 8.0 to 9.6). The samples examined were

liquid and of such a consistency that it was not necessary to dilute the stools. A few samples which were turbid were centrifuged and the supernatant fluid used for the estimation. The pH value of 12 typical rice-water cholera stools was determined both by the quinhydrone electrode and the Hellige's comparator. The readings obtained by the colorimetric method approximated closely with those taken by the electrical method. The deviation with the colorimetric method was uniformly towards the acid side and varied from those taken by the electric method by about 0.2. This deviation

was most marked when brom-thymol blue was used as an indicator and not with the other indicators. The results recorded are those obtained by the colorimetric method.

Approximately 65 per cent of the typical rice-water stools without visible faecal matter were distinctly alkaline in reaction. The majority of the alkaline stools were within the range of pH 7.5 to 8.5. The reaction of about 35 per cent of the rice-water stools was below pH 7.0, but not below pH 6.0. Fluid stools with visible faecal matter were distinctly on the acid side. There was no appreciable difference in the

TABLE I

The reaction of stools collected during the acute stage of the disease (within 2 days of the onset of symptoms) from a series of 150 clinically cholera patients

Character of stool.

R.W. = Typical rice-water stool.
 R.W.Bd. = Rice-water stool tinged with blood.
 R.W.B. = Rice-water stool containing bile.
 F. = Liquid stool containing visible faecal matter.

The bacteriological findings.

V+ = *Vibrio cholerae* (agglutinable to full titre with standard 'O' serum) isolated from the specimen.
 V- = No vibrio isolated from the specimen.

In this series 105 samples of cholera stools collected on different days of the disease were examined. The isolation of vibrios from stools of different reactions is shown in table IV.

TABLE IV

Showing the pH of the stool and the isolation of *V. cholerae* from stools of different reactions

The reaction of the stool	Number of samples examined	Number and percentage from which vibrios were recovered	Number and percentage from which vibrios were not recovered
pH 6.0 to 7.0 ..	44	32 or 73 per cent	12 or 27 per cent
pH 7.1 to 8.0 ..	35	32 or 91 per cent	3 or 9 per cent
pH 8.1 to 9.0 ..	26	24 or 92 per cent	2 or 8 per cent

It will be seen that the percentage of successful isolations of *V. cholerae* was higher in alkaline

stools than in acid stools. The relative frequency of alkaline and acid stools on different days of the disease is shown in table V.

TABLE V

The relative frequency of acid and alkaline stools on different days of the disease

Day of disease	Number of samples examined	PERCENTAGES OF SAMPLES OF STOOLS OF DIFFERENT REACTIONS		
		pH 6.0 to 7.0	pH 7.1 to 8.0	pH 8.1 to 9.0
2nd ..	24	21	46	33

The relative frequency of acid stools increases as the patient gets better. The frequency of isolation of vibrios from stools of different reactions on the second to the fifth days of the

disease are shown in table VI. The number of samples examined on the sixth, seventh and eighth days were too few to be included in the table.

lected during the first two days after onset of symptoms was determined by the colorimetric method.

2. Approximately 65 per cent of typical

TABLE VI

The frequency of isolation of vibrios from acid and alkaline stools on different days of the disease

Day of disease	Number of samples examined	NUMBER OF SAMPLES OF STOOLS OF DIFFERENT REACTIONS AND THE PERCENTAGE FROM WHICH VIBRIOS WERE ISOLATED					
		pH 6.0 to 7.0		pH 7.1 to 8.0		pH 8.1 to 9.0	
		Number	Per cent positive	Number	Per cent positive	Number	Per cent positive
2nd	24	5	40	11	91	8	88
3rd	30	13	69	8	100	9	100
4th	26	14	86	7	100	5	100
5th	14	8	88	3	100	3	100

V. cholerae were isolated from nearly all the alkaline stools. Vibrios were isolated from 40 per cent of the acid stools examined on the second day of the disease and with increasing frequency in the acid stools passed during the next three days. On the fourth and fifth days vibrios were found in 86 and 88 per cent of the samples of acid stools. This suggests that there occurs in the intestines considerable multiplication of vibrios by the third or fourth day as a result of which vibrios can be found in increasing frequency in acid stools.

Summary

1. The hydrogen-ion concentration of samples of stools of 150 cholera patients col-

rice-water stools without visible faecal matter were alkaline. The majority of these samples had a pH value between 7.5 to 8.5. About 35 per cent of the stools were acid (pH below 7.0 but not below 6.0). Stools containing faecal matter were distinctly acid in reaction.

3. In a series of 30 cholera patients whose stools were examined daily, vibrios were found in nearly all the alkaline samples and in a much smaller proportion of the samples whose reactions were on the acid side.

4. An analysis was made of the frequency of the stools of varying reactions of different days of the disease and the frequency with which vibrios can be isolated from stools of different reactions.

A Mirror of Hospital Practice

AN UNUSUAL CASE OF ABORTION TREATED BY CURETTING

By D. R. LEWIS, M.B., F.R.C.S. (Edin.)
Civil Surgeon, Maubin

A BURMESE woman, aged 39, was brought to the civil hospital, Maubin, at 8 p.m. on the 17th March, 1938, with the history that she had had vague pains in the lower abdomen for the past 6 weeks and that there was slight loss of blood *per vaginam* during all this period. She was said to be in the fifth month of her eleventh pregnancy. It was further reported that at about noon on the day of admission she noticed some substance drop from her vagina which she found to be a hand of a foetus.

On arrival at the hospital the patient had a temperature of 101°F. and her pulse was 130 per minute. The os was dilated, just enough to admit one finger. There was no bleeding and the uterus was soft. She was given an enema and it was decided to let her rest for the night and to operate on her the next day. Accordingly she was given a full dose of mistura hypnotica and she slept well that night.

The next morning she was put under chloroform and the uterus was evacuated of its contents by means of a blunt curette. The foetus had undergone

decomposition and was found lying in the uterus soaked in purulent fluid. It came out piecemeal. There was smart bleeding from the uterus during the process of evacuation of its contents. The placenta was firmly adherent to the uterine wall and had to be scraped out. Bleeding did not stop until 2½ c.cm. of pituitrin and 10 c.cm. of normal horse serum had been given intramuscularly. Despite the loss of blood the patient's pulse continued to be steady and bounding. After evacuation the cavity of the uterus was douched with hot water to which had been added lotio acriflavine and liquor adrenalin hydrochloride. The uterus was thereafter packed with gauze soaked in lotio acriflavine 1 in 1,000 and the vagina was packed with iodoform gauze. A 'T' bandage was applied and the patient put to bed. An injection of 5 c.cm. of a 5 per cent solution of prontosil 'Bayer' was given intramuscularly. Two hours after the operation the patient had a rigor and her temperature shot up to 103°F. She slept well that night and the next morning her temperature was normal. The gauze plug inserted into the uterus was removed and there was no offensive discharge.

The patient was up and about on the 4th day after the operation and demanded permission to return home.

This is a remarkable recovery. The foetus had undergone decomposition in the uterine cavity and there was pus in it at the time of curetting.

SIMPLE FRACTURES AND DISLOCATIONS OF THE ASTRAGALUS

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S.E.
Surgeon, King George Hospital, Vizagapatam (S. India)

and
P. KESAVASWAMI
Radiologist

SIMPLE fractures and dislocations of the astragalus are not common and when they occur they are the result of serious injuries such as falls from a height on the foot. Various types of dislocation and fractures have been reported.

months' duration. He had fallen from a tree on his foot and was unconscious after the fall for one day. He was treated in his village without proper medical aid.

On admission the patient walked with difficulty and pain, with his right foot inverted and adducted. On examination the ankle joint was found broader and there was a marked prominence on the antero-lateral aspect of the joint. The muscles of the right leg were markedly wasted. On palpation the head of the talus was palpable on the antero-lateral aspect in front of the external malleolus. Movements of dorsi-flexion and plantar-flexion were limited. Inversion and eversion of foot were painful. X-ray showed a forward and lateral

The problem of treating these conditions is difficult when the cases are seen at the time of injury and becomes greater when seen long after, without proper treatment. The following two cases illustrate the two different types of injuries of the astragalus.

No. 1. Case illustrating a simple forward and lateral dislocation of the talus in the right ankle joint.

A male, aged 35 years, was admitted in 1935 for treatment of pain in the right ankle of 8

dislocation of the astragalus without any injury to the malleoli. He was operated on under spinal anaesthesia and astragalectomy of Whitman's type was done.

He made an uneventful recovery. He was able to walk three months after operation and can now walk six miles without fatigue.

No. 2. Case illustrating a simple fracture of talus with forward and upward displacement of anterior fragment in the right ankle joint.

A male, aged 31 years, was admitted early in 1936 for the treatment of pain in the right foot of 4 months' duration. The accident occurred

Case 2

Showing the fracture of the astragalus about its middle with forward and upward displacement of the anterior fragment.

Showing the condition of the joint after Whitman's astragalectomy before discharge.

while he was getting down from a train which was just coming to a stop. He slipped and twisted his right foot which caused him severe pain. The ankle joint swelled rapidly for which first aid was given. Subsequently the limb was put in plaster after x-ray examination.

On admission he walked with a marked limp. There was marked fullness in front of the ankle joint. There was a globular swelling of the size of a small walnut on the antero-medial aspect of the joint in front of and below the medial malleolus. This swelling felt bony hard on palpation. Movements of ankle were very markedly limited. On x-ray examination, the astragalus was found fractured in the middle with the anterior fragment tilted forwards and upwards. There was no injury to the malleoli. The ankle joint showed osteo-arthritic changes.

Under spinal anaesthesia, astragalectomy of Whitman's type was done removing all the osteoid tissue inside the ankle joint. The patient made an uneventful recovery and was able to walk in ten weeks' time with a boot, lateral iron and inside T strap. The patient has reported that he is able to walk long distances and is able to attend to his duties.

The problem of old fractures and dislocations of the astragalus when they come late is best solved by astragalectomy of Whitman's type as these two cases illustrate.

A LINGUAL ABSCESS

By C. L. DAMANIA, M.B., B.S.

Assistant Surgeon, Vadali Dispensary, Vadali

A WOMAN, aged about twenty-five, came to consult me complaining of a painful swelling of the tongue for the past four days. On examination I found that the mouth was kept open and the tongue was markedly swollen and protruding a little. No redness was noticed. The back of the throat was not visible, as there was considerable tenderness over the tongue and the patient would not allow me to depress the tongue with a spatula. Temperature was 100.5°F. Pulse normal. Respirations normal. Bowels had not moved for the last three days. There was marked difficulty of swallowing even of liquids. The neck was swollen and the lymphatic glands were palpable.

There was no history of urticaria. There was no history of an insect bite, nor of having taken any drugs, e.g., mercury.

One minim of croton oil in a drachm of water was poured over the tongue and the patient swallowed it with great difficulty. Turpentine enema was given with a very good result. An ounce and a half of saturated solution of magnesium sulphate was given slowly per rectum afterwards and was retained. The tongue was painted with 5 per cent cocaine in adrenalin. An injection of 10 c.cm. polyvalent antistreptococcic serum (P. D. & Co.) was given intramuscularly. The patient refused to allow incision of the tongue and would not remain at the dispensary. Cocain, 5 per cent in adrenalin, was prescribed for application, every two hours. Hot fomentations to the neck and mouth were advised.

Patient had six watery stools during that night; at about 12 p.m. the swelling burst underneath the tongue and about an ounce and a half of pus escaped. When I saw her next morning, I noticed that the swelling had gone down considerably and there was less pain. Hydrogen peroxide and potassium permanganate gargles were ordered alternately and the patient felt completely relieved of her complaint by the evening.

JUNE

CINCHONA SUPPLIES IN INDIA

We have many times in the past referred to the cinchona problem in this country, but it is such an important one that we feel no apology is needed for raising it again. In a land where a huge percentage of the population is crippled by malaria and where there are large tracts of country climatically suited to the cultivation of the cinchona plant, self-sufficiency in the matter of the supply of the cinchona alkaloids is surely a legitimate ideal.

It is so obvious an ideal that it has repeatedly been the avowed policy of the Government of India during the last three-quarters of a century, since the cinchona plant was first cultivated in India. We deliberately choose the word 'repeatedly' because it has not been their *continuous* policy and that is where much of the trouble lies. Had the government pursued a consistent policy from the beginning the present position would never have arisen, but working against a slight climatic handicap they failed either to keep pace with the Dutch planters in Java or to provide the necessary protection to the private concerns which were attempting to grow cinchona on a commercial scale, so that India soon fell out of the world market, and Java acquired a complete monopoly. The idea of self-sufficiency from an Empire standpoint was raised during the war and was in 1918 adopted as the government policy, but the efforts to develop this policy were only half-hearted and at the first excuse it was abandoned or at least modified to self-sufficiency for India; even this modified policy has never been pursued with any vigour, and attainment is still nowhere in sight.

Recently, the subject has been seized upon as suitable for the political platform; the Kina Bureau—the Amsterdam syndicate who control the quinine market—are made the chief villains of the piece and the Government of India the chief dupes; the latter are accused of depriving India of any chance of developing her own quinine cultivation by the 'terrible agreement' with Java. This agreement is, in our opinion, not a very favourable one to the interests of malaria control in India, but it is a very natural one from the Java point of view—the Dutch demand that if they sell us quinine at a price below the market one it shall not be resold again at a competitive price. This unfortunately, but inevitably, also involves in the price restriction the quinine produced in this country. The local governments who grow quinine, Bengal in particular, are further accused of making a handsome profit out of the cultivation, manufacture, and sale of quinine, and of maintaining a price which is beyond the pockets of

the poor fever-stricken ryot. This all sounds very terrible when thundered out in the Assembly or on the political platform, but the solution of the problem is not as simple as one would gather from the critics. In the first place the cinchona planter in Java has to live: he could, we believe, reduce the price of quinine by half, if he could sell three times as much as he is selling to-day, but if the Kina Bureau were to allow the price to fall and the consumption did not rise correspondingly, a number of plantations in Java would go out of commission, supplies would fail, and the price would go higher than ever. The cinchona alkaloids are an essential commodity to malarious countries and so that the Kina Bureau, whilst protecting the Java planters, is also indirectly serving the interests of all malarious countries.

Nevertheless, whatever forward policy the government adopts, it is necessary to make some immediate provision for India's hundred million annual malaria-sick, and, as India's quinine output is in the neighbourhood of 70,000 pounds, and her potential requirements at least 1,000,000 pounds, the margin has to be purchased from Java, who are in the position to say 'these are our terms; take it or leave it'; in actual practice India's consumption has never risen above 200,000 pounds per annum which means that four out of every five malaria sufferers receive no treatment, or that a greater proportion receive inadequate treatment.

The position of the Government of Bengal, a cinchona producing province, is also quite understandable, and though we seldom find ourselves in the position of defending our natural enemy, the finance department, we do not, on this occasion, picture them, as do the politicians, in the rôle of Shylock squeezing an extortionate profit from the ague-stricken peasant. They find that they can produce quinine at about Rs. 6-8 when the market value is Rs. 22 a pound. If they made a generous gesture and said 'we will take a reasonable margin to cover overhead charges and interest on capital expenditure (not taken into consideration in the above figure) and sell our quinine at Rs. 10', the Government of Bengal would lose their profit, but who would gain? Certainly not the ryot, and the gesture would have no effect on the world price of quinine. On the other hand it is reasonable to ask that the whole of this profit—or balance of quinine after production cost have been paid, whichever way one cares to look at it—should be available for the malaria-sick of Bengal, either through dispensaries or other means of distribution, or alternatively that the profit should be devoted to extending their present cinchona plantations, which have now passed their prime and have reached the stage of producing a yearly-diminishing output of bark.

In the last number of the *Records of the Malaria Survey of India*, there is an article on quinine supplies in India, by Colonel A. J. H.

Russell, the Public Health Commissioner with the Government of India, which is an explanation, or an apologia as the critics of this government would probably prefer to call it, of the policy of the Government of India.

This paper is a very valuable exposition of the problem and it has clarified many points on which there was obviously considerable misconception, but it gives no indication of the government's future policy and the only conclusion at which the writer arrives is as to the extreme complexity of the problem. We are a little disappointed that he did not develop more the question of the substitution of totaquina, or of some standardized cinchona febrifuge, for quinine. His references to this subject include the following sentences 'In the opinion of many experts, cinchona febrifuge and totaquina are almost as effective as quinine for mass treatment purposes; moreover, they can usually be produced at a lower cost' and 'apart from the changes in the relative costs, however, it seems that at present the drug of choice for mass treatment in India is an improved cinchona febrifuge . . .'. But there is very much more to be said on this subject.

We have always taken the view, and it is one that we still hold, that, if the various governments in India would make up their minds to provide totaquina, or some other cinchona febrifuge, for their hospitals and dispensaries, on a very much more generous scale than they do now, and to restrict the use of quinine to special cases, a very big step towards the solution of India's cinchona problem would have been made.

Colonel Russell raises an old bogey, namely, that if cinchona febrifuge became very popular, the price might rise to the present price of quinine. This is a red herring that is repeatedly drawn across the trail by those interested in quinine manufacture. One does not imagine for one instant that our policy would appeal to Java; as we have suggested above, and Colonel Russell supports this view, at a word from Amsterdam the production of quinine in Java could be trebled, and the price lowered, and so why should they be interested in an article whose only virtue is that it can be produced more abundantly and cheaply. Moreover, they have for years studied the cultivation of cinchona from the point of view of the special alkaloid, quinine, and it is on the fact that the climate of Java is so suited to the growth of this high-quinine-yielding bark that the quinine monopoly of Java depends.

The position in India is quite different. There is no restriction of output; on the contrary all the available bark is used for the extraction of the alkaloids. If only quinine is extracted the alkaloidal output will obviously be much less than if the whole of the utilizable alkaloids are extracted; and if the various alkaloids are not separated and refined, certain processes in the manufacture will be simplified,

therefore not only will there be more total alkaloids available for use but the cost of production per pound must necessarily be considerably less. We cannot conceive of any conditions, except a purely artificial and temporary one brought about by interested parties, in which the price of the total alkaloids could rise to the price of the single alkaloid quinine, though it is possible that the price of quinine might be forced down by the popularity of the total alkaloids.

But this is not by any means all there is to be said in favour of the substitution of the total alkaloids for quinine in malaria therapy. The areas in India which are suitable for the cultivation of the high-quinine-yielding species of cinchona, viz, *Cinchona ledgeriana*, are limited and it is doubtful if sufficient acreage could be found to grow bark for our total requirements, but there are other more hardy species, *Cinchona succirubra*, and the hybrids, *C. officinalis* and *C. robusta*, which produce a lower percentage of quinine—though enough to fulfil the requirements for the manufacture of totaquina—and a high percentage of the other alkaloids, and which, growing well under much less climatically favourable conditions, could be cultivated over wide areas in India. If this were done India could be made independent of outside supplies of cinchona alkaloids.

One might criticize those responsible for the government plantations and cinchona factories and say why have they not already adopted this policy: their reply is a simple one—'the demand is still for quinine and not for the total alkaloids and we must shape our policy to meet this demand'. So that before they criticize the government cinchona planters and manufacturers, or the local governments, or the Government of India, or finally the Kina Bureau, let our readers first consider if they are themselves altogether blameless. Do they prescribe cinchona febrifuge or quinine? Do they indent for cinchona febrifuge or for quinine for their hospitals or dispensaries? Do they teach their students that in the vast majority of cases cinchona febrifuge by mouth is the treatment of choice in malaria?

We do not mean to imply that the Government of India are blameless. Far from it: their lack of foresight in the past allowed India to drift into this difficult position, and in the more recent past their policy has been half-hearted and vacillating. However, we cannot now be extricated by a stroke of the pen or the terminating of an agreement. The cinchona tree grows slowly; it is about 8 years before any yield may be expected and a much longer period before this yield reaches its maximum. We believe that at present an expert, commissioned by the Government of India, is touring the country to see what are the possibilities of extending cinchona plantations. If this means that the Government of India is reviving and is proposing to pursue more actively what is

still, we believe, their avowed policy, namely, self-sufficiency for India in her cinchona supplies; the news will be very welcome; and we hope that in reshaping this policy they will view the problem in all its aspects. We believe that the substitution throughout India of a standardized cinchona febrifuge for quinine

in hospitals, in dispensaries, and in all public-health anti-malarial schemes offers the best means of escape from the present impasse. Whatever policy they do adopt, we hope it will be a permanent one, and not the kind that attracts the attention of the first economy expert that comes along.

Special Article

THE ERGOT PROBLEM AND THE PRACTITIONER

By B. MUKERJI, M.D., D.Sc. (Mich.)

(From the Biochemical Standardization Laboratory, Government of India, All-India Institute of Hygiene and Public Health, Calcutta)

Historical and general

Ergot is the compact mycelium of the fungus *Claviceps purpurea* which develops in the ovary of the rye (*Secale cornutum*, N. O. Gramineæ). Its action on the human uterus came to be recognized nearly four centuries ago through widespread epidemics of disease called 'ergotism' which resulted from eating bread made of rye infected with the fungus. Frequent abortions occurred in women sufferers during these outbreaks and this naturally attracted pointed attention to the possible rôle which this fungus might play in bringing about uterine stimulation. The earliest authentic reference to the medicinal use of ergot was made by Adam Lonicer (Clark, 1927) who stated that ergot powder was very efficient in bringing on labour pains. In the seventeenth century, ergot was used extensively for the purpose of criminal abortion and in consequence its use was forbidden by many authorities. It was however reintroduced in the eighteenth century, and gradually found a recognized application in obstetrical practice. Its entry into British official medicine dates from a brief reference by Parmentier (Barger, 1931) and more particularly from a detailed paper by Desgranges, an obstetrician of Lyons in France. Papers on the properties of ergot by Stearns (Barger, 1931) and by Prescott (Barger, 1931) of America were also responsible for giving an impetus to its adoption in the *British Pharmacopœia*. It is interesting to note that though many other medicinal herbs and drugs of various kinds were used all over the world for their oxytocic properties in labour and the puerperium, most of them are lost to-day, with the exception of ergot which is still serving mankind. Indeed, it is the oxytocic *par excellence*, as it is the only effective drug which can be given by the mouth. Even midwives can use it with impunity to stop fatal post-partum hæmorrhage in outlying places where medical aid is either not available or not easily forthcoming.

A perusal of the old literature on ergot shows that physicians possessed a remarkably clear conception of the chief action of the drug and also the best way to secure such action clinically, long before the complex chemical constitution of ergot was worked out and its active principles isolated. A quotation from Buchheim (Clark, 1927) will indicate the state of knowledge about ergot therapy about the middle of the nineteenth century. 'Ergot is used very frequently to stimulate the contractions of the uterus when there is prolonged weakness of the pains. Violent and prolonged pains usually commence ten to twenty minutes after administration of the drug and delivery soon follows. This can only happen in safety when there is no mechanical obstruction due to such causes as contracted pelvis, abnormal position, etc., and when the cervix is fully dilated, although the pains are not strong enough to produce delivery. In other conditions, the violent contractions can easily produce injury to the uterus... Ergot from very wet places is inactive. Preparations lose activity on keeping and no method of producing a stable preparation has been discovered. It is best to give the drug as powder 10 to 20 grammes every 15 to 20 minutes, until the desired action occurs'. These remarks made nearly 80 years ago appear to be true without much alteration even to this day, when considerable advances have been made in our knowledge about ergot.

Owing to the importance of ergot in obstetrics, many chemical and pharmacological studies have been made of the various active constituents isolated from it from time to time. In spite of such studies, the clinical use of ergot has not been entirely satisfactory up to the present time, and obstetricians have observed a marked variability in the potency of different preparations of this drug. During recent years, a considerable amount of interest has been focused on the ergot problem through the discovery of a new active principle which is probably responsible for most of the oxytocic activity of ergot. This discovery is likely to have a very important bearing on the therapeutic application of the drug. As the subject is of vital interest to practitioners, an attempt has been made in this article to review the present status of the ergot problem with special reference to the suitability or otherwise in practical therapeutics, of the pharmaceutical preparations of ergot available in the Indian market.

Chemistry of ergot

Let us first see what are the chemical constituents of ergot and what are the active principles in the drug, for which it is so much prized in medicine. Ergot may be said to be a veritable storehouse of chemical substances, as will be seen from the following table (modified from Barger, 1937).

seldom found in freshly collected specimens—a fact which is not sometimes sufficiently well stressed. These amines are really produced, as a result of putrefaction, in extracts of both animal and plant origin. Histamine and tyramine are the most important amines of the group and it has been shown fairly conclusively that both of them are effective only when injected

Ergoclavine ([α]_D²² + 124°) is probably a molecular compound of an alkaloid resembling ergotoxine and one resembling ergotinine. (Küssner.)
Sensibamine (Stoll) is probably a similar but much less stable molecular compound of ergotamine and ergotaminine.

1. Amines present in ergot

Amongst the substances referred to in table I, the two chief groups of substances which have been considered responsible for the characteristic action of ergot are (1) the amines and (2) the alkaloids. Though the amines are almost always found associated with ergot preparations, they are not specific for the drug and are

subcutaneously, intramuscularly or intravenously but are destroyed either in the gastro-intestinal tract or in the liver when introduced through the oral route. Even when administered hypodermically, histamine produces only a very transitory effect upon the uterus of experimental animals, and it is believed that the doses required as a parturient would be so large as

to be dangerous on account of the depressant effect of histamine on blood pressure. As ergot preparations are definitely proved to be active by the oral route, it is clear that this activity does not lie in its amine content. The amines, therefore, cannot be the clinically-useful constituents of ergot, and their action on the uterus in *in vitro* experiments may be taken altogether out of therapeutic consideration.

2. Alkaloids present in ergot

It is now generally agreed that ergot, like many other substances of natural origin, owes its characteristic effects to the presence of the alkaloids. A number of these alkaloids had been isolated from it at wide intervals over a period of 60 years, but the exact relationships of these alkaloids to each other and to the activity of the drug as a whole were not clearly understood. The rapid and remarkable advances in our knowledge of ergot alkaloids within recent years through the researches of Jacobs and Craig (1932-36) in America, Smith and Timmis (1930-37) in England, and Stoll and Burekhardt (1935, 1937) in Switzerland have however clarified the problem a good deal. It is now possible to state that ergot contains five pairs of inter-convertible isomerides which differ from each other in chemical composition and physical properties. All the five pairs of isomeric alkaloids are particularly well characterized and their molecular formulæ have been established and confirmed by hydrolysis. The alkaloids with their molecular formulæ and years of discovery are described in table I. Each pair consists of a lævo-rotatory alkaloid having a powerful pharmacological action and a strongly dextro-rotatory one with but little pharmacological activity. The inert alkaloids are sparingly soluble in organic solvents and crystallize readily without the solvent of crystallization. The potent alkaloids, on the other hand, have a remarkable power of forming 'additive' compounds with the solvent and with the isomeric inert alkaloids. Ergoclavine and sensibamine (see bottom of table I) have been shown to be such crystalline molecular compounds. The chemical constitution of the various pairs has also been successfully investigated and it has been established that they are all derivatives of *lysergic acid*. This finding has thrown some light on the physical behaviour, solubility, deterioration, etc., of the ergot alkaloids. It is not necessary for our purposes here to go into the details regarding the chemical constitution and properties of each member of the series. The alkaloids shown in the left-hand column of table I are the pharmacologically potent ones, and therefore we may confine our remarks to these active principles only. For purposes of description, these may be conveniently classified into two groups:—

(1) *The ergotoxine group*.—The first four pairs of alkaloids may be included in this group. Ergotoxine is the most abundant and the best

known representative of this group and one of the first active principles isolated in pure form. It is an amorphous alkaloid, very sparingly soluble in water and is easily precipitated from colloidal solutions by electrolytes, notably salts and mineral acids. It is however soluble in some of the organic solvents like alcohol, benzene, carbon bisulphide, etc. Ergotamine, the next best known constituent, was isolated as a crystalline base by Stoll in 1920 and described by Spiro and Stoll in 1921. In its solubility and other physical properties it resembles ergotoxine very closely, though its salts (tartrate and methanesulphonate) are generally rather more soluble than those of ergotoxine. Ergoclavine, as has been pointed out, is not an independent alkaloid, but is considered to be a compound of ergosine and ergosinine and sensibamine, a similar mixture of ergotamine and ergotaminine. This chemical relationship indicates that both these alkaloids will behave like ergotoxine in their biological reactions on the system. These may therefore be included in the ergotoxine group of alkaloids.

(2) *The ergometrine group*.—In 1932, Moir working with watery extracts of ergot reached the conclusion from clinical investigation that 'the characteristic and traditional effect of ergot was caused not by ergotoxine, ergotamine, tyramine or histamine, but by a substance still unidentified'. Dudley in 1935 isolated and identified the substance in question and named it 'ergometrine'. Ergometrine, as will be seen from the table, is comparatively simpler in structure to the previously known ergot alkaloids. It is soluble in water to some extent as a free base but gives salts which are freely soluble in water and easily absorbed from the alimentary canal. Following closely upon Dudley's work, the discovery of a water-soluble alkaloid was reported from three different laboratories, two in the United States of America and one in the continent of Europe. These were named ergostetrine (Thompson, 1935), ergotocin (Kharasch and Legault, 1935) and ergobasin (Stoll and Burekhardt, 1935). On account of some discrepancies in the physical properties, at first it seemed that four different alkaloids had been discovered. But certain definite similarities, both in their physico-chemical and biological behaviour, led to the belief that all of these new substances might be different names of the same alkaloid. After an exchange of specimens, it has now been decided that all the four alkaloids are identical (Kharasch, King, Stoll and Thompson, 1936). Strictly speaking, therefore, the ergometrine group contains a single alkaloid which has been named differently by different workers. The Council of Pharmacy and Chemistry of the American Medical Association have decided to call the new alkaloid 'ergonovin' to ensure uniformity in nomenclature and to avoid the difficulties regarding the priority of claim of discoverers. As the *British Pharmacopœia* has

retained the original name of 'ergometrine', it will be advantageous for our readers to refer it as 'ergometrine' throughout this article.

Pharmacology of ergot

Until 1930, it was generally assumed that all the desirable activity of ergot in obstetrics was primarily due to ergotoxine. With the discovery of ergotamine, it was shown that this alkaloid was also a potent oxytocic. These two alkaloids therefore are not only very similar chemically, but pharmacodynamically also they are generally identical. Dale and Spiro (1922) stated that qualitatively they were equal, and quantitative differences were so slight that, for all practical purposes, the two substances may be said to be the same, with the exception that ergotoxine is probably slightly more toxic (Lozinski, Holden and Diver, 1933). Ergosine has not been studied in detail pharmacologically and ergocristin has only been very recently discovered. From the meagre data that are available, it seems that these two alkaloids may be very similar to ergotoxine in their pharmacodynamic reactions.

Reports regarding the pharmacological action of ergometrine have already appeared from several sources (Rothlin, 1935; Davis, Adair, Chen and Swanson, 1935; Brown and Dale, 1935; Ghosh and others, 1936). It will be of interest to compare the pharmacological syndromes produced by the two chief alkaloids, in order to understand the full significance of their behaviour on the human uterus. Table II shows the important pharmacological characteristics of ergotoxine and ergometrine. It will be

seen that along with differences in the chemical composition, solubility and melting points, ergometrine exhibits significant pharmacological peculiarities. Ergotoxine produces a typical gangrene of the cock's comb, rise of blood pressure, depression or paralysis of isolated rabbit uterus and a reversal of adrenaline effect—all pointing to a paralytic effect on the motor sympathetics. Ergometrine, on the other hand, does not exhibit any of these peculiarities even in higher doses. Rothlin (*loc. cit.*) showed that a 10 to 20 times stronger dose of ergometrine had no adrenaline reversal effect on blood pressure and a 100 to 200 times stronger dose caused no adrenaline inhibitory effect on the isolated rabbit uterus. The action on the uterus of ergometrine is particularly worthy of note. Ergometrine brings about a long persistent rhythm of powerful contractions with gradual increase in the tonicity of the uterus. A typical tetany of the corpus uteri may be seen sometimes in experiments on human parturient uterus, lasting for one to two hours without complete relaxation at any time. This type of contraction simulates closely the contractions ordinarily initiated during the puerperium. Ergometrine produces hardly any rise in blood pressure and there are no unpleasant side effects even with three to four times the clinical dosage. On account of its low molecular weight, ergometrine is more easily absorbed and is almost twice as potent as the larger molecule of ergotamine or ergotoxine. By the oral route, ergometrine action starts within 5 to 8 minutes. Ergotoxine, on the other hand, is characterized by delayed absorption and the typical uterine action never

TABLE II
Ergotoxine vs. Ergometrine

Name of drug	Absorption and toxicity	Blood vessels	Uterus	Other effects	Seat of action
Ergotoxine ..	Delayed absorption by mouth. More toxic than ergometrine.	Strong constriction: B. P. markedly raised. Cyanosis of cock's comb and gangrene.	Isolated rabbit uterus depressed or paralysed. Virgin, parous or puerperal uterus of other mammals—contraction; tone predominating over rhythm. Action delayed.	Inhibitory action on adrenaline present, blood sugar—no effect: pupils—contraction.	Central excitation with general sympathetic stimulation. Motor sympathetics inhibited and paralysed (1 : 10,000,000).
Ergometrine ..	Fairly rapid absorption by mouth. Less toxic than ergotoxine.	B. P. varies according to anaesthesia. Pithed cat—slight rise. Anaesthetized cat—fall. Cyanosis—present. No gangrene of comb.	Isolated rabbit uterus—stimulated in very dilute solutions (1 : 2,000,000). Long persistent rhythm of powerful contractions and increase in tone as in early puerperium. Action quick.	Inhibitory action on adrenaline—nil. Dilatation of the pupil, constriction of blood vessels, relaxation of intestinal movements. Blood sugar raised.	Specific paralysing action on motor sympathetics—almost nil. (1 : 500,000).

appears before 40 to 60 minutes, and even then the effects are sometimes rather erratic. The uterine response also is of a different type; an increase in the tonicity of uterine musculature is more often marked than an increase in the rhythmic contractions. Ergotoxine action, however, persists for several hours, much longer than that of ergometrine.

Medicinal preparations of ergot

From all the experimental evidence available, it becomes readily apparent that any ergot preparation in order to be of use clinically must contain significant amounts of the specific alkaloids. The amines, though always identified with ergot preparations, are redundant constituents, and may actually interfere with the action of the alkaloids (Thompson, 1930). It has been estimated that clinical activity is obtained when the total alkaloids of ergot are present to the extent of 0.05 to 0.1 per cent calculated as ergotoxine ethanesulphonate or ergotamine tartrate. Since the two members of the various pairs of alkaloids (referred to in table I) are readily transformed into each other, it is a matter of doubt to what extent each occurs as such or arises during the process of separation. The ratio of inactive to active alkaloids varies from 1.4 to 2.2, but it may well be lower. The amount of ergometrine in Spanish ergot is considered by Smith and Timmis (1931) to be 10 to 15 per cent of the total but assays by Hampshire and Page indicate a somewhat higher proportion (about 20 per cent). From the clinical viewpoint, ergometrine ought to prove of greater therapeutic utility than ergotoxine. It has been claimed that this new alkaloid is responsible for 75 to 85 per cent of the oxytocic action of ergot on the human uterus. It is important, therefore, that any extract of ergot must contain this principle, if it is to

justify its inclusion in the therapeutic armamentarium. Though ergometrine may be considered more important during recent years, ergotoxine cannot be left altogether out of consideration. It is probable that ergometrine initiates the uterine contraction which is carried on for a longer period by ergotoxine, so that both of them are of value and probably give a combined action. In the preparation of liquid preparations of ergot, it is necessary to see that the final extract contains at least the minimum amount of specific alkaloids of both the ergotoxine and ergometrine group. These requirements can be fulfilled only by a proper selection of methods of extraction and preparation and by employing a method of either chemical or biological standardization which will accurately estimate the alkaloidal content and physiological activity of the preparations. Let us now see how far these specifications are fulfilled in the commercial ergot preparations, so commonly used by practitioners.

In table III is given a number of preparations of ergot which are commonly met with on the market in India. Apart from the numerous proprietary and patent preparations of British and foreign manufacturers which are used in special emergencies by individual practitioners, the preparations that are most commonly prescribed are the liquid preparations of ergot mentioned in the *British Pharmacopæia* of both 1914 and 1932. According to the *British Pharmacopæia* 1914 'extract ergot liq.' is made with distilled water, 90 per cent alcohol being added subsequently to give a concentration of 30 per cent in the final product (ergot content—1 gm. per 1 c.c.). From the physical and chemical properties of the ergotoxine group of alkaloids, it will be clear that the occurrence of these alkaloids in any considerable proportion in these preparations is not likely. Ergometrine being slightly soluble in water and moderately soluble

in dehydrated alcohol will, however, be present. In fact, Moir first detected the presence of the new alkaloid while experimenting with the liquid extract of ergot made according to the specifications of the *B. P.* 1914. Ergometrine is effective in dosages of about 0.5 to 1 mg. orally, and, if this amount is present, demonstrable oxytocic action will take place.

The *B. P.* 1932 employs a different method of preparation, using fat-free ergot (defatted with petroleum ether) and a 1 per cent tartaric acid in diluted alcohol (50 per cent) as a menstruum. When the *B. P.* 1932 was published, ergometrine had not been discovered, and the physiological activity of ergot was believed to be entirely due to the ergotoxine group of alkaloids. It appears however that this method of extraction has considerable advantages over that in the *B. P.* 1914. Thompson's studies (1935) show that the carefully-prepared acid-hydroalcoholic extracts of ergot contain all of the active principles of the drug, are rich in alkaloids, both water-soluble and water-insoluble, and remarkably prompt and effective in their action. In the *United States Pharmacopœia* also the official method requires that crude ergot be first defatted with petroleum ether and then extracted according to a standard method using 2 per cent hydrochloric acid, instead of tartaric acid and dilute alcohol, as the menstruum. Most of the non-official liquid preparations mentioned in table III are also made more or less according to the principles adopted in the *B. P.* and the *U. S. P.*, i.e., they use an acid hydroalcoholic menstruum. Many of these preparations are also standardized physiologically before being placed on the market.

Assay of active constituents of ergot

As this paper is primarily meant for practitioners, it is not intended to give the details of all the methods which have been adopted from time to time in various laboratories. The following methods are considered to be of value :—

(a) *The cock's comb method.*—In 1926, the *United States Pharmacopœia* first adopted a method for the biological standardization of the ergot extracts. The principle of this method lies in the fact that when a particular extract is injected into the breast muscles of a cock, the bright red colour of the comb changes, becoming darker. This colour change of the comb is compared with the colour produced by a 'reference standard' fluid extract or ergotoxine ethanesulphonate (Edmunds and Hale, 1911). This method is still in use and is thought to be a good test for measuring the specific alkaloidal activity of ergot preparations. There are, however, difficulties in the employment of this technique as the gangrene of the comb can also be produced by some of the inactive amines. Further, as ergometrine apparently does not produce any gangrene of the comb, it is likely that its presence will not be detected quantitatively by this test.

(b) *The rabbit uterus method of Broom and Clark.*—This method is widely used and is fairly reliable for estimating the ergotoxine group of alkaloids. It is based upon the well-known pharmacological action of antagonism of epinephrine and ergot alkaloids upon the augmentor sympathetic nerve supply to

smooth muscle. This method, which has been the mainstay of pharmacologists in many parts of the world, however, suffers from the drawback that it cannot measure the ergometrine content of ergot preparations. Ergometrine has very feeble sympathetolytic properties and hence the adrenaline contraction of rabbit uterus is not reversed by it.

(c) *The colorimetric method.*—In view of the chemical complexity of ergot and its preparations, it is not surprising that chemical standardization of the drug should have been looked upon with disfavour and until recently more difficult pharmacological methods have been resorted to in the assay of ergot preparations. Qualitative chemical tests were devised long ago, but prior to 1930, when Smith described a quantitative colorimetric test, no reliable method for the estimation of ergot alkaloids was available. This method is based upon the reaction of van Urk (1929) wherein para-dimethyl-amino-benzaldehyde is used to produce a blue colour which can be compared with a standard. This method measures the total alkaloidal content of ergot, including both the active and inactive members, and has now been adopted in the *British Pharmacopœia*. As ergotoxine always forms from 60 to 80 per cent approximately of the total alkaloids, this method can be conveniently used to measure roughly the ergotoxine content. It has been generally shown that figures obtained by this method agree favourably with the Broom and Clark method of ergotoxine estimation. As ergometrine also gives the colour reaction, this is the only method which attempts to estimate both types of active alkaloids in ergot.

In view of the importance of estimating ergometrine separately, Hampshire and Page (1936) have described a method by which the water-soluble alkaloids (ergometrine) and the water-insoluble alkaloids (ergotoxine group) in ergot could be determined. This method promises to be one of the most useful methods for the assay of ergot preparations, particularly in view of the fact that the estimation of ergometrine biologically is difficult. The pregnant uterus method of Thompson (1935) offers practical difficulties and the human uterus method described by Dudley and Moir (1935) and Kopp (1935) is not easily done without the co-operation of the patients and the help of an obstetrician. Brown and Dale's method (1935) of observing rhythmic contraction in a quiescent uterus has not been sufficiently tried. Until a more convenient laboratory method for biological assay is described for ergometrine, the colorimetric test, particularly by the method of Hampshire and Page (*loc. cit.*), would probably be the best way of assaying ergot preparations.

The present status of medicinal preparations of ergot on the market

A large number of official liquid extracts of ergot, both of Indian and foreign origin, have been tested during the last 10 months at the Biochemical Standardization Laboratory of the Government of India, under the direction of Brevet-Colonel R. N. Chopra. The assays were carried out both by the colorimetric method as described in the *B. P.* 1932, with the modification subsequently described in the *Addendum* to the *B. P.* 1936. These findings were checked in a large majority of cases by the 'rabbit-uterus' method of biological assay. The results indicate that a very large proportion of the liquid extracts of ergot available in the Indian market contain either a trace of, or no active principles at all. There are a number of preparations of *B. P.* 1914 (watery extracts) which produce no colour reaction whatsoever. Tested on rabbit uterus in Dale's bath, these preparations show a pseudo-stimulation for which the

amine content is probably responsible. Such extracts are expected to contain significant amounts of ergometrine, but attempts to obtain any colour reaction even after extraction failed. The B. P. 1932 preparations are better, but even these are not above reproach, as many of them do not contain enough active alkaloids to satisfy the minimum B. P. requirements. Though the samples are not representative of all the provinces in India, the results clearly reflect the serious state of affairs that is existing in the country. It will be apparent to every practitioner who uses official liquid extracts that many of the preparations prescribed by him could not have produced any appreciable oxytocic effect on their patients. Whatever effect was observed clinically in the case of post-partum hæmorrhage was probably due to the inherent nature of the uterine muscle to contract when the foetus and placenta are expelled and not due to the stimulation produced by the administration of ergot preparations.

Probable causes of the poor quality of ergot preparations

At the suggestion of the director, Brevet-Colonel R. N. Chopra, intensive research is now being conducted at the Biochemical Standardization Laboratory to find out, if possible, the reasons for such a state of affairs. Until the investigation is completed, it will not be possible to make any definite pronouncements on the subject. A few general remarks may however be made as a guide to both the physicians prescribing these preparations and the manufacturers who are producing these drugs.

(a) *Deterioration of crude ergot.*—The ergot fungus is not present in the grain fields of this country and practically all the crude ergot is imported into the country from Spain and Portugal, and recently also from Russia. Spanish ergot has been considered the best but Russian specimens have also received high rating by several authorities. After being dried at low temperatures, the ergot is generally shipped to this country in tin containers which are supposed to be water-proof and air-tight. If kept properly, such ergot should not deteriorate rapidly. Burn and Ellis (1927) examined a sample of whole ergot which was kept in a bottle and known to be at least 14 years old, and they expressed the belief that ergot, if preserved in its original form, would lose very little of its activity, particularly when it is stored in a dry condition. As the method and place of storage cannot be always guaranteed, both the B. P. and the U. S. P. insist that ergot must not be kept longer than one year. Because of the scarcity of the drug and the Spanish war, the market price of good ergot, which satisfies all the specifications laid down above, is rather high and it becomes difficult for many manufacturers to use the high-grade crude drug for the production of liquid preparations at a competitive price. The local manufacturers in India are further

exposed to the danger of buying all sorts of deteriorated and mouldy ergot which are dumped into the Indian ports for want of any drug control laws in the country. The deteriorated samples are sold at a very much cheaper rate. Any preparation made from such ergot will naturally not be found up to the standard.

(b) *Faulty method of extraction.*—The B. P. 1914 method of ergot extraction does not require a preliminary defatting of crude ergot. Evidence has slowly accumulated which indicates that, if the crude drug is first defatted, the yield of total alkaloids is very much better than under ordinary conditions. Both in the B. P. 1932 and the U. S. P. 1936, the official method enjoins that the crude drug be first defatted with petroleum ether and then extracted. Petroleum ether being a costly reagent, it is probable that many manufacturers resort to cheaper solvents, such as petrol, ether, etc. The results obtained by the use of these solvents have not been as yet carefully studied but it seems probable that these are not suitable agents for defatting purposes. It has often been seen in laboratory experiments that the same sample of ergot will give more intense colour reaction, if treated with petroleum ether than with crude petrol or ether. Further, it has been brought to the writer's notice that many manufacturers do not follow strictly the directions given in the pharmacopœias, with regard to the use of the acid hydro-alcoholic menstruum in the various stages of the extraction process. The writer's experience is too limited in this field to state that lack of attention to some of the details might be responsible for the poor alkaloidal content in the market preparations of ergot, but there seems to be hardly any doubt that some of the details described in the pharmacopœias are not without significance and should be carefully followed.

(c) *Imperfect assays before releasing finished products into the market.*—There are quite a number of firms who manufacture liquid extracts of ergot, without being aware of the complexities of technique involved in the process. They have not the scientific staff and expert personnel who can be entrusted with the important task of assaying the finished product. It is imperative that every batch of liquid extract should be very carefully assayed, preferably both by the chemical and the pharmacological methods, before issue. The chemical method is indeed a very handy method for an approximation of the amount of specific alkaloids present. It may be resorted to in every case before pharmacologic testing. The biological assay by the adrenaline-reversal method is a complicated affair and in inexperienced hands as much as a 100 per cent error may easily be made. If the colorimetric method gives a satisfactory yield of 40 to 60 mgm. of total alkaloids calculated as ergotoxine, there is every likelihood that such an extract would also show a satisfactory adrenaline reversal. It is

further desirable to estimate the ergometrine content separately by the Hampshire and Page method. It has been observed that all specimens do not contain this particular alkaloid. Stoll (1935) showed that Russian ergot did not contain any ergometrine but the Spanish and Portuguese samples were rich in it. The ergot fungus produces, according to its race and habitat, sometimes one and sometimes another alkaloid. If this is true, and in view of the important oxytocic action of ergometrine, it is desirable that some guarantee should be available regarding its presence in ergot preparations. Liquid extract of ergot freshly made according to the specifications of B. P. 1932 from crude ergot, kindly supplied by a manufacturing concern in Calcutta (Bengal Chemical and Pharmaceutical Works, Ltd.), has been found in this laboratory to yield a satisfactory colour reaction for total alkaloids. A comparatively less intense but definite colour reaction is also obtainable when an extract from this was tested separately for ergometrine content. It should be possible to repeat such results with samples obtained from the open market.

(d) *Deterioration of liquid preparations.*—Perhaps the greatest disadvantage of liquid extracts is the tendency to deterioration on keeping. All ergot preparations, especially those containing water, deteriorate with age. This deterioration is a matter of importance and has received much attention during the past few years. According to the Association of American Drug Manufacturers, the deterioration is particularly noticeable within the first six months after their manufacture and then continues very slowly. Many factors, such as temperature, storage, exposure to air, hydrogen-ion concentration of the medium, have been incriminated. According to Edmunds and Gunn (1934), low temperatures are best for maintaining the stability of ergot preparations. An additional difficulty, therefore, is experienced in countries such as India where the climate is very hot and humid.

Fluid extracts of ergot prepared by the U. S. P. method were examined by Thompson (1930) after storage under various conditions. He found that 50 per cent loss of activity occurred in 5 years when the extract was stored in ampoules *in vacuo* at 0°C., while under ordinary conditions, *i.e.*, exposed to air, a similar loss occurred in one month. If the extract was kept in an amber bottle, half filled and corked, 50 per cent loss occurred in three months. In 1932, Swanson reported on the effect of hydrogen-ion concentration on the stability of extracts of ergot under ordinary conditions of storage. He found that, at a pH of 2.7, there was practically no loss of activity in two years while at a pH of 5.3 there was 98 per cent loss during the same period. Others have also stated that increased acidity apparently enhances the keeping qualities. Swoap, Cartland and Hart (1933), on the other hand, believe that the best method of

reducing the amount of deterioration is packing in one ounce containers rather than adjusting the acidity. Most investigators (Wokes and Elphick, 1930) are however agreed on the danger of storage of the extract in bulk.

The remedy

Ergot is a drug which is chiefly used to stop post-partum hæmorrhage, an emergency condition where energetic treatment is required. The physician cannot afford to risk his reputation, and probably the life of the patient, by using preparations of doubtful strength. The liquid extracts of ergot on which the physician pins his faith have probably all been aged for a year or more before being sold and probably also have spent another year or so in the cubicle of the pharmacy before being passed on to the patient. It is very unlikely that a pound bottle of liquid extract is consumed in a retail pharmacy within a short period. The patient who gets her dose from a fresh bottle may be lucky, but there must be others who will have to be satisfied with the last dregs from a time-worn ill-corked bottle. The physician ends his duty by prescribing, the pharmacist is happy as long as he serves the prescription from properly labelled bottles, and the patient swallows the rather unpleasant mixture in the fond hope that dramatic results will follow. But can any results be expected from preparations containing, in a large percentage of cases, no specific alkaloids?

The question naturally arises—is there any way out of such a state of affairs? A number of proprietary ergot preparations are available on the market which are claimed to be stable and some of them are also physiologically standardized either by the ‘rabbit-uterus’ or the cock’s-comb method. As this standardization refers only to the ergotoxine content, the presence of ergometrine, though possible, is not ensured in these preparations. Pure preparations of the alkaloids of ergot, like ergotoxine ethanesulphonate, ergotamine tartrate (Gynergen), ergometrine hydrochloride, or ergonovin hydraerylate (‘ergotrate’), etc., are now available and these may be confidently used, particularly the ergometrine class of preparations. The use of purified active principles will naturally be costly and cannot be made available to most of the hospitals and dispensaries with a limited budget. Apart from the question of cost, it has its disadvantages. It should not be forgotten that, though the purified principles ensure physiological action and are invaluable in certain pathological conditions, *e.g.*, ergotamine in migraine, the extracts are perhaps best of all from the obstetrical viewpoint, since they give a combined action of both the water-soluble (ergometrine) and water-insoluble principles (ergotoxine group).

Researches are now being conducted in many laboratories in this country as well as abroad, to investigate the conditions necessary to make

liquid preparations of ergot stable. If this aspect of the problem is solved and preparations made available to the patients, containing specific alkaloids in significant amounts to make intelligent dosage possible, much will be achieved. In the present state of affairs, it seems desirable for the practitioner to make careful enquiry regarding the freshness of the liquid preparations sold by the pharmacists who dispense his prescriptions. This is easier said than done. The other alternative is to insist that wholesale firms, at least in this country, should supply liquid extracts of ergot in small packings, preferably in one ounce containers and that drug-stores and stockists be advised to store them in a cool and dark place. Every bottle should bear the mark of careful assay and, further, the date of assay should be indicated on the container. If this is not possible, the case for using ergot powder as in the old days may be reconsidered. It has been suggested by Burn and Wokes (1929) and later again by Burn (1929) that dried defatted ergot in a dose of 1 gramme daily in a capsule should be given *post partum* in place of liquid extract of ergot. Dried ergot, especially if defatted by treatment with purified petroleum ether, retains most of its activity for at least two years when stored in a dry place. It is usually active for a much longer period.

Acknowledgment

This review of the present state of knowledge about ergot and its preparations was undertaken at the suggestion of Brevet-Colonel R. N. Chopra, the director of the laboratory, and the author wishes to place on record his grateful thanks for his permission to publish this article. A preliminary report was read at the Annual Reunion Meeting of the Medical College, Calcutta, in December 1937.

Medical News

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE TENTH CONGRESS

THE Tenth Congress of the Far Eastern Association of Tropical Medicine will be held at Hanoi (address 'Igesante', Hanoi, Indochine) from the 24th to 30th November, 1938.

All licensed medical, dental and veterinary practitioners are eligible for membership. The membership fee for the period 1934 to 1938 is £3 (or Rs. 40-2) and should be paid to the local provincial secretaries of the Far Eastern Association of Tropical Medicine, to whom the names of members in their areas should be submitted. The members are also requested to inform the local secretaries whether they propose attending the Congress. The titles of any papers which it is proposed to place before the Congress should be submitted to the local secretaries at any early date. Arrangements will be made for the reading at the Congress of any paper submitted by a member who is unable to attend.

The Ninth Congress held at Nanking in 1934 decided that sections on food problems and sanitary measures with reference to sewage and garbage disposal should also be added to the programme of the Tenth Congress.

Further information may be obtained from the local provincial secretaries or from Lieut.-Colonel G. Covell, M.D., D.P.H., D.T.M. & H., F.R.E.S., I.M.S., Director, Malaria Institute of India, and Local Secretary of F. E. A. T. M. for Government of India, Kasauli, Punjab, or the Honorary General Secretary, Far Eastern Association of Tropical Medicine, Parapattan 10, Batavia (Centrum) Java.

UNITED PROVINCES MEDICAL COUNCIL

(Abstracted from the *Minutes of the meeting of the United Provinces Medical Council held at Lucknow on 25th March, 1938*)

RESOLVED that the name of Dr. Muzaffar Ali, M.D. (Vienna) of Bhopal may now be registered.

The applications for registration of Drs. Bertha Chase and Mildred E. Burton of Clara Swain Hospital, Bareilly, were considered to decide whether the M.D. qualifications of the University of Vermont (U. S. A.) and University of Louisville Medical School (U. S. A.) be accepted as registrable qualifications and added to the schedule.

Resolved that the applications be rejected. The registrar was, however, asked to direct the attention of the applicants to rule 5 on pages 18 and 19 of the United Provinces State Medical Faculty Rules.

Resolved that the following be added as paragraph 5 in the application form—

'When registered, I promise to abide by the rules and regulations framed, or to be framed from time to time hereafter, by the United Provinces Medical Council under the United Provinces Medical Act, III of 1917'.

Resolved that the amount charged for reciprocal registration be raised from Re. 1 to Rs. 5 as in Bengal.

SUMMARY OF TUBERCULOSIS NEWS FOR APRIL 1938

INDIA is represented at the International Union against Tuberculosis through the King George Thanksgiving (Anti-Tuberculosis) Fund. The Fund Committee has nominated Major-General E. W. C. Bradfield, C.I.E., O.B.E., K.H.S., I.M.S., and Dr. A. C. Ukil, as councillor members for the year 1938.

His Highness the Maharaja of Nawanagar recently laid the foundation stone of the tuberculosis sanatorium on the Bhuj-Bharatpur road, Cutch.

A press communiqué issued by the Nizam's Government surveys the medical and public health department's work in fighting tuberculosis. Besides the 150 hospitals and dispensaries where tuberculosis cases are treated, there are two special tuberculosis clinics and a new one is being built at Dhabipura. A special tuberculosis hospital at Lingampalli will be completed within the next three months. Plans have been completed for a sanatorium at Anantagiri about 50 miles from the city.

The Mayor of Bombay has inaugurated a campaign in aid of Her Excellency the Marchioness of Linlithgow's appeal for the King-Emperor's Anti-Tuberculosis Fund by starting a 'Rupee Fund'. Numbered receipts will be given to all donating one rupee. Arrangements have been made for donations to be made through banks, petrol stations, garages and big stores.

In the first instance 100,000 tickets are being issued and every donor stands a chance of winning one of the 100 prizes from Rs. 5,000 downward. Altogether Rs. 19,000 will be distributed in prizes for the numbered receipts. The numbers have already been chosen by Lady Lumley. Immediately Rs. 1,00,000 has been collected, the above prizes will be distributed and a further drive for another collection of Rs. 1,00,000 will be made with similar prizes.

INSPECTION TOUR BY THE VICEROY OF DELHI ANTI-MALARIA SCHEME

'A WELL-GOVERNED city should possess a sound water-supply, should be reasonably free from overcrowding, should be adequately drained and sewered, and should be protected so far as is reasonably possible from endemic and epidemic disease', said His Excellency the Viceroy, while informally addressing press representatives at the Muttar road sewage disposal works, after he had finished an inspection tour of certain works carried out by the Delhi Improvement Trust.

'In these days', he said, 'when the Government of this country is becoming more and more a matter of persuasion, it is in my opinion wise to miss no opportunity of educating public opinion and of quickening the social and civic conscience.'

Delhi has a sound water-supply, though even the recent extensions, which raised the capacity to 21 million gallons per diem, are unlikely to suffice for very long. The peak demand of 1937-38 was 17 million gallons per diem and the Joint Water Board are now actively considering further extensions. In other respects, however, conditions fall far short of reasonable standards, and the works now in progress, or projected, are intended to relieve overcrowding, to provide for the efficient disposal of sewage and to protect the city and New Delhi from malaria.

MOSQUITO BREEDING GROUND

I saw some of the extensions and other works of the Trust on 17th March. The works seen on the present tour include the largest individual anti-malaria work, one smaller anti-malaria work and the new sewage disposal system. The anti-malaria works are designed to facilitate control of mosquito breeding by the elimination of extensive breeding grounds. On this side of Delhi and New Delhi they extend from Metcalfe House in the north to the Purana Kila and the Barapula Nala in the south and the idea underlying them is the same, namely, regrade drains and open surfaces so that flood and storm water may in all, save very exceptional years, run off before breeding can take place.

The original programme, which was estimated to cost Rs. 14.79 lacs and included a few lesser works to the west of the city and important canal closing scheme

in the Pul Mithai neighbourhood, has made good progress and almost all the works are complete. This canal closing scheme however remains and will, it is hoped, be taken up in 1938-39. New money is being found to regrade one more drain in the Jumna village neighbourhood and to straighten and pitch the Darhalia Nala and to improve the Najafgarh drain into which the Darhalia Nala falls. The additional expenditure in 1938-39 for these certain other works will be about Rs. 2.4 lacs.

NEW VACCINE TO CONTROL ANTHRAX

AN anti-anthrax vaccine believed to be a considerable improvement over existing products for the control of anthrax has been evolved at the Imperial Veterinary Research Institute, Muktesar, and will be shortly available, according to the director of the institute, whose annual report for the year 1936-37 has just been published.

The material for the vaccine was obtained from the Director of Veterinary Services, Burma, and the vaccine prepared on the method in use in South Africa. The tests conducted at the institute on the vaccine have yielded highly satisfactory results.

Work on the manufacture of a tetanus anti-toxin is also in progress and it is hoped that the institute will in the near future be able to issue this product also.

A Comparison of Insulin and Cardiazol Convulsion Therapies in the Treatment of Schizophrenia

By H. PULLAR STRECKER, M.D. (Würzburg),
L.R.C.P. (Edin.)

(From the *Lancet*, Vol. I, 12th February, 1938, p. 371)

DEMANDS UPON TIME

AN undoubted advantage of cardiazol treatment is the great saving of time; also its management is less exacting. Convulsions are induced two or three times a week, and as the whole process does not take more than five minutes of the doctor's time, he, with the aid of two or three nurses, can treat 40 to 50 patients in one morning. Insulin treatment is given six times a week, each treatment lasting about five hours from beginning to end, during which the doctor must not leave the patients. With the aid of two or three nurses, one doctor can treat 8 to 10 patients in one morning.

The after-treatment necessitates a similar amount of work with both methods, except that with insulin the nurses must be capable of dealing with after-shock, should it appear. Both treatments should be accompanied by psychotherapeutic encouragement and by occupation therapy. The duration of the whole course of treatment is roughly the same; cardiazol requires an average of 6 to 8 weeks and insulin 8 to 10 weeks.

ADJUSTABILITY TO CLINICAL REQUIREMENTS

Although the more lengthy and exacting procedure, insulin treatment has the advantage that it can be adjusted to any degree from mild hypoglycemia to deep coma; cardiazol convulsions are not adjustable, and only the number induced is subject to control. Contrary to expectation, the biochemical changes produced by the two methods have much in common; the effects of cardiazol, however, are fully spent in a minute, whereas those of insulin extend over hours. Thus the element of shock does not predominate in insulin treatment; quite a number of patients recover without the necessity of reaching the coma stage, and

the gradual mental 'unfolding' which takes place during hypoglycemia—layer by layer so to speak, as witnessed by lucidity and increasing insight—shows the unique therapeutic possibilities of insulin treatment.

Since the depth and duration of hypoglycemia, and the time and method of terminating it, can be suited to clinical requirements, insulin affords a wide therapeutic range, and different techniques are in use according to the clinical type of schizophrenia.

MORTALITY-RATE, COMPLICATIONS, CONTRA-INDICATIONS

In the hands of the experienced, the mortality-rate of the two treatments is equally low. It was 1 per cent among the first 700 insulin patients, and 0.5 per cent among the first 600 cardiazol patients, but with accumulating experience it fell to 0.4 per cent among 500 patients recently treated in Switzerland. There is less likelihood of emergencies arising with cardiazol than with insulin hypoglycemia, where laryngeal spasm, failure to awake from coma, or cardiovascular collapse may be encountered. Cardiazol is more unpleasant to the patients, but their apprehension can be alleviated by giving, 30 to 45 minutes before the injection, morphine sulph. gr. 3/8, hyoscine hydrobrom. gr. 3/200, and atropine sulph. gr. 1/100. I prefer pre-medication with insulin, which completely eliminates unpleasantness.

The contra-indications—namely, any form of cardiovascular disease, as well as respiratory, renal, or hepatic disease—are the same for both treatments. So are their principal after-effects (occasional vomiting or transient attacks of tachycardia). Passing alterations of the T wave appear to be more common with insulin while with cardiazol luxation of the jaw or arm has been known to happen.

The fact that most patients gain weight while undergoing either form of treatment shows that there is no detrimental effect on their general health. The question whether or not hypoglycemia and induced convulsions are as harmless to the brain as clinical observation suggests, remains an open one, but the results of recent animal experiments are reassuring in respect of hypoglycemia as well as of induced convulsions.

PERMANENCE OF BENEFIT AND INCIDENCE OF RELAPSE

As regards permanence, treatment is too recent to admit of far-reaching deductions; however, a high proportion of the recoveries obtained in Vienna and Budapest four and three years ago, when treatment was begun, has been maintained. It is difficult to differentiate between the incidence of relapse of the two methods, for only one reference regarding cardiazol has been published. Angyal and Gyárfás, treating 44 patients with cardiazol, obtained 17 complete or incomplete remissions and report 4 relapses (23 per cent). With insulin Frostig treating 53 patients (27 complete remissions) had 4 relapses (15 per cent). Beno treating 49 patients (35 complete, incomplete, or partial remissions) had 5 relapses (14 per cent), while Müller, surveying 495 Swiss patients (200 complete or incomplete remissions), noticed 13 relapses, which is only 6.5 per cent.

It should be pointed out that, with either method, poor results or relapses may be often due to the technical error of not giving a long enough course of treatment.

REACTION OF CLINICAL TYPES OF SCHIZOPHRENIA TO THE METHODS

The methods are not equally effective with all types of schizophrenia. Hebephrenia and dementia simplex both give relatively poor response to either method; in the other types the order of improvement with cardiazol is generally inversely that with insulin. For example, catatonic excitement and paranoid types are more responsive to insulin, whereas stupor responds better to cardiazol. This is of practical importance and shows the value of combining or of alternating the two methods, since patients proving refractory to cardiazol may readily respond to insulin and *vice versa*. Angyal and Gyárfás, by supplementing the treatment of those refractory to cardiazol by a period of insulin, found their remission-rate increased from 44 per cent to 63 per cent.

CONCLUSION

The results obtained with insulin and cardiazol convulsions in the first years of illness show that they constitute a decided advance in the treatment of schizophrenia. It would be a mistake to neglect either method, or to practise one to the exclusion of the other. Both have their clinical indications and they can be selected according to the technical facilities available. A combination should be attempted wherever suitable, and their alternate use is recommended in refractory cases.

Injection Treatment of Inguinal Hernia

A RESUMÉ OF A POST-GRADUATE LECTURE AT ST. MARY'S HOSPITAL

By A. E. PORRITT, M.Ch. (Oxon.), F.R.C.S. (Eng.)
(From the *Lancet*, Vol. II, 9th October, 1937, p. 835)

THE rationale of the injection method of treating inguinal hernia is to fill up the inguinal canal with fibrous tissue, produced by the injection of a chemical irritant, to such an extent that, first, a hernial sac cannot get down the canal, or, secondly, contents cannot enter a pre-existing congenital sac.

HISTORY

The method is by no means new. Approximately 100 years ago it would seem to have had a considerable vogue in America and in France. Its originator was George Heaton of Boston, who published his results in 1843 and subsequently in book form (1870). Closely associated with him was Warren, also of Boston, and their methods were copied by Velpeau of Paris. Heaton himself used 'quercus alba' as his chemical irritant; his American co-workers and Velpeau tried iodine, Lugol's solution, cantharides, and several

mixtures of essential oils. They all adopted the procedure of one massive injection, the patient being—of necessity, one imagines!—confined to bed.

The advent of antiseptic and, later, aseptic surgery, and the publication between 1880 and 1890 by Halsted and Bassini of their operative methods for the treatment of hernia, led to the relegation of the injection idea. With the exception of the work of two men this state of affairs persisted until five or six years ago, since when, in America, a great deal of investigation has been carried out and innumerable papers published on the injection technique. The two who filled in the intervening period were Ignatz Mayer of Detroit and Pina Mestre of Barcelona, to whom must be given the credit for the present-day ambulant method of treatment. Mayer, working over a period of thirty years, and using a solution the essential constituents of which were zinc sulphate and carbolic acid, produced a series of 2,000 cases in which he claimed 98 per cent success. Pina Mestre, using a tannic acid solution, published in 1927 a series of 10,000 cases, showing almost equally good results, and no fatalities. Such figures promoted ardent research in America, with the result that there the method is to-day well approved and widely accepted. In England, apart from the work of Delisle Gray, it seems to have found very little recognition.

The series of 100 cases described here is the result of an attempt to evaluate the therapeutic and economic possibilities of the method. As the ultimate result of the treatment seemed the most important factor to be considered, they have been selected from about 150 cases as being those which it has been possible to follow up for periods varying from three years to six months. The remainder consists of those who have too recently come under treatment, those with whom it has been impossible to keep in touch, and those, only eight, who failed to complete their treatment. Before considering the selected 100 in detail certain general aspects require mention.

ANATOMY AND HISTOLOGY

Even at the risk of being obvious one cannot over-emphasize the importance of a sound knowledge of the anatomy of the inguinal canal and its contents. Injections should be made deep to the aponeurosis of the external oblique and extend at approximately regular intervals from the crossing intercolumar fibres of the external oblique at the external abdominal ring on the inner side to beyond the internal ring on the outer side, and from the conjoint tendon above to the inguinal ligament below.

Nelson and Rice have conducted an admirable series of experiments on both animals and men, which demonstrate the histological changes following injection. Their results may be briefly summarized as follows:—

6-15 hours: polymorph leucocytic response with occasional round cells and some oedema.

24 hours: signs of transient cellular necrosis.

5th day: evidence of fibroblasts.

8th day: many fibroblasts and new blood vessels.

14th day: definite fibrous tissue formed.

42nd day: dense scar tissue.

In other words, the histological result is a 'foreign body granuloma'. The earlier stages of these changes I myself confirmed on guinea-pigs, late results being unavailable owing to overdosage adversely affecting the life of the animals concerned!

CHOICE OF CASE

This paper deals only with inguinal herniæ, although it includes recurrent herniæ that are really 'incisional'. But many workers have successfully used the method for femoral, umbilical, and ventral herniæ, and there seems no reason why the technique should not be judiciously extended to all types.

Sex is immaterial. Inguinal hernia is relatively much less common in women, but the method can be equally well applied in them, the anatomical differences making the technique slightly more difficult. Inability to invaginate the labium majus into the inguinal canal

makes localization of the needle point by touch impossible, but on the other hand the boggy of the spermatic cord is removed.

By experience one has found that the important factors in selecting cases are the size of the external abdominal ring and the amount of fat in the subcutaneous tissue of the groin. All herniae of course must be completely reducible. The size of the actual hernia is of small import so long as it can be efficiently retained by a truss. But it has been found that in general with an external ring that admits two fingers treatment is likely to prove difficult or at least prolonged, and that the more fat there is overlying the inguinal canal the less likely are injections to be well placed. It seems probable that excessive subcutaneous fat, apart from increasing technical difficulties, implies, firstly, excessive extraperitoneal fat in which injections seem to cause more necrosis and less fibrosis, and, secondly, poor muscle power, with the consequent liability to further strain being thrown on an already weakened area.

Thus the young adult, with good musculature and minimum subcutaneous fat, appears to be the ideal type for injection. One more requisite he should have—enough intelligence to co-operate in his treatment, particularly in the wearing and non-removal of his truss. For this reason alone children are in general not suitable cases.

The only other contra-indications worthy of mention are imperfectly descended testicle, the sliding type of hernia (if diagnosed), infective skin conditions of the groin, and hæmophilia. Such conditions as active venereal disease, ascites, or pregnancy, will obviously preclude the possibility of injections. But for chronic renal disease, diabetes, pulmonary tuberculosis, etc., which have in various papers been given as contra-indications, the method would seem to me to have a very definite field of utility. My series includes successful cases of all three conditions.

THE TRUSS

An essential adjunct, and to some extent a drawback, to the injection treatment is the wearing of a truss continuously during the course and for some time afterwards. The object of this support is to prevent any strain being thrown on the newly formed granulation tissue before it has had time to consolidate and become firm fibrous tissue. A well-fitting and comfortable truss is therefore of the utmost importance as it has to be lived in for some months, day and night—and in the bath! For this reason I have devised a truss, which has been made for me by Messrs. Weiss and Son, London, W.I, to cope with these requirements. It consists of a vulcanized hard rubber pad attached to a steel spring coated with the same material. This has the advantages of being cleanly, light, immersible in water and, after preliminary heating, capable of being moulded exactly to the contours of the individual patient. Small studs allow of rubber straps (abdominal and perineal) being fitted and used as required. In many cases they are not needed at all and patients' testimonies convince me that this type of truss is very satisfactory in all respects. Most patients in this series have done manual work—often very heavy—in them, and many have played games and even enjoyed the luxury of swimming while under treatment.

I always advise that the patient should wear the truss, and sleep in it, for a week or two before injections begin, so that he may be thoroughly used to it. Once treatment begins it must be removed only at the actual time of injection and then preferably by the surgeon.

SOLUTIONS

There appears to be as yet no unanimity of opinion upon the ideal solution to be used. This should be painless when injected, give no general systemic reaction, be non-toxic if injected intravenously or intraperitoneally, non-injurious to the tissues locally, and capable of producing the maximum fibroblastic reaction with the minimum of exudation. The solution used in this series—that of Mayer (zinc sulphate

1 dr., phenol crystals 6 dr., glycerin 4 dr., aqua cinnamoni 1 oz., sterilized redistilled water 2 oz.)—admittedly does not fulfil all these requisites. It produces good and non-harmful local results and no general reaction, but often gives some pain and is toxic if injected intraperitoneally—and probably therefore intravenously. Now that this series is completed I intend to transfer my allegiance from a caustic

to a solution of which the best to date appears to be Guitanol—a mixture of tannic and gallic acids, as used by Fowler in a series of 700 cases—Proliferol, or Sylnasol—a solution of sodium psyllate, used by Harris and White in a series of 100 cases, and by Biederman. The original Pina Mestre solution with a tannic acid basis has been approved (1936) by the American Medical Association Council on Pharmacy and Chemistry, and used extensively by Jameson. Winters has employed colloidal potassium guaiacol sulphate, and McMillan and Cunningham a mixture of phenol, alcohol, and tincture of thuja. Even sodium morrhuate has its supporters.

TECHNIQUE

The patient lies upon a couch. In the average case there is no need to adopt a slight Trendelenburg position or to place a pelvic rest under the buttocks, although these manœuvres may be of assistance in dealing with the early stages of a big hernia or with an obese patient. The truss is then removed and the pubic hair cut with scissors. It is better not to shave as this often leads to dermatitis and discomfort under truss pressure. The spot chosen for injection is locally anesthetized. At first this can be accurately determined by a finger invaginating the serotum into the inguinal canal. Later surface landmarks or the results of previous injections must be the guides, and towards the end of treatment a small cough with the patient lying and a finger covering the inguinal canal will demonstrate residual weak spots.

The needles used are 22 or 23 gauge with a medium bevel. The needle is inserted vertically to the skin surface and will be found to meet two resistances—the skin and the aponeurosis of the external oblique. Just deep to this latter is the correct level for injection. Preliminary aspiration to exclude the needle being in a blood vessel should always be done.

The dose will of course vary with the solution used. A preliminary 0.5 c.cm. followed subsequently by 1 c.cm. doses has been used with Mayer's solution. Injections can be given bi-weekly or even at shorter intervals according to the reactions of the individual patient. It is most important that they be given very slowly. The first drop will probably give an unpleasant stinging sensation, which however passes off in a few seconds—the remainder of the injection being practically painless. The patient should be made to describe the position of the initial sensation as this may help considerably in localization. If pain in the testicle is complained of, the point of the needle is too close to the cord and must be moved accordingly. Vague pains moving across the pubis, towards the anterior superior spine, to the perineum or the thigh are of little significance. But any mention of abdominal pain is a danger signal implying that the sac or even the peritonum proper have been penetrated. In this case the injection must be stopped immediately.

At a period varying from half an hour to three hours after the injection a feeling of vague discomfort develops in the groin of varying intensity, according to the type of patient and the stage of treatment. This discomfort is not sufficient to interrupt either the patient's work or his sleep, although it may last for as much as twelve hours.

Opinion varies about the end of the inguinal canal which should be injected first, the majority of workers starting at the outer limit or internal abdominal ring. I have favoured the external ring for the first injection, since localization is then very exact, and further, any possible risk of incarceration is thereby avoided.

When treatment has reached the stage of there being no visible or palpable impulse on coughing with the patient recumbent, he is then given a fortnight's rest still wearing the truss. If on re-examination all is satisfactory, the truss is discarded at night. Two weeks later, all being well, gradual removal of the truss for an increasing number of hours daily is allowed, this stage taking about a month varying with the occupation and intelligence of the patient. Thus it will be seen that some two months elapse from the time of the last injection to the time of complete discarding of the truss. Allowing for a preliminary wearing of the truss for a week or two before injections begin, and for an average of 10 to 12 injections at bi-weekly intervals, the whole treatment takes about four months—during which of course it must be remembered the patient is ambulant and able to live a normal life and carry on his usual occupation.

RESULTS

The 100 cases under consideration have all been injected during the last three years and have been followed up for a period of not less than six months.

Of the 100 patients 97 were males and three females. This does not give a true idea of the relative sex frequency, as the method was only extended to females this year. The average age of the patients was 38, the oldest being 66 and the youngest 17. Of the hundred, 64 were employed in manual labour, often of the hardest kind, and 36 in sedentary occupations.

The 100 patients were responsible for 110 herniæ. Of these 69 were right sided and 41 left, these figures including 10 bilateral cases. The herniæ were simple bubonocœles in 82 cases, and either scrotal or labial in 28. Five cases of recurrent herniæ after operation were dealt with. The average interval between the appearance of the hernia and the beginning of treatment was two years, the shortest period being one day and the longest eighteen years.

For these 110 herniæ, 1,032 injections have been given, an average of approximately 9.4 per hernia. The average number of injections required to close the external abdominal ring was four.

Of these 1,032 injections, three have been considered as intraperitoneal. The result was very alarming, the clinical condition being one of severe shock. This came on very rapidly—within a few moments, and passed off equally rapidly within half an hour. Treatment was complete rest, brandy by mouth, heat to the abdomen, and, in one case, an injection of adrenaline, in another of eoramine. All three cases left hospital within two hours of the injection and appeared none the worse afterwards.

Some 14 injections, apart from these three, produced severe reactions, either in the direction of immediate acute pain or of later prolonged swelling, tenderness, and discomfort. Occasionally, transient swellings in the upper part of the scrotum were noticed, particularly after early injections. These are typically painless. No case of testicular atrophy has been observed, and one patient with a bilateral hernia has since injection successfully sired a son.

Two cases are definitely failures, both these being elderly men of adipose build and having big scrotal herniæ coming through a very enlarged external ring. In both cases the hernia was reduced to the inguinal canal, but it proved impossible to hold them back in this region. There were five cases that came into another category—'recurrence'. One feels that in these, recurrence simply expresses inadequate treatment, although two of the five came back over a year after apparent cure. All responded satisfactorily to further injections.

ECONOMIC ASPECT

It is chiefly the able-bodied young to middle-aged adult who becomes afflicted with hernia, i.e., the productive worker. If this class can in the main be saved from hospitalization and loss of wages the economic advantages are self-evident. While admitting that generalities are misleading a minimal estimate of the

position in this country produces interesting figures. On the basis of a weekly wage of £2 10s. and hospitalization costs of £3 per week, the injection treatment effects at a conservative estimate a saving of £25 per patient either to the patient, the hospital, or the charitable aid societies. If 50 London hospitals operate on 100 cases each per year that might equally well be treated by injection, the loss in work, wages, and hospital costs amounts to £125,000, and if London accounts for 25 per cent of the hernia cases treated annually in the country, the figures mount up to half a million sterling. Only a keen desire to avoid exaggeration leads one to quote nominal figures which probably but half represent the case. It seems that this aspect of the treatment alone would make it worthy of careful consideration by hospitals, charitable aid societies, insurance companies, public health bodies, the Services, and even perhaps the Ministry of Health itself.

Two other considerations are worthy of mention. A general acceptance of the treatment would free a large number of hospital beds annually for the reception of more acute or more worthy cases. On the analogy of American figures (Biederman) it seems probable that there are some 2,000,000 hernia cases in this country going untreated because the people concerned either cannot afford operative cure or are frightened by the thought of operation. Such people represent a big entry on the debit side of the physical fitness ledger of the country.

CONCLUSIONS

Recurrences after operation, even in the hands of the best surgeons and when large series of cases are considered, give the unpleasantly high figure of about 10 per cent. Max Page in one series even found it as high as 25 per cent. Fallis in a series of 1,600 cases arrived at a figure of 7.5 per cent. Injection offers a better prospect than this—7 per cent in the present small series and figures as low as 2 per cent to 3 per cent in much larger series in America.

This result is achieved without any of the risks of anæsthesia or surgical interference. Complications are of a minor nature and relatively few in number; no mortality at present has been reported.

Both operation and injection aim at repairing the inguinal canal weakness by fibrous tissue formation. The former leads to a definite uncontrollable amount being produced which may or may not be sufficient to effect its purpose; the latter to a regulated and requisite amount, which even in the event of a 'recurrence' can be increased or replaced by a few additional injections.

It is certainly not intended to imply that the injection treatment is the 'cure-all' of hernia. It has obvious limitations, but within those limitations it would appear from the present series to be so free from risk, painless, economic, and efficacious as to merit an extended and prolonged trial.

Cholecystitis

By J. W. McNEE, D.S.O., M.D., D.S.C., F.R.C.P. (Lond.)
(From the *British Medical Journal*, Vol. II, 1937, p. 731)

THE subject of gall-bladder infection has been discussed in recent years at many times and in many places, especially by hospital physicians and surgeons. It is a good choice for discussion at an Annual Meeting of the British Medical Association, because its great frequency and clinical importance may then be emphasized to the general practitioner, who, after all, has the main opportunity and responsibility of recognizing inflammation of the biliary tract in its earliest and most important stages.

The combined results of many observations, by physicians, surgeons, and pathologists, seem to show without any doubt that disease of the gall-bladder is now the commonest of all organic troubles of the digestive tract. This has been repeatedly stated by

Hurst. Statistics in different countries and in different clinics must vary, but Piersol has recently published an analysis of the admission to the gastrointestinal clinic of the University of Pennsylvania Hospital and shown that 16.3 per cent of patients were diagnosed as suffering from gall-stones, duodenal ulcer, cancer of the stomach, gastric ulcer, and chronic appendicitis followed, in this clinic, in order of frequency, but these are merely the results in one American hospital. I am unable to present the statistics of any large series of gastrointestinal cases in Britain, but it may safely be accepted that cholecystitis is now established here as one of the most common and important intra-abdominal diseases. It is obviously my duty in opening this discussion to give a general survey of the problem before us and not to spend undue time on matters which will be dealt with in greater detail by subsequent speakers.

AGE, SEX, AND TYPE OF PATIENT

It must nowadays be realized that the female who is 'fat, fair, forty, and fecund' is by no means the only type subject to biliary disorders and to their common sequel of gall-stones. It is true that cholecystitis is more common in females than in males, for reasons which have many times been discussed and which need not detain us now. Gall-bladder troubles are, however, quite common in men, and it may be emphasized that cholecystitis occurs in young men and young women, and even in children. These facts are, I think, not yet sufficiently and universally realized. With the increase of outdoor games and exercise in young people this disease may diminish; but there are many, mostly living in cities, who have sedentary occupations in offices and factories and are prone to dyspepsia and biliary disease. In acholuric jaundice, a disease generally recognized in youth, there is a special tendency to disorders of the biliary tract—both pigment stones and cholecystitis.

ÆTIOLOGY

I have already referred to sedentary occupations as increasing the risk of cholecystitis, and indeed the factor of biliary stasis is the only important predisposing cause on which almost everyone will agree. It would not be justifiable here to discuss disturbances in the physiology of the biliary tract as a cause of biliary symptoms, since so little is known with absolute certainty. Problems concerning the sphincter of Oddi, contraction of the gall-bladder, and spasm of the main bile ducts are all involved here; and frankly, in my view, the time has not yet come to bring questions of disturbances in the physiology of the biliary tract into the realms of ordinary practical medicine. We have enough to deal with at present in gall-bladder pathology, due to microbial infection of the gall-bladder and biliary tract, the essential cause of the subject we are discussing, namely, cholecystitis. Here, too, we are faced with the difficulty of reconciling the divergent views of physicians and surgeons for the ultimate benefit of our patients. This matter will no doubt be examined fully by Sir Arthur Hurst and Sir David Wilkie, and I need only place the general position before you.

The points of importance are:

1. What are the common microbes which infect the gall-bladder, and what is their relative frequency?
2. By what route is the gall-bladder infected—by passage along the ducts from the intestine or by the blood stream? Do the microbes in fact exist mostly or partly free in the bile, or is the infection essentially deep-seated in the wall of the gall-bladder?

The importance of focal sepsis in teeth, tonsils, appendix, or elsewhere in the ætiology of cholecystitis is an essential part of the problem, which I only mention to give a lead to other speakers.

VARIETIES

Cholecystitis with gall-stones.—It is obvious that in the past the diagnosis of cholecystitis was seldom made before the common sequel of gall-stones had occurred

and given rise to obvious signs or symptoms. Even nowadays the frequent accidental discovery of gall-stones of inflammatory origin at post-mortem examinations shows either that a diagnosis was missed or that the symptoms were insufficient to make the patient seek treatment for biliary disease. It must be remembered that in patients who have already developed gall-stones recurrent attacks of cholecystitis are common and often severe.

Acute infective cholecystitis.—This is a surgical emergency and needs no discussion.

Catarrhal cholecystitis.—This is the variety I wish to bring into the forefront of discussion to-day. It is due to infection with organisms of obviously low-grade virulence, and often smoulders on without giving rise to serious or acute symptoms for a long period of time. It is difficult to diagnose, but if untreated is likely to be followed by gall-stones and many other complications.

SYMPTOMS AND DIAGNOSIS

Moynihan, in the days of the rapid development of gall-bladder surgery, described the 'inaugural symptoms of gall-stones'. These, we know now, were the symptoms of the preceding cholecystitis, but at a later stage than we must now identify them. At that time it is fair to say that the early stages, except of the acute and fulminating variety constituting a surgical emergency, were seldom if ever sought for or recognized. It is the diagnostic problem involved in the common catarrhal cholecystitis that I wish to emphasize, and a correct diagnosis will often be missed and treatment too long delayed if the doctor fails to investigate further all cases of dyspepsia which do not respond to simple treatment. He may, and generally does, consider the possibility of gastric or duodenal ulcer, and is disappointed when the x-ray examination by barium meal which he advises yields a negative result. He may think of chronic appendicitis; but up to the present he too seldom thinks of the great frequency of gall-bladder disease as a cause of dyspepsia. The association of flatulence with the dyspepsia is suggestive, but by no means conclusive.

It is best at the very outset, when considering how the diagnosis of gall-bladder infection may be proved, to admit the difficulties involved. The diagnosis by simple clinical methods is easiest when gall-stones are present. Biliary colic occurs in roughly 40 per cent of such cases, while recurrent acute attacks of cholecystitis lead to obvious signs in the right upper quadrant. Further, it is in these cases that cholecystography is of such great diagnostic value. Even when gall-stones are absent the local signs of tenderness or pain or both below the right costal margin may, along with the presence of flatulent dyspepsia, strongly suggest the diagnosis. The real difficulty arises in the cases—and they are many—in which a catarrhal cholecystitis is associated with dyspepsia only, without local pain or tenderness over the gall-bladder at all. These are the early cases in which medical treatment may be of avail. How are such cases to be completely and positively diagnosed so that proper treatment may be carried out? Ordinary simple clinical methods fail us here—what help can we obtain by other methods?

I must first refer to cholecystography, but omit any lengthy discussion. I will only say that in my experience, which is now considerable, the use of the dye followed by x-rays generally does not yield information of positive diagnostic importance in the early cases of catarrhal cholecystitis in which physicians are so interested. I am too often confronted with an x-ray diagnosis of 'pathological gall-bladder', or 'poor filling', or 'faintness of shadow', which are taken to indicate disease, when I know full well the differences in technique and the differences in absorption of the dye, even on different days in the same person. On the whole I am still very chary of accepting a diagnosis of early cholecystitis on x-ray evidence, whatever improvements in technique may later make possible.

We now come to the method of duodenal intubation, and here I feel on quite different and much more

secure ground. I would go so far as to say that in early cholecystitis it is at present the only diagnostic method on which we can positively rely. It is far too little used in Britain, but is a routine method in America and elsewhere. I have indicated in a recent paper some of the reasons why it has not yet obtained its proper place in diagnosis with us; and I feel this defect must be remedied. Perhaps, as in many tests of this kind, too much was at first claimed for the method; but of its diagnostic value in experienced hands I have no doubts at all.

DIFFERENTIAL DIAGNOSIS

This is at times easy, but is often difficult unless the technique of duodenal drainage is employed. This section might easily detain me too long, for the differential diagnosis from chronic gastritis, pylorospasm, peptic ulcer, carcinoma, and peripyloric adhesions would require consideration. Moreover, peptic ulcer and chronic cholecystitis may coexist: I have seen a number of examples of this combination. The clinical differentiation between cholecystitis and chronic appendicitis is not easy; and here again the duodenal tube may be the only real help. Diseases of the liver itself, especially early cirrhosis, are frequently confused with gall-bladder infections. I have made this mistake too often and have seen the cirrhotic liver exposed by the surgeon when my confident diagnosis was chronic cholecystitis. I deliberately omit more than a reference to important diseases situated outside of the abdomen—such as coronary thrombosis—which have frequently been mistaken for cholecystitis.

TREATMENT

I will only deal with some general principles. I have already alluded to the difficult problem of deciding on the site of the microbial infection and the important bearings the solution of the problem must have on treatment by drugs excreted in the bile. Next I must refer especially to the form of treatment now commonly known as 'non-surgical drainage of the biliary tract'. This treatment began with the use of the duodenal tube, repeated emptying or rather partial emptying of the gall-bladder being

induced by the direct injection through the tube into the duodenum of either a concentrated solution of magnesium sulphate or olive oil. Later it was found in practice that the passage of the duodenal tube was unnecessary, the same drainage of the biliary tract being obtained by giving the patient a small dose of concentrated magnesium sulphate solution on an empty stomach. I am convinced of the great value of this form of treatment when persisted in daily for months.

As regards diet in the treatment of early cholecystitis and the prevention of gall-stones, I am far less strict (except when obesity forms part of the problem) than are many physicians. I do not see the need for restriction in cholesterol-containing foods, since the body can obtain a supply from so many foods. The only essential restriction is cooked fat, and especially 'fried foods', which aggravate the common flatulent dyspepsia. I do not exclude butter or milk in moderate amount and olive oil (a food) has great value in preventing flatulent dyspepsia and in emptying the biliary tract, although it does not dissolve gall-stones.

It must be remembered that in cholecystitis the liver itself is damaged or deranged in function, and a sojourn for treatment at a spa which specializes in hepatic diseases and in the other frequent accompaniments of cholecystitis, such as obesity, may be of great value. Disordered function of the liver, so commonly associated with cholecystitis, is claimed by some to be concerned in the aetiology of migraine, but I must state that I have never seen migraine in direct association with hepatic disease.

CONCLUSION

In conclusion, my plea is for the more general recognition of the great frequency of cholecystitis, of the difficulties that must be faced in making a correct diagnosis, of the methods that are of real practical use in diagnosis and treatment, and of the great diagnostic value of the duodenal tube. Further, I would express my belief that catarrhal cholecystitis can be cured in its earliest stages by medical treatment, and that in this way we may hope to diminish the incidence of gall-stones with their frequent dangers and complications.

Reviews

THE MEDICAL ANNUAL: A YEAR-BOOK OF TREATMENT AND PRACTITIONER'S INDEX.—Edited by H. L. Tidy, M.A., M.D. (Oxon.), F.R.C.P., and A. R. Short, M.D., B.S., B.Sc., F.R.C.S. Fifty-Sixth Year. 1938. John Wright and Sons Limited, Bristol. Pp. lxxi plus 696. Illustrated. Price, 20s.

UNDOUBTEDLY the most important medical event of recent years has been the introduction of the sulphanilamide group of drugs, and we do not consider that it is any exaggeration to place this beside Ehrlich's introduction of the arsphenamines in assessing its historical importance. The medical journals of to-day seem to be largely devoted to records of the latest triumphs, the failures, and the disasters associated with the administration of one or other of this already very large group of drugs.

In this year's *Medical Annual*, there is an excellent section on the subject under the title sulphonamine, in which the chemical, pharmacological, experimental, clinical and toxicological investigations during the last two years are reviewed, and in many other sections there are references to the therapeutic use of these drugs. They are unquestionably of great therapeutic value in many infections and can be administered to most patients with impunity, but we have still much to learn about their toxicity in individual cases.

Most recent advances in surgery are in the special branches: an exception is the injection treatment for varicose veins. A recent survey of the results of this method of treatment, as compared with ligature, has shown that in Sweden the death rate from pulmonary embolism is 1 in 3,000 against 1 in 400 following ligature: bed-ridden patients are the worst subjects for injection. Regional ileitis seems to be well established as a new disease, and one which lends itself to surgical treatment. In the treatment of the Raynaud group more experience has been gained in sympathectomy and better results are being obtained when the stellate ganglion is preserved. Further advances in chest surgery are recorded.

Typhoid fever seems to be in the news again this year and in England sanitary complacency has been severely shaken by some serious epidemics. The question of the advisability of undertaking inoculation of the population in the event of, and in the presence of, an epidemic has raised considerable discussion during the year, but does not seem to have attracted the attention of the reviewer, who is content to give some details of a report of the effect of inoculation in the Italian army: there is of course no question that wisdom before the event is the best course.

The sections on blood diseases, including anaemia, are most disappointing. In these sections the reviewer has

persistently interpolated his own views, which in the opinion of many hæmatologists are not always well founded, in a most irritating manner. His outlook is peculiarly insular. In commenting (quite unnecessarily) on Wills' very important experimental work on macrocytic anæmia in monkeys, he says that her fears regarding the limited efficacy of the more purified liver extracts in macrocytic anæmias are unsupported by clinical evidence: the reviewer's own experience being apparently limited to pernicious anæmia, he ignores the other macrocytic anæmias in some of which it has been definitely shown that the 'anahæmin fraction' is not curative, whereas the less refined liver extracts are.

Under Banti's syndrome, a full page—the amount of space devoted to the whole subject of pernicious anæmia, with its vast current literature—is devoted to one paper, admittedly a useful analysis—mainly, we fear, because it happens to support one of the reviewer's particular theories.

We cannot agree with the reactionary views of Professor Davidson regarding monocytic leukaemia. There may be some difficulty in differentiating the individual monoblast and myeloblast, but experienced hæmatologists are usually able to make a diagnosis at the first examination and any possible doubt is dispelled by following the case for a very short time. In the same way, the clinical picture of the two groups present differences, though individually there will be overlapping. Nor can we agree that the distinction is only one of academic interest; the final prognosis may be the same (as Henry Ford says, 'We are all on the spot'), but the immediate prognosis is not.

Histidine in the treatment of peptic ulcer which raised some of our hopes to such heights is now decently buried; let us hope that its sad story will at least provide a warning to the experimenter and to the clinician, and possibly material for the psychologist.

Indian readers will be particularly interested in the section of Yoga. A few serious medical studies have been made recently and are well reviewed here.

The publishers have obviously taken considerable trouble not to increase the bulk of the book or decrease the quality of the paper. They have economized by cutting out the illustrations of new instruments. This was we suppose necessary, but we miss them.

There is in some of the sections a little too much 'chat' by the reviewers. With a more ruthless use of the blue pencil many pages could have been saved without loss to anyone (unless the reviewers receive their remuneration by the line). A more frequent change of reviewers would help to maintain the standard; some writers are extremely conscientious but others get careless when they have to do a thing year after year. However, this excellent publication maintains a high standard and is still the best book of its kind in the English language.

L. E. N.

RECENT ADVANCES IN PATHOLOGY.—By G. Hadfield, M.D., F.R.C.P. (Lond.), and L. P. Garrod, M.A., M.D., B.Ch. (Camb.), F.R.C.P. (Lond.). Third Edition. 1938. J. and A. Churchill Limited, London. Pp. xii plus 420, with 65 illustrations. Price, 15s.

We always have the greatest sympathy for the authors of this excellent series, *Recent Advances*. The problem which they have to face in deciding on their method of approach must be a sleep-robbing one. The various authors have solved it in various ways; this fact demonstrates the wisdom of the publishers in not attempting to uniformize the series except in the matter of title, the general up-to-date-ness of the contents, and the format of the book. Some authors have produced a short up-to-date textbook on their subjects, others a series of barely connected essays.

In the case of the book under review our sympathy with the authors is combined with a great admiration for the skilful way in which (the textbook solution being obviously out of the question) they have avoided the essay method by secreting from each chapter a sufficiency of reticulin to produce enough reticulum

(*sensu restricto*) to form the cellular reticulum (in the sense of the authors), a connected if not a homogeneous tissue.

The revision has been considerable and in the authors' words 'little more than half of the previous text is retained'. In some instances the new information available made rewriting of the chapter necessary but in others a ruthless exclusion of useful sections was required to make room for fresh matter, and for this reason, whilst we strongly advise readers to supplement their libraries by the addition of this volume, we also suggest that they retain the previous one.

The new chapter on resistance to infection is an example of masterly compression of a vast subject. That on the reticulo-endothelial system is an old friend which we are glad to see retained: it has however been revised and brought up to date. We do not know any short account that gives a clearer conception of the new knowledge on the ætiology of the anæmias than the section on gastric function and anæmia. Another very important chapter is the one on deficiency diseases; in this there is a very clear account of the specific changes that are brought about by deficiency in the various vitamins: our present knowledge is well summarized and the huge gaps in this knowledge clearly indicated.

The authors have a particularly lucid style, and they have avoided all use of the pathologist's jargon, which makes the book very suitable for the student and the clinician; to the library of the teacher of pathology, it is almost an essential addition. There are numerous photomicrographs of sections of morbid tissues; these are well chosen and excellently reproduced, and show in every instance what they claim to show, which is unusual, even in books of high standing.

A HANDBOOK ON DISEASES OF CHILDREN INCLUDING DIETETICS, WELFARE AND THE COMMON FEVERS.—By B. Williamson, M.D. (Edin.), M.R.C.P. (Lond.). Second Edition. 1936. E. and S. Livingstone, Edinburgh. Pp. xii plus 329. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Price, Rs. 7.

In this publication the word *handbook* has regained what surely must have been its original meaning, a small or handy volume that covers the subject completely but concisely. The word, and more particularly its German equivalent *handbuch*, is now applied to any complete treatise, even up to the size of an encyclopædia of twenty volumes, each of which is a severe strain on the wrist when held in the hand.

With its moderate size, round corners, and flexible cover this book is obviously designed, not only to be held comfortably in the hand but to be slipped into the student's pocket; for it is an ideal book for the student and one that the practitioner will find very useful for refreshing his memory.

The various diseases that are common, more pronounced or exhibit special features in childhood, as well as those that are peculiar to this time of life, are dealt with concisely and on the whole adequately. There is practically no reference to tropical diseases, which is certainly a point in favour of the book as the crude attempts to include them made by writers of similar books, who naturally have no first-hand experience, often shakes one's confidence in the book as a whole. On the other hand, the short remarks on malaria in this book are sound; the author lays emphasis on the fact that only benign tertian malaria is likely to be encountered in England and he recommends adequate doses with quinine, in fact 10-grain doses for a child of 10 years might be considered a little high; but he does not mention euquinine with its obvious advantages in the case of children. He has the courage, which few writers have, to refer the reader to the manufacturers' 'folder' for more precise details regarding the dosage of atabrin.

There are a few minor errors that may be attributed to the type setter, for example, the spelling 'acroflavine' on p. 249.

A TEXTBOOK OF X-RAY DIAGNOSIS.—By British Authors. (In three volumes.) Volume I—Edited by S. C. Shanks, M.D., P. Kerley, M.D., M.R.C.P., D.M.R.E., and E. W. Twining, M.R.C.S., L.R.C.P., D.M.R.E. 1938. H. K. Lewis and Company, Limited, London. Pp. xii plus 591, with 398 illustrations. Price, Volume I—50s.

THE need for an authoritative book of reference on x-ray diagnosis has been felt by the British physician and surgeon for some time. A number of atlases, small textbooks, and books on special subjects, and many good American books have been published, but they have failed to supply the want to the satisfaction of many readers, who are not unnaturally slightly prejudiced in favour of their own national point of view. This book is therefore particularly welcome.

The editors have attempted to provide within reasonable limits 'a comprehensive survey of the present position of x-ray diagnosis'. Diagnostic radiology is becoming an increasingly complex specialty and it is difficult for any one person to be equally expert in all its branches. The editors have therefore sought, and obtained, the collaboration of a number of radiologists and clinicians, experts in their particular branch of the subject, who, if one can judge from the quality of the first volume, have produced an authoritative work which will appeal primarily to the clinician, but also to the pre- and post-graduate student of radiology.

The publishers have been extremely generous in the matter of illustrations and nearly every conceivable condition is illustrated. But the book is by no means an 'atlas', as the subject is dealt with fully in the text and is made comprehensible, even without the illustrations.

There are three parts in this first volume, but of the 578 pages of the text 330 are occupied by the radiology of the respiratory system. The whole subject is very well covered, and in each case the clinical picture and the pathological changes are described and correlated with the radiological findings.

The other two sections are on the cardiovascular system and the urinary system. As the writers quite rightly say, the radiography of the heart, the orthodiagram or the telerradiograph, cannot possibly replace other methods of investigation of the heart, but they may be useful supplementary aids to these other methods.

The editors are to be congratulated on their wise choice of contributors, these on the quality of the contributions, and the publishers on the very high standard of book production they have achieved. The second volume has just been received and will be reviewed in the next number of this *Gazette*. The third has been promised within a few months.

THE INFANT: A HANDBOOK OF MODERN TREATMENT.—By Eric Pritchard, M.A., M.D. (Oxon.), F.R.C.P. (Lond.). 1938. Edward Arnold and Company, London. Pp. xi plus 744. Illustrated. Price, 18s.

THOSE who like the writer have regarded Dr. Pritchard's *Physiological Feeding of Infants and Children* as a sort of bible for the nutrition of children will welcome another volume from one who justly made for himself a reputation as one of the foremost pediatricians of Great Britain. The reader should, however, read the preface carefully in order to understand what the book is. He will then know what to expect of it. It is, as its name denotes, a *handbook of treatment* and not a textbook on children's diseases. For this reason it is a book which will appeal and be useful to the practitioner rather than to the student. The medical man or woman will find in its pages the garnered wisdom of many years of practice, most of which was carried on at the Infants' Hospital, Vincent Square. Many of the methods and ideas are Dr. Pritchard's own and this gives the book a freshness and originality which makes its reading a pleasure. Dr. Pritchard emphasizes that the book is one for reference, but actually it is much more than that and the first chapters especially can be read straight through

without the least feeling of lack of continuity. In many ways they are the best in the book perhaps on this account. They deal with the subject of nutrition and deal with it most effectively. Dr. Pritchard speaks with the authority of long experience. His methods are not 'fancy' ones, they are based on common sense as well as theory of nutrition and many fallacies are exploded. Children brought up on Dr. Pritchard's regime are not likely to be starved and they will enjoy their meals without a doubt. The mother also has reason to be thankful to a doctor who avoids being faddy in food matters and who recognizes psychological as well as physiological principles.

The chapter on the new-born and premature infant is another mine of wisdom. After that the systems are dealt with in turn. This portion of the book naturally does not lend itself so easily to continuous reading but the style is never boring and never gives the impression of 'potted' information. It is significant to note that in most cases the treatment for a particular malady is divided into two portions and that the prophylactic treatment is placed first and thoroughly stressed. It will not be wrong to trace this emphasis to Dr. Pritchard's association with welfare centres. He was in charge of the welfare centre at the St. Mary-le-bone Dispensary which was perhaps the first centre in England.

There are two valuable appendices. One contains prescriptions and pharmacological preparations; the other gives the technique of a number of clinical procedures. Both of these will be found most useful to doctors dealing with children.

The book is well got up and the type, though not large, is very clear and easy to read.

R. Y.

EMERGENCY SURGERY.—By H. Bailey, F.R.C.S. (Eng.). Third Edition. 1938. John Wright and Sons Limited, Bristol. Pp. 852, with 816 illustrations. Price, 50s.

THIS book is far too well known to necessitate any detailed description and it already enjoys too high a reputation to make fulsome praise anything but an impertinence. One would prefer to announce the arrival of a third edition and to leave it at that, but in return for the gift of so handsome a volume a little more than this seems to be due.

The first chapter is on intravenous transfusion and the second on blood transfusion. The order is a natural one, but carries a special significance. How often does one hear the plea 'unfortunately I couldn't give a blood transfusion as no donor was available', when the patient's life could quite well have been saved by a saline or other isotonic transfusion? The next two chapters are on anaesthesia and surgical equipment, respectively: for the latter Mr. Hamilton Bailey has reclaimed the word 'armamentarium', so much more suited to the surgeon's use, but by prescriptive right almost the property of the physician. Thence the author has passed on to the specific emergencies with laparotomy rightly occupying the first place.

The author in the preface to the first edition pictured a patient with an urgent surgical condition and an isolated surgeon called in to deal with the situation. 'Should these pages', he writes, 'help the latter to save the former, their main object will be fulfilled'. They undoubtedly have in the past and will in the future many times over.

We cannot conclude without mentioning the really superb book that the publishers, the well-known publishers of that journal-de-luxe, the *British Journal of Surgery*, have produced.

SURGICAL DISEASES OF THE MOUTH AND JAWS.—By E. C. Padgett, B.S., M.D., F.A.C.S. 1938. W. B. Saunders Co., Philadelphia and London. Pp. 807, with 334 illustrations. Price, 45s.

THE rapid progress of surgery in modern times has led to the development of many of the special branches to a size to which in days gone by general surgery alone could claim. For example, surgical diseases of

the mouth and jaws can without any undue effort provide sufficient material for a complete volume. Admittedly, three different spheres of influence are involved in this subject; general surgery, dentistry and rhino-laryngology are all equally interested. In writing this book the author has approached the subject from the standpoint of broad surgical principles, and general pathology. An attempt has also been made to cover the report of the Curriculum Committee of the American Association of Dental Schools, made in 1935.

This book of 807 pages of printed matter consists of 42 chapters. The preliminary chapters deal with the method of examination, surgical regional anatomy, principles of asepsis, and management of injuries to the soft and hard tissues. The fractures of the upper and lower jaws are discussed in some detail with clear descriptions of necessary dental splints and contrivances. Incidentally, these chapters cover a great deal of dental surgery. Regarding the treatment of facial erysipelas and cellulitis, there is a short reference to prontosis without adequate details of its dosage and modes of administration. There are two chapters dealing with acute and chronic inflammations of the pharyngeal and buccal cavities. To the neuralgias of this region one chapter has been assigned which could have been further amplified. The correction of mandibular prognathism has been carefully described and the plastic operations on the face, including hare-lip and cleft palate, are clearly set out. There are several chapters on benign and malignant tumours for which the requisite operative procedures and the methods of irradiation have been clearly described. The following chapters deal with surgical and prosthetic restoration of deformities, and the important subject of anaesthesia finds a place in the last chapter.

In conclusion, we would like to congratulate the author on a noteworthy contribution to the literature of oral surgery. We have no doubt that he has succeeded in producing a volume which would be found useful to both the general and the dental surgeon. It would also be of interest to the 'nose and throat' specialist, the dermatologist, the radiologist, and the post-graduate student. This is no small praise for a book on special surgery. The printing and illustrations are excellent and there is a useful index.

P. N. R.

SURGICAL ANATOMY OF THE HEAD AND NECK.—

By J. F. Barnhill, M.D., F.A.C.S., LL.D. 1937. Baillière, Tindall and Cox, London. Pp. xiv plus 922, with 431 illustrations, many in colour. Price, 90s.

In an appreciative introduction, Dr. McKibben, Professor of Anatomy in the School of Medicine, University of Southern California, says that 'Professor Barnhill has for many years been a good and successful surgeon. His teaching has made a great contribution to the practice of otolaryngology throughout the country'. In the preface, we have the statement of the author that 'his teaching has amounted to a sort of anatomical clinic'. From the beginning it was evident to him that the most efficient post-graduate teaching could be done only 'when each student was required to do his own dissecting and prepare his own specimens'.

This is a book of considerable size, consisting as it does of over 900 pages and 431 illustrations and 35 chapters or, as the author prefers to call them, 'periods'. Each 'period' deals with a part of the regional anatomy of the head and neck together with pertinent applied anatomy and physiology. Illustrations are copious, but as they are near the end of the book, far away from the text, constant reference becomes irksome. We are sorry to note that there are several statements to which exception may be taken, e.g., 'boils and carbuncles originate in the sebaceous glands as a result of staphylococcal infection!' (p. 1). About the 'carotid sinus' the author is of opinion that 'the bulging carotid of the bifurcation; the sympathetic nerves which form a plexus upon it and the carotid body all are parts'; this is a sentence carrying

little meaning to the uninformed (p. 33). Regarding the surgical removal of the mixed parotid tumour, the author recommends 'an antero-posterior incision over the gland' (p. 450). We take it that the incision is meant to be parallel to the branches of the facial nerve. Further, the author's statement that 'after general anaesthesia, in some instances, nephritis is attributed to the anaesthetic, especially to ether', is open to serious objection. The use, according to the author, of a local anaesthetic 'often simplifies the operation, the whole procedure seems less formidable under local' (p. 398). Such loose statements are hardly justifiable in a work which is intended for post-graduates. The names of many authorities have been quoted but no references are given.

It is apparent that this book is the work of an experienced teacher and that the underlying principles are sound and practical. For post-graduate studies it is necessary to presume that the ground-work has been prepared, otherwise constant repetition and inclusion of obvious and elementary matters would increase the bulk of the book and consequently its price which is not an insignificant matter at the present time. The illustrations are, on the whole, very good and the language, though didactic, is easily readable. The fact that the book has been printed by subscription shows that there are a large number of people who appreciate the author and his past work. We hope that this book, in spite of its shortcomings which may be easily remedied, will be found useful not merely to specialists dealing with the head and neck, but also to the general practitioner. The printing and binding are both very good and there is a useful index.

P. N. R.

A SHORT TEXTBOOK OF SURGERY.—By C. F. W. Illingworth, M.D., F.R.C.S.Ed. 1938. J. and A. Churchill, Limited, London. Pp. viii plus 702, with 8 plates and 179 text-figures. Price, 21s.

THERE are many who are inclined to deny the utility of abbreviated textbooks of surgery because they are related to the so-called 'catechisms and aids'. There is, unfortunately, no short cut to success in the mastery of surgery. Obviously, therefore, the author of *A Short Textbook of Surgery* has attempted, by his novel nomenclature, to avoid the indignity of being included in the category mentioned above. It has to be admitted that surgery has attained unwieldy proportions, but that is no excuse for the encouragement of cramming.

This short textbook of surgery, consisting of 702 pages, belies at the very outset its name. In the preface, the author states that he has endeavoured to mould his book in a form suitable for under-graduate and post-graduate students, and to make it comprehensive while keeping within the bounds of a single volume. Such an endeavour is beset with many snares; for instance, for the treatment of tuberculous sinus we are instructed to expose the sinus to regular doses of ultra-violet light. What are these 'regular doses' and is it really possible, we ask, to expose a tortuous and deep-seated sinus to regular doses of ultra-violet light? There is a brief paragraph on filarial elephantiasis, wherein it is stated that 'this condition arises in persons infected with the *filaria sanguinis hominis* and is due to lymphangitis caused by the irritation of parasites present in the lymph vessels. It is common in tropical Africa'. This book, obviously, is not intended for the Indian student who has a closer acquaintance with the *Wuchereria bancrofti*.

Dealing with fractures of the clavicle, Sayre's archaic method is honoured with two excellent illustrations depicting a form of barbarity about which the hairy male and the female with well-formed breasts would have much to say. For the treatment of gastric and duodenal ulcer, a dietary regime such as Sippy's is recommended, but it is nowhere mentioned what Sippy's treatment consists of. Yet, in order to exclude nothing perhaps for the doubtful benefit of the post-graduate student, there is a paragraph on simple tumours of the small intestine. We have noted with some surprise

that for appendicectomy the grid-iron and Battle's incisions are still recommended, while the paramedian incision is reserved only for the pelvic appendix. The brief reference to amœbic liver abscess is totally inadequate for the Indian student. We regret very much that we are unable to recommend this handsome well-printed book to the student of surgery in this country.

P. N. R.

TEXTBOOK OF EXPERIMENTAL SURGERY.—By J. Markowitz, M.B. (Tor.), Ph.D., M.S. in Exp. Surg. (Minn.). 1937. Baillière, Tindall and Cox, London. Pp. xvi plus 528 and 330 figures. Price, 31s. 6d.

It does not take the reader long to discover that this is a book of considerable merit. In an interesting foreword, Dr. D. C. Balfour writes, with some truth, that 'of all factors contributing to the remarkable advances which have been made in surgery during the past fifty years, none has been of greater importance than the influence of laboratory experimentation'. This is a book of convenient size, although it consists of 528 pages, and, as may be expected, it makes in places difficult reading, in spite of a generous display of effective illustrations. The pressing surgical problems of the day have been subjected to experiments on animals with varying degrees of success. It was once believed that pulmonary complications after inhalation anaesthesia were due to aspiration from the mouth, but further experience shows that these are just as common after spinal anaesthesia, suggesting thereby that infective emboli may play an important part. In the somewhat arid and technical chapter on operating-room equipment, the author has unexpectedly burst into rhyme to lament the prevalent ignorance of physiological facts:

'Why does the donkey bray, papa,
Why does the donkey bray?
'The reason for the donkey's bray,
Is that the beast was born that way'.

We are afraid that such incongruous levity does not really lead to 'brighter surgery', if that was the author's intention.

It is claimed that the difficulties of aseptic intestinal anastomosis have been overcome by the 'basting stitch' method which is clearly explained with diagrams. The artificial production of chronic peptic ulcer in the dog cannot yet be said to have reached the stage of finality. It appears that in addition to the chemical factor of defective neutralization of ejected gastric juice, there are also certain mechanical factors, of which the rôle of trauma is yet to be determined. The problem of peritonitis is no nearer solution. It is also claimed, however, that, by the intra-peritoneal injection of a mixed vaccine, immunity against post-operative infection can be achieved in a large measure. The mutilating experiments on the pancreas, liver and the biliary apparatus have been continued without achievement of any appreciable success. The pathology of obscure bone diseases is now being investigated with the help of animal experiments. It is further claimed that by the section of the *ligamentum teres* of the femoral head, Perthes' disease of the hip is produced in the young rabbit. One is left incredulous with such an assertion, for what is true of the young rabbit need not necessarily be true of the human child. There is no evidence that in the latter the vascular supply of the femoral head is dependent on the vessels transmitted by this ligament. Within the domain of neurosurgery, the involuntary nervous system is destined to see some major developments in the near future. There is good reason to believe that substances almost, if not quite, identical with adrenalin and acetyl-choline are liberated when the sympathetic and parasympathetic respectively are stimulated. It is reported that Professor von Lichtenberg is treating chronic pyelonephritis successfully by denervation of the renal pedicle. The modern surgeon cannot afford to ignore the so-called 'James-Lange theory' of emotions which

postulates that an emotion is a visceral change of which the organism becomes aware. Herein we find another intimate meeting-ground between surgery and physiology. The chapters on blood vessels and transplantation of the viscera present new possibilities in surgery, but we need not here go into details.

In an epilogue the author expresses the hope that this book may become a contribution to the teaching of surgery. W. G. Mayo has rightly remarked that in medicine, understanding must precede belief. The work of John Hunter is not yet completed; animal experiments alone will not succeed without a Lister behind them. Circumscribed though it is by obvious limitations, experimental surgery has its possibilities. This book may, therefore, be regarded as a primer for those who aspire to tread this difficult path.

One final word of caution is needed. An effective answer has not yet been made to the protests of animal lovers. The Anti-Vivisection Society of England points out that in the year 1936, 822,167 experiments were performed on living animals in that country, and 27,402 animals were allowed to recover consciousness after the operation and were kept alive. These are cold statements of fact but what they imply in the infliction of needless suffering on helpless animals is almost incalculable. We have no access to American statistics which, there is no reason to doubt, must be at least proportionately larger. Notwithstanding the scientific basis of this book, instances of needless cruelty to dogs are not difficult to find. Animal lovers may claim with justifiable indignation that there is a clear case for more vigilant control over animal experiments.

P. N. R.

LIPPINCOTT'S QUICK REFERENCE BOOK FOR MEDICINE AND SURGERY: A CLINICAL, DIAGNOSTIC AND THERAPEUTIC DIGEST OF GENERAL MEDICINE, SURGERY AND THE SPECIALTIES, CULLED EXTENSIVELY AND INTENSIVELY FROM MODERN LITERATURE, AND SYSTEMATIZED.—By G. E. Rehberger, A.B., M.D. Tenth Edition. 1937. J. B. Lippincott Company, Philadelphia and London. Pp. viii plus 1354. Illustrated. Price, 65s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 48-12

'This book consists of eleven parts, dealing respectively with (1) general medicine and surgery, including neurology and the diseases of infancy and childhood; (2) gynaecology; (3) genito-urinary diseases; (4) obstetrics; (5) skin diseases; (6) diseases of the eye; (7) diseases of the ear; (8) diseases of the nose; (9) diseases of the throat; (10) orthopaedics, including fractures and dislocations; and (11) drugs, the whole field, indeed, of practical medicine, excepting psychiatry.

Each disease or disorder is treated alphabetically. First is given a distinguishing, or diagnostic, definition, or description, of the affection, with pictures wherever these are useful. Diagnostic laboratory tests are supplied where required. Next comes a full enumeration of the causes of the disease; then its prognosis, or its expected duration and final outcome. Finally, treatment is given as concisely, explicitly and completely as possible (except, as a rule, for operative technique) so as to obviate the necessity for referring to other works for technique, dosage of drugs, formulæ, etc. In addition quarantine and prophylactic measures are considered where indicated.'

Part eleven contains an alphabetical list of all the drugs mentioned in the body of the work, with the nature, or constitution, of each drug; its solubility; the dosage at different ages; mode of administration; pharmacological action, and toxic effects.

An outstanding feature of this publication is the numerous coloured illustrations, particularly those depicting skin diseases.

In this edition very thorough revision has been effected in, we are informed, almost every section. If we may make a critical suggestion for the next edition, it is that rewriting of the sections rather than patching

up is indicated, for example, though we have no copy of the first, the 1920, edition to confirm our suspicions, we suspect that much of the original section on pernicious anaemia has been preserved, so that the reference to the really important parenteral liver therapy, which is of course there all right, is difficult to find. There is a reference to Greenspon's (unconfirmed) work, which has no direct bearing on treatment. The hypochromic anemias are dealt with under the heading 'chlorosis' and the old prescriptions containing inadequate amounts of iron are retained.

A new departure is a very serviceable and very attractive green binding in the place of the old rather-drab red case.

PRACTICAL BACTERIOLOGY, HAEMATOLOGY AND ANIMAL PARASITOLOGY.—By E. R. Stitt, M.D., Sc.D., LL.D., P. W. Clough, M.D., and M. C. Clough, M.D. Ninth Edition. 1938. H. K. Lewis and Company, Limited, London. Pp. xiii plus 961. Illustrated. Price, 30s.

Just twenty years ago the reviewer became possessed of the fourth edition of this remarkable book. In this there was a total of 497 pages, including the index. The ninth edition contains 961 pages, very nearly twice the size, but the book still remains a masterpiece of the art of condensation of facts, and the increase has been necessitated by the great additions to our knowledge and the application of so many new clinical tests to the investigation of disease in the last two decades, all of which had to be included.

It is of course impossible for such a comprehensive book to be quite up to date and free from error but when one considers the immense amount of information given the omissions and errors noted were very few and only in quite unimportant subjects, as in the life history of *Gnathostoma spinigerum* for example, a rare helminth infection in eastern countries.

If there is any criticism to offer it is that the practice of condensation has been extended to the illustrations so that many of them, particularly in the helminthological and entomological sections, are so small, that they are of little use as no detailed diagnostic characters are discernible, also many of the figures have too many illustrations crowded into a small space.

Notwithstanding the many changes that have been made in successive editions this book still remains, in our opinion, the best general book available for reference on all matters of laboratory technique for the isolated worker, especially in the tropics.

P. A. M.

POULSSON'S TEXTBOOK OF PHARMACOLOGY AND THERAPEUTICS. Second English Edition. By S. Aistead, M.D. (Liverpool), M.R.C.P. (Lond.). 1938. William Heinemann (Medical Books), Limited, London. Pp. xi plus 557. Illustrated. Price, 25s.

THE progress of pharmacology since the publication of the last edition has necessitated rewriting of certain portions and modifying a few others to incorporate all the recent advances in the knowledge of the mode of action of drugs. The present volume is based on the *British Pharmacopœia* (1932) and its *Addendum* (1936) as well as the *United States Pharmacopœia IX* (1936).

The author has collected a large amount of material and has shown excellent discrimination in the comparative emphasis laid on various subjects. Adequate attention has been paid to the description of pharmacological action to enable the reader to appreciate the rational basis of therapeutics. The therapeutic uses included in this book are such as serve to illustrate the pharmacological principle but in no sense it is a book on therapeutics, an art which can only be dealt with properly at the bedside.

The first section of the book deals with organic remedies acting after absorption and to the second section belong numerous other organic remedies that act locally. Such a grouping is not always scientific and although the author claims that the drugs belonging to the first section have as a rule a local action which

is insignificant, the inclusion of the cocaine series in this section does not appear a happy one.

The third section deals with the salts of light metals, alkalis, acids, and halogens, and the heavy metals and metaloids are dealt with in the fourth section. The last two sections deal with ferments and foodstuffs, and the anti-toxin and bacterial products. These agents play a very important part in modern therapeutics and a thorough study of them as in the case of other sections would have been welcome. Apart from this, the description of the various drugs is exemplary. Details of a large number of new remedies have been included and the dosage is given in both the English and the metric systems.

This is a valuable book, containing a vast amount of information which has been compiled with considerable care. It will repay perusal by any medical man and will prove a useful reference volume to every practitioner. It is written in an easy and lucid style, and deserves the popularity it enjoys in many countries.

R. N. C.

OCCUPATIONAL TREATMENT OF MENTAL ILLNESS.—By J. Ivison Russell, M.B., Ch.B., F.R.F.P.S. (Glas.), D.P.M. 1938. Baillière, Tindall and Cox, London. Pp. xvi plus 231, with 41 illustrations including 6 plates. Price, 6s.

As the author states in the preface, this book is primarily concerned with the needs of the mental hospital nurse. Nevertheless, it is a book which almost any member of the staff of a mental hospital could read with benefit. A large variety of occupations suitable for the treatment of mental patients are described fully and, whenever necessary, the description is supported by diagrams. The author seems to think that occupational therapy involves the segregation of the sexes. No useful purpose is served by such procedure. Further, female patients sometimes work better and more cheerfully at occupations usually allotted to men, and *vice versa*. No mention is made of an occupation which frequently elicits great pleasure in some patients, namely, the care of birds and animals. Sericulture is another occupation which some patients find greatly to their taste. The old-fashioned printing press affords a particularly suitable type of occupation to patients of both sexes but this form of therapy is not included by the author. The author has some excellent advice to give on the disposal of manufactured articles, a problem with which most mental hospitals have to contend. Taken as a whole this is a most valuable book which should find a place in the occupational therapeutic department of every hospital.

O. B-H.

APPROVED LABORATORY TECHNIC. CLINICAL, PATHOLOGICAL, BACTERIOLOGICAL, MYCOLOGICAL, PARASITOLOGICAL, SEROLOGICAL, BIOCHEMICAL AND HISTOLOGICAL.—By J. A. Kolmer, M.D., Dr.P.H., Sc.D., LL.D., L.H.D., F.A.C.P., and F. Boerner, V.M.D. Second Edition. 1938. D. Appleton-Century Company, London and New York. Pp. xxvii plus 893, with 12 plates and 380 illustrations in the text. Price, 30s.

SCIENCE is measurement. It is therefore very essential that all the instruments used should be conformed to a single standard. Such a standardization is possible to achieve. It is also essential that the users of the instruments should conform to certain standards, but here, as one is dealing with the human factor, standardization is not so easily achieved. If laboratory medicine is to establish its claim to be a science, even if the human factor cannot be eliminated, at least methods should be standardized. To achieve this object a committee was formed by the American Society of Clinical Pathologists to select the methods most suitable for general use and least likely to introduce errors and variations in results. The first edition of this book was the result of their labours in this direction.

There were five main section headings—General Laboratory Methods, Clinical Pathological Methods,

Bacteriological Methods, Serological Methods, and Chemical Methods. From this it will be seen that the project was an ambitious one. It was also a successful one, and the book was accepted as a final court of appeal on points of technique, with the authority of the Society behind it. The second edition does not appear to be published under the direct auspices of the Society of Clinical Pathologists, but of a body of 28 collaborators. The original edition has been thoroughly revised, chapter by chapter, and five new chapters have been added.

A single method is usually described, but occasionally an alternative method is given. The descriptions are clear and, as far as we can judge, the methods chosen are the best ones for most circumstances, if not for all; the employment of expensive apparatus disqualifies, for general use in this country, some of the methods described.

We have a few criticisms. Co-ordination has not been complete—for example, in the chapter on methods of examination of the blood there is a section on 'methods for laboratory diagnosis of kala-azar' which is short but adequate. In a later chapter on 'diagnostic bacteriologic methods' there is also a section on 'laboratory diagnosis of kala-azar' which is misleading and quite useless. This incidentally is preceded by a section on the diagnosis of granuloma inguinale in which the causative organism is described as 'small oval bodies' resembling the 'Donovan bodies of kala-azar'; there is some confusion here.

The methods described for the examination of faeces for protozoa and helminths are all sound, and one's confidence in the writers is raised when one finds that they do not attempt to give false criteria for the differentiation between the ova of *Tœnia saginata* and *T. solium*, or of *Ancylostoma duodenale* and *Necator americanus*, respectively, but it is surely a little confusing to describe *Diphyllobothrium latum* in the text, and give an illustration of the ovum of *Dibothryocephalus latus*.

This new edition is quite up to the high standard of its predecessor and we can thoroughly recommend it as a standard reference book for the laboratory. When funds are limited, the wide scope of this book makes it the book of choice for this purpose.

L. E. N.

ESSENTIALS OF PSYCHIATRY.—By G. W. Henry. Third Edition. 1938. Baillière, Tindall and Cox, London. Pp. xii plus 465. Price, 22s. 6d.

Not only to doctors but to nurses and students, Dr. Henry's *Essentials of Psychiatry* must by now be a well-known book. This third edition is well up to date and contains a good deal of new matter. There is an excellent chapter on psychiatry in the general hospital, a feature of medical practice not yet thought of in this country. The chapter on psychiatric nursing also repays careful study. In the chapter devoted to treatment, no mention is made of medicinal treatment or of the new 'shock' treatment through the administration of insulin or cardiazol. Although neither of these forms of therapy is yet fully established, the interest they have aroused among psychiatrists the world over would seem to warrant notice in a book of this description.

- O. B-H.

CHEMISTRY OF THE BRAIN.—By Irvine H. Page, A.B. (Chem.), M.D. 1937. Baillière, Tindall and Cox, London. Pp. xvii plus 444. Price, 34s.

THE strangeness of the name of this book is gradually explained as the reader goes through the introductory chapter. The book appears to be a real approach, on scientific and methodical lines, in the field of chemical investigation into the hitherto uninvestigated diseases of the brain, including nervous and mental diseases.

It cannot be denied that very little work in the way of finding out the exact chemical constitution of the brain has been done. The author is of opinion that the economic liability of nervous and mental diseases is, in a social sense, so vast that much more interest

should be taken by the medical profession as a whole to solve some of these uninvestigated problems.

The value of this statement becomes quite apparent when one thinks that in the United States alone more than half a million persons live in institutions for nervous and mental diseases.

In the present volume the author has laid great stress on the rôle of lipoids, firstly, because the brain is composed largely of these substances and, secondly, because the chemistry and metabolism of these substances are little understood, the literature on the subject being comparatively meagre.

The author has taken great pains to make a search for the thoughts and efforts of previous investigators upon the subject and has laid down in this volume a commendable summary of the work done previously on the subject. He has brought together data which are widely scattered in the literature in as orderly a fashion as is possible.

The perusal of the book should carry conviction to the reader that the author's attempt to remove this important subject of the metabolism of the brain from the realm of speculation to one of reality by scientific experiments and reasoning is a real advance in the right direction and merits praise and commendation.

J. P. B.

AIDS TO BIOCHEMISTRY.—By E. H. Cooper, D.Sc. (Lond.), F.I.C., A.R.C.S. (Lond.), and S. D. Nicholas, B.A. (Oxon.), A.I.C. Second Edition. 1938. Baillière, Tindall and Cox, London. Pp. viii plus 213. Price, 43s. 6d.

In this little book the author has dealt with both theoretical and practical consideration and practical experiments in biochemistry and has put them in a clear and simple way. It is intended primarily for students not only for purposes of revision but also as a sort of a laboratory guide.

The first edition of this book was published over 10 years ago and, owing to the vast progress of biochemistry during the period, a large section of the book had to be rewritten in order to bring the contents up to date. Two additional chapters on hormones and hydrogen-ion concentrations have been included and the chapters on carbohydrates and vitamins have been extended.

The book will be found useful to students of biochemistry not only as a manual for revision for purposes of examination but also as a laboratory guide for experimental work.

J. P. B.

OCCIDENTAL THERAPEUTICS IN THE NETHERLANDS EAST INDIES DURING THREE CENTURIES OF NETHERLANDS SETTLEMENT. (1600—1900.)—By Dr. D. Schoute. 1937. Published by the Netherlands Indian Public Health Service, Batavia. Pp. iv plus 214

DR. SCHOUTE recently undertook to supply 'a concise summary in a universal language' of the material from his two previous publications on the history of medicine in the Netherlands East Indies.

In his preface to his book, Dr. de Langen refers to the classical remark of the French Field-Marshal, Lyautéy, 'La seule excuse de la colonisation c'est le médecin'. To this remark coming as it does, not from a doctor but from a soldier, colonizer, and administrator, we draw the attention of the foreign administrators in this country. Even if it were possible—and we do not believe that it is—to achieve anything but a spurious semblance of material prosperity amongst a disease-ridden population, real prosperity can only be enjoyed to the full by healthy, and therefore happy, people.

The account given covers a period of three hundred years from the days of the earliest Dutch colonists in 1600 to the end of last century. Records covering the early years are few and the writer has drawn on captains' logs and other records connected with shipping. These tell an alarming story: if the ship completed its

journey at all—which it often failed to do being lost with all hands—the average death rate on board during the voyage between Amsterdam and Batavia was 8 per cent and was occasionally as high as 40 per cent of the personnel—but it must be remembered that the voyage took anything up to 400 days, a striking contrast to the present-day 130-hour trip which the K. L. M. air-liners make in each direction three times a week.

The Dutch administration was interrupted at the beginning of last century by European wars and for five years no ship arrived in Java from the Netherlands. From 1807 to 1811 they enjoyed the not very sympathetic rule, to medical science at any rate, of a military-minded French governor Daendels; he was turned out by the British Raffles, who remained for about five years. The latter's influence on medicine and science generally appears to have been good, and he remodelled the medical services on the Bengal lines. He was followed by Sir John Fendall. These two British administrators appear to have remained in Java for all this time because nobody told them not to, and when at last they had given up all hope of persuading the British Government to declare the country a British possession, they gracefully handed it back to the Netherlands.

The references to individual diseases are few, but in the section on cholera there is a record of some incredible decisions at which a body of Batavian physicians, who were called together to deal with a severe cholera 'epidemy' in 1851, arrived. These commenced with the statement that the disease was not infectious—in the widest sense of the word—and that, as no means to ward off cholera were known to be successful, none should be attempted!

Medical progress was slow, as it was in all colonies, and lagged behind that in the European mother country, but an evolutionary movement was apparent at all times throughout the last century.

The record is one of great medical as well as historical importance, and we congratulate the author on his achievement. The English is excellent throughout except that he uses a few unusual words, such as 'epidemy', and the reader in this country will take a little time to get accustomed to the words 'India' and 'East India Company', used, as they are throughout, to indicate the Netherlands East Indies and the United Netherlands East India Company, respectively.

THE DIARY OF A SURGEON IN THE YEAR 1751-1752.—By John Knyveton. Edited and Transcribed by E. Gray. 1938. Published by D. Appleton-Century Company, Inc., London and New York. Pp. xiv plus 322. Illustrated. Price, 10s. 6d.

THE reviewer was not aware that he had a suspicious nature but there are a few points about this book that invite scepticism. We have singularly little information about the 'journal' itself. Was it written in English? The 'journal', as it now appears, is not written in the English of 1751—the word 'prosy' was, according to the S. O. E. D., used first in 1821, seventy years later—nor incidentally in the English of to-day. In fact the style is like that of Pepys' Diary, which was written three-quarters of a century before, and deciphered three-quarters of a century after, the date of the John Knyveton's diary. We might also add that the literary style is not that of Ernest Gray, of the preface; this, like his grammar and arithmetic, is unique. Never have we known any writer to take such liberties with the participle!

'This George Knyveton was a distant ancestor of a very close friend of the editor, the leather-bound Journal in which the Diary is written appearing whilst helping this friend sort out some old family records, and being presented to him, as one especially interested in the History of Medicine'.

'Bearing all these things in mind, the hospital of those days can better be imagined than described'.

'Physicians and surgeons as a whole were growing tired of the dogmatism of the ancient authorities—Aristotle, Hippocrates, and Galen, whose theories had held sway for some five hundred years'.

Why only five hundred years? This might have been a misprint, but it is not so, for the writer is quite determined to stand by his 'five hundred years'.

'Galen died in A.D. 200, but his view that the body was composed of certain "Humours" (originally four in number), disease resulting from absence or overproduction of one special "Humour", dominated the medical outlook, as we have said, for five hundred years'.

Why was it necessary to disguise the name of the hospital or even of the surgeon? (Incidentally the name of the hospital is very thinly disguised: from Soho Square to which hospital does one walk 'across the park' and thence along the Mall to Westminster Abbey?)

However, this is all by the way. The diary itself is full of good things and we can thoroughly recommend it to any one who wishes to learn something of the state of medicine two hundred years ago. The philosophy and humour exhibited making the reading very pleasant; for example, the diarist's observation that one of the differences between town and country practice was that in the former more saw-dust was thrown on the floor of the operating theatre is, we feel, too good to be true: so also are his remarks on the value of the natural acids of certain fruits in the prevention and cure of scurvy.

We can recommend this book to the physician, especially if he is interested in literary detective work as he will find this book a simple exercise, and to his patient, especially the patient who is critical of the medical profession of to-day as he will soon learn to be thankful that he was not born two hundred years earlier.

L. E. N.

IDEAL WEIGHT: A PRACTICAL HANDBOOK FOR PATIENTS.—By W. F. Christie, M.D. 1938. William Heinemann (Medical Books), Limited, London. Pp. x plus 111. Price, 5s.

THERE are many books on diet written for the laity, but it is sometimes difficult for the physician to find one that is altogether suitable to recommend to his patients. So many of these books contain fantastic statements and uphold unorthodox theories to which the physician feels he cannot subscribe. On the other hand, it is usually advisable to recommend to the patient whom he is putting on to a reducing diet some book in which he can look up essential facts. This particular book contains no wild theories about the mixing of proteins, fats and carbohydrates, nor does it suggest the eating of nothing but milk and potatoes one day and avoiding these substances for all the rest of the week: in fact he advocates no particular 'stunt', but gives a plain straightforward statement of a number of important facts regarding the requirements of the body and the composition of foods, which are in the main accurate. We say in the main because a few of the statements are not strictly accurate, for example, that the caloric value of clear chicken soup is nil, or that the chemical composition of the vitamins is quite unknown.

The book is written in 'popular' language and any technical words that are used are explained.

The book on the whole will be a very useful one to the physician and his patient.

L. E. N.

DISEASE AND THE MAN.—By R. F. Lapham, A.B., M.D. 1937. Oxford University Press, London and New York. Pp. viii plus 143. Price, 8s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THIS book is written to emphasize the importance of treating the individual patient as well as his disease, a thing that is liable to be neglected in these days of improved scientific investigation of patients by

laboratory experts in that more rational treatment may be recommended to the physician in charge of the case.

Although written from the American standpoint it will be found useful to young practitioners of every country because it mainly discusses human nature, a thing that is essentially the same in all peoples of the world.

ILLNESS: ITS STORY AND SOME COMMON SYMPTOMS. A GUIDE FOR THE LAYMAN.—By S. H. Belfrage, M.D. (Lond.). 1938. Oxford University Press, London, Humphrey Milford. Pp. 173. Price, 3s. 6d. Obtainable from the Oxford University Press, Bombay and Calcutta

In the foreword the object of this small book is stated to be to give instruction to the lay public so that they will obtain medical advice at an early stage of disease and thus benefit by early treatment.

This object is laudable but the method of presenting the subject is not likely to attain it. The thirty pages of part one are devoted to a general discussion on elementary health principles, and part two, which covers over 130 pages, is headed 'some common symptoms'. This section is not likely to be of much use to the layman for it is probable that long before he has developed many of the syndromes described under this heading he will have consulted a doctor.

Then many of the conditions described, are not *symptoms* but short outlines of the pathology and course of *diseases*. Treatment is touched upon and the reader is informed what the doctor should do when he is called in, this seems unnecessary and will perhaps cause embarrassment and disagreement between the doctor and patient if the doctor who is consulted has other views than those given in the book.

A further objection to the book is that it is very carelessly written; for example, 'Also, if there is decay of the teeth or a septic condition of the gums, as in pyorrhoea', is a typical 'sentence'.

FESTSCHRIFT. BERNHARD NOCHT. VON SEINEN FREUNDEN UND SCHULERN. 1937. Kommissionsverlag Friederichsen de Gruyter and Company, Hamburg. Pp. 704. Illustrated.

This volume, produced to celebrate the 80th birthday of Bernhard Nocht, is composed of 116 contributions on every aspect of tropical medicine by as many authors, all of whom are well known in the world of tropical medicine and who represent every important country of the world. It is artistically bound in rough cloth and is a fitting tribute to one of the leaders of modern thought in tropical medicine and a very pleasing way of recording the world-wide appreciation of this great worker's contributions to medical knowledge. The frontispiece is a beautifully reproduced photograph of Nocht himself and depicts him as a rugged kindly old man. It is a book that every worker in tropical medicine should be proud to place on the shelves of his library.

P. A. M.

MEDICAL RESEARCH COUNCIL: SPECIAL REPORT SERIES NO. 227. 'EPIDEMICS IN SCHOOLS: AN ANALYSIS OF THE DATA COLLECTED DURING THE FIRST FIVE YEARS OF A STATISTICAL INQUIRY'.—By The School Epidemics Committee. 1938. Published by His Majesty's Stationery Office, London. Pp. 289. Illustrated. Price, 4s. 6d.

This Report contains the interim report of a committee appointed by the Council seven years ago to investigate the subject of epidemic and other illness in schools from both scientific and practical standpoints.

The study of disease as a phenomenon affecting any individual has been a principal object of scientific effort for thousands of years, and the methods of investigation have reached a high level of precision. The study of the communal or mass factors of disease

is also ancient, but although results of great importance have been obtained there is much less knowledge of this aspect of medical science than of disease in its relation to the individual. The accurate description of demographic factors of ill health is hardly a century old in this country, and the experimental study of disease as a mass phenomenon has been in progress for only a few years.

The Medical Research Council decided that the British Public School provided an excellent opportunity to study epidemic disease in semi-isolated communities and therefore appointed 'a committee, the members of which had expert knowledge of different aspects of the subject, and the active co-operation of the authorities and staff of a representative sample of public schools was fortunately secured'.

'As in all new undertakings, many difficulties—some foreseen, others unexpected—had to be overcome. Yet, despite these, the preliminary results relating to purely practical issues of illness in boarding schools are of important value. Some examples may be quoted. The Committee found that at the beginning of their inquiry about half of the children in the school population under survey had had their tonsils removed, and that this proportion increased through the years of observation by more than six per cent. As they say, 'it was obviously important, in the public interest, to discover if possible whether this mass attack upon one of the normal structures of the body was justified'. The conclusion reached is that its justification is doubtful. Actually the incidence of naso-pharyngeal infections such as influenza, colds, and sore throats, upon boys and girls with or without tonsils did not differ. It is indeed noted that in a group of 384 boys whose tonsils were removed during school life, the sickness experienced before such removal was worse, and after removal about the same, as that of the population as a whole. This shows, what expert clinical experience supports, that in selected cases the operation is of value; but it is far from justifying a ritual now practised upon more than 50 per cent of the children admitted to schools of this class.

'This report for the first time provides the general reader with an account, based upon an adequate sample, of the kind of information which schools can give, and enables him to judge what contributions to knowledge of hygiene and general epidemiology may reasonably be expected from this source'. The report will naturally be read with great interest by sanitarians, but we also commend it to school medical officers, and head masters and mistresses of schools.

MEDICAL RESEARCH COUNCIL: SPECIAL REPORT SERIES, NO. 228. 'A STUDY OF EPIDEMIC INFLUENZA: WITH SPECIAL REFERENCE TO THE 1936-37 EPIDEMIC'.—By C. H. Stuart-Harris, C. H. Andrewes and W. Smith with D. K. M. Chalmers, E. G. H. Cowen and D. L. Hughes. 1938. Published by His Majesty's Stationery Office, London. Pp. 151. Illustrated. Price, 2s. 6d.

ADVANCE in the study of influenza was held up for a long time by the absence of a suitable experimental animal. This has now been found, in the ferret. Thus, an absolute means of determining whether an attack is influenza or some other respiratory affection is available.

'It is clear that a means of differentiating epidemic influenza from febrile catarrh by clinical examination only, and independently of determining the presence or absence of the influenza virus, would constitute an important advance in the study of these problems. Among other differences, Dr. Stuart-Harris found that whereas the onset of epidemic influenza is usually sudden, in febrile catarrh it is often insidious; that in influenza constitutional symptoms predominate, while in febrile catarrh respiratory symptoms are most common; that the cough in influenza is short and dry, while in febrile catarrh it is more often paroxysmal, irritating, painful and productive. While such differences allow

fairly good means of diagnosis in the case of groups of patients, they are by no means as certain in the diagnosis of the condition in individual patients. So, although these combined clinical and laboratory investigations have clarified the problem to be solved, they cannot yet be regarded as having provided the medical practitioner with a certain method of differential diagnosis by clinical examination alone. The distinction

between the two conditions will obviously acquire great practical importance if a means of dealing with one of them should be found, of such a kind that it is inapplicable to the other. A method based on specific immunity to the influenza virus cannot be expected to have any useful action against different organisms'.

This and other important investigations on influenza undertaken by the authors are reported here.

Abstracts from Reports

A REPORT OF THE SIXTY-THIRD YEAR'S WORK IN INDIA AND BURMA OF THE MISSION TO LEPERS

September 1936—August 1937

WHEN Mr. Wellesley C. Bailey passed away in his sleep on 28th January, 1937, an epoch in the history of the Mission to Lepers came to its close. This apostle to the lepers had been the founder of the Mission sixty-three years before, and he was the last remaining personal link that held together the first beginnings and the work of to-day.

There is an appropriateness in the fact that in the year when an epoch in the mission's history closed, some new significant step should mark the opening of another. Within a week or two of Mr. Bailey's death the pioneers of the first after-care scheme in India for arrested cases were beginning to clear the jungle in a part of the six thousand acres of virgin forest land which has been set apart in the Central Provinces for the re-establishment in civic life of arrested cases, and of healthy children of lepers.

There is great significance in this project—for it would have been regarded as an impracticable vision only a few years ago. It emphasizes both the hopefulness and the limitations of treatment, and this dual emphasis is what is to-day required. Leprosy, on the one hand, can no longer maintain the unenviable reputation of being an altogether relentless, untreatable disease. On the other hand, though treatment (widely conceived and well-executed) can in many cases arrest and drive back the onslaught of the disease, and can render the infective case non-infective, there is unhappily evidence that patients who have known the joy of seeing their symptoms disappear watch with distress their reappearance, nearly always after they have had to return to conditions of poverty, stress, and under-nourishment. Sociological problems are knit into the very fibre of the medical problems attaching to the treatment—and prevention—of leprosy. This new scheme is calculated to give ex-patients a stake in the land, a healthy occupation carried on under sympathetic oversight, and such necessary support as may be required until the settler has won for himself resources for times of difficulty. Effective social rehabilitation for the ex-patient is almost as important in the leprosy worker's task as is direct medical treatment.

In the Homes of the Mission there has continued to be development—during the past year. No large building projects in any one station have been engaged in, but numerous smaller ones add up to make a considerable total of development during the year. During the twelve months' period under review the following buildings have been completed—two new women's wards at Dhamtari, and the first wing of a special section for boys with leprosy; operating theatres at Champa and Naini; a house for contagious leper boys at Purulia, additions to the girls' observation compound, and the entire re-modelling of the healthy boys' home; two new wards at Chevayur, near Calicut, one for boys and one for girls; a dispensary at Miraj and additional accommodation for adults; observation wards for boys and girls at Chandkhuri—that is, for those who have only very early symptoms, or are passing through their parole period after treatment before discharge; hospital

buildings at Champa and Subathu for sick cases, or those requiring surgical attention; and a small home for young children of leper inmates at Kothara, near Ellichpur. Two further wards have also been donated by the mission to the nided leprosarium at Vengurla. And at several homes—Purulia, Nasik, Vadathorasalur, and elsewhere—water supply has been improved. Thus has the work continued to advance in size and usefulness.

It will be noted that much of the last year's development has been in providing more adequately for children suffering with leprosy. While the very early case is better outside an institution than in, if he attends a clinic but retains the home link, there are unfortunately many children for whom the institution is the only means by which they may be assured of proper care, and there is still a wide field for further development in this direction.

Among the adult patients the proportion of contagious cases in relation to the total continues to increase. This is as it should be, and the public should not forget the service which is being rendered to it as well as to the patients by the segregation of such cases. This higher proportion of contagious cases will probably lead to less striking statistics of results of treatment in future, and it seems very likely—unless there is some notable progress made in research work upon treatment—that the peak has been reached of the steadily ascending curve representing cases who have become disease-arrested in successive twelve-month periods during the last ten years. In 1936 the total of cases arrested without deformity having begun was 1,038. Any decline in future years must not be misinterpreted by failure to relate it to this other fact, since the highly contagious cases only respond very slowly to treatment, and frequently never clear up at all.

The mental and spiritual factors are ones upon which the mission has always laid emphasis, and it is encouraging to note the growing conviction of those who are primarily interested in the disease as a purely medical problem that these factors are of highly important, if not paramount, significance. There was a tendency in the past to say, 'We are interested in the strictly medical side of your work, the injections, the treatment of this and that symptom. The rest, of course, is outside our field of interest'. But now it is more and more being realized that the physical and psychological are inextricably interwoven.

There is a sense in which the finances of the mission continue to be satisfactory. They have enabled the work to grow steadily, and we are profoundly grateful to all who have helped make up the total of Rs. 8,12,315 spent on the mission's work in India and Burma during 1936. Apart from the amounts received by the Indian Auxiliary and by direct contribution to individual institutions, over three lakhs of rupees were sent from the headquarters in London of the Mission to Lepers; and represented contributions from many corners of the world. A Scottish Highland farmer may be the supporter of some leper boy in south India. A Sunday school class away in Tasmania may have made itself responsible for the support of a homeless leper woman, forsaken of her own kith and kin, who has turned to a Home in the heart of the Central Provinces. There is romance written large in much of the income which comes from outside India,

The balance of the total was received from Government and local grants. From whatever source the income has come we are most grateful, and express our warm thanks.

There is another sense, of course, in which the financial position is most disturbing. So much remains to be done; so many are the calls for help; so great the opportunities of bringing not only cheer and comfort, but a new life. The mission has its aims and programmes for the future, and this next year should see the erection of the first buildings of a new home near Fyzabad. But there remain many opportunities which cannot be taken for lack of greater resources; and we again commend the work to the public for its support.

FINAL REPORT OF THE LEAGUE OF NATIONS MIXED COMMITTEE ON THE RELATION OF NUTRITION TO HEALTH, AGRICULTURE AND ECONOMIC POLICY*

THE report is the result of two years' work by an international committee of agricultural, economic and health experts under the auspices of the league. It is concerned for the main part with the economic aspects of nutrition policy and with its relations to agriculture. To complete the picture, a chapter on the physiological side of the problem from the interim report of the committee (The Problem of Nutrition, 4 Vols., 1936) has been included, modified in the light of recent nutrition research.

The report is divided into three parts. The first part, which has three chapters, gives a general survey of the problem and of the work already carried out. The introductory chapter traces the activities of the mixed committee since its inception and of other international bodies working on the problem of nutrition. The second chapter outlines the development of the science of nutrition and indicates the rôle played by nutrition in the striking improvement in public health and in the increase in population which occurred in the course of the past century. The third chapter summarizes the contents and conclusions of the report and reproduces the recommendations published by the committee in its interim report.

The second part of the report is devoted exclusively to the health aspect of nutrition. It contains a clear account of the main principles of the 'new knowledge of nutrition' as they have been developed by recent research; a description of the nature and functions of the most important vitamins and minerals and of the diseases resulting from their deficiency; an analysis of the nutritive qualities of various foods, and their classification as 'energy-bearing' or 'protective'; the dietary requirements of particular classes of persons, expectant and nursing mothers, infants, children of pre-school and school age, adolescents, recruits and adults; and a summary of the dietary standards adopted by the technical commission of the Health Organization of the League of Nations and of the valuation placed by this commission on various important foodstuffs.

The third part of the report contains a more detailed examination of the economic and agricultural considerations connected with nutrition policy. It begins by tracing the main changes which have occurred in food consumption habits during the last few decades and reaches the conclusion that average consumption in most countries of western civilization has on the whole been tending in the direction of improved nutrition. The second chapter discusses the problem of the adaptation of agriculture to the desired changes in consumption. It is demonstrated that agriculture has shown considerable powers of adaptation in the past, in particular where no obstacles have prevented changes in demand from expressing themselves through changes in price. It is argued that an extension of the movement towards better nutrition should prove of benefit to

national agricultural systems, calling both for an increased production of protective foods—fruit, vegetables and dairy products—and for an increased output of various cereals for fodder.

Denmark in changing over from the production of cereals for export into animal husbandry as the basis of her export trade did not for this reason cease to produce cereals. Instead, she actually doubled the national production of cereals—mostly in the form of feeding stuffs for farm animals.

Chapter III is concerned with the relation of food prices to consumption and shows that the demand for most foodstuffs—particularly for the protective foods—is very sensitive to price changes. The effects of price movements on the mutual substitution of various foodstuffs, the significance of seasonal price movements, and the differences in elasticity of demand in various income groups are also discussed.

The following chapter considers the main determinants of food prices on the supply side—technique and costs of production, commercial policy, marketing organization and distribution costs. Particular reference is also made to the contribution of the co-operative movement in reducing retail food prices.

The fifth and sixth chapters of part III are devoted to the rôles of income and of nutritional education in influencing consumption habits. The improvements in diet which accompany increased income are demonstrated from the results of family budget studies in various countries. A comparison between the existing distribution of incomes and the costs of minimum nutritionally adequate diets shows that malnutrition of important sections of the population, and particularly of families with many young children, even in such relatively prosperous countries as the United States and the United Kingdom, can be directly traced to the effects of poverty.

The committee realizes that the raising of the income level in the different countries is essentially a national problem of a long-range character. But it draws attention to the possibility of improvements in social services, which may in part remedy malnutrition due to poverty, such as family allowances, the provision of school meals, of milk for expectant and nursing mothers, etc. Much can also be done on the side of education to improve nutrition, and in this connection attention is drawn to the considerable variations in the quality of diet obtained by families spending at the same levels (relative to the size of the family). A summary is given of the various techniques of nutritional education which have been applied in different countries, and in some cases an indication of the effects achieved.

The report concludes with a collection of evidence relating to the present state of nutrition in various parts of the world, demonstrating that in spite of the considerable progress that has taken place in recent decades, the problem is still an urgent one. 'The malnutrition which exists in all countries is at once a challenge and an opportunity: a challenge to men's consciences and an opportunity to eradicate a social evil by methods which will increase economic prosperity'.

ADMINISTRATION REPORT OF THE BALUCHISTAN AGENCY FOR THE YEAR 1ST APRIL, 1935, TO THE 31ST MARCH, 1936

On the night of 30th May, 1935, there were 112 indoor patients in the Civil Hospital, Quetta. Of these 73 were killed, while amongst the staff seven were killed including Major Bird, I.M.S., officiating civil surgeon, Quetta, who died three weeks after receiving severe injuries. The staff lost no time in rendering first aid to the injured and at dawn of the 31st morning work of first aid was in full swing in the general post office compound.

The staff of the Kalat Hospital and State Dispensary, Mastung, also displayed great energy in dealing with injured cases under the direction of the Political Agent, Kalat. A military medical relief party with two I. M. S. officers proceeded to Mastung on 3rd June

* Ser. L. O. N. P. 1937. II. A. 10, 327 pages. Price 7s. 6d. \$2.00.

and a field ambulance on 5th June. The Kalat Hospital was moved to Mangochur for relief work there. In the districts many injured were treated in the hospitals in Sibi, Loralai, Chaman, Pishin and Fort Sandeman, where they were removed by their relatives. In Sibi excellent work was done in connection with relief trains passing through from Quetta taking injured to Lahore and Karachi.

A special earthquake hospital was established at Pishin on 11th June, 1935, to which some injured cases were removed and on 15th August, 1935; this was taken over as a mission hospital and finally closed on 25th September, 1935. A special earthquake hospital was also established at Mastung Road by mission doctors on 13th June, 1935, and its cost was defrayed by Kalat State.

Quetta.—Martial law was proclaimed in Quetta on 1st June and the administration of Quetta including medical and public health passed to the military authorities from that date. Both injured and survivors were evacuated and within 10 to 12 days the population of Quetta was reduced to about 4,000 who were either local inhabitants or government servants.

The resources of the civil medical and sanitary departments were put at the disposal of the military authorities. The sanitary staff were however quite inadequate to meet urgent demands. An I. M. S. officer lent from the Punjab was appointed chief health officer and he took over charge of the public health department from the military about the middle of June. Other public health staff were also sent from the Punjab including medical officers of health, sanitary inspectors and sweepers.

The following table shows the strength of public health staff on different dates :—

	Medical officers of health	Sanitary inspectors	Sweepers
15th June, 1935 ..	11	11	273
26th June, 1935 ..	11	19	313
31st December, 1935.	2	5	264

This I. M. S. officer returned to the Punjab on 25th October, 1935, and the duties of chief health officer from that date came under the chief medical officer.

A refugee camp was opened at the brewery in July 1935 and a small dispensary was established there for the local needs of the people. The population gradually increased until it reached about 15,000 in December 1935, the increase being due to import of labour and salvage operations.

After the conditions consequent on the earthquake were overcome and dealt with, sanitary standards were well maintained and many groups of latrines and incinerators were erected in many areas—many of the groups being erected by the sanitary staff themselves.

The staff of the Civil Hospital, Quetta, were at first employed on the race-course. On 23rd July, 1935, the civil hospital staff returned to the site of the old civil hospital and opened a civil hospital in tents, where the sick were dealt with in the normal way and full activities as a civil hospital resumed. In October 1935 huts were constructed on the same site and the accommodation of the civil hospital became about 100 beds.

There were no epidemic diseases. As a preventive measure the whole population of Quetta was inoculated against cholera and vaccinated against smallpox in the months of June and July 1935. About 6,000 inoculations and 7,000 vaccinations were done. In view of the outbreak of cholera in Sind an inspection post was established at Mach on 24th June in which the railway authorities co-operated. All incoming trains were inspected until the epidemic in Sind died out and the danger of imported cases was over.

Anti-malaria work was taken up towards the beginning of July 1935 in all surrounding areas. Quinine was freely distributed in areas round Quetta

and surrounding villages. In May 1935 before the earthquake a preliminary reconnaissance on malaria was undertaken by Major H. W. Mulligan, I.M.S., and on 25th July, 1935, a malaria survey arrived in Quetta under Major Mulligan.

In June 1935 the number of flies in Quetta enormously increased and became a great nuisance. Extensive fly measures were carried out with good results.

Exhumation of bodies.—The work of removal and disposal of the dead was stopped after the town was sealed. It was resumed by Rover Scouts under Mr. Hogg on 20th July, 1935.

At first all exposed bodies were disposed of and then bodies exhumed during clearance of roads. The scouts worked up to 17th October, 1935, and exhumed during this period 691 bodies. Exhumation work after this date was carried on by men of the road construction battalions trained in this work. A medical officer of health controlled this work in the city under the general control and supervision of the chief medical officer. All precautions were taken in dealing with these bodies such as immediate burning of all infected bedding and clothing and disinfecting the places from where removed by a solution of disinfectant.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL M. J. HOLGATE, O.B.E., has been appointed to officiate as Surgeon-General with the Government of Bombay, with effect from the 2nd April, 1938, afternoon.

Lieutenant-Colonel L. S. Modi, Superintendent, Central Jail, Nagpur, is appointed to officiate as Inspector-General of Prisons, C. P. and Berar, with effect from the 3rd April, 1938.

Lieutenant-Colonel A. C. Loganadan, Chief Health Officer, Delhi, has been appointed Officiating Assistant Director of Public Health, Punjab, Central Circle, with effect from the 14th April, 1938, vice Lieutenant-Colonel C. M. Nicol, granted leave.

Lieutenant-Colonel B. F. Eminson, Civil Surgeon, Hyderabad, Sind, is appointed as Civil Surgeon, Karachi, with effect from the 28th March, 1938 (afternoon), vice Lieutenant-Colonel M. J. Holgate transferred to the Bombay Presidency. Lieutenant-Colonel Eminson should also continue to officiate as Director of Health and Prison Services, Sind, in addition to his own duties pending further orders from Government.

Lieutenant-Colonel J. C. De, Superintendent, Campbell Medical School and Hospital, Calcutta, is appointed to be Civil Surgeon, 24-Pargannas, vice Lieutenant-Colonel K. S. Thakur, granted leave.

Lieutenant-Colonel B. G. Mallya, Civil Surgeon, Howrah, is appointed to be Superintendent, Campbell Medical School and Hospital, Calcutta, vice Lieutenant-Colonel J. C. De, transferred.

Lieutenant-Colonel P. Banerjee, Civil Surgeon, Burdwan, is appointed to be Civil Surgeon, Howrah, vice Lieutenant-Colonel B. G. Mallya, transferred.

Lieutenant-Colonel N. C. Kapur, Civil Surgeon, Chittagong, is appointed to be Civil Surgeon, Burdwan, vice Lieutenant-Colonel P. Banerjee, transferred.

Lieutenant-Colonel M. A. Nicholson, an Agency Surgeon, on return from leave, is posted as Chief Medical Officer in Central India and Residency Surgeon, Indore, with effect from the afternoon of the 8th April, 1938.

Major B. Chaudhuri, Senior Medical Officer, Port Blair, is appointed as Superintendent, Cellular Jail, Port Blair, in addition to his own duties, with effect from the afternoon of the 16th March, 1938.

Major D. MacD. Fraser, Civil Surgeon, Dehra Dun, returned from leave on 29th March, 1938, forenoon.

Major J. E. Gray, whose services have been placed at the disposal of the Sind Government, took over charge of the Office of the Civil Surgeon, Hyderabad, with attached duties, on the forenoon of the 7th April, 1938.

Captain M. Jafar is appointed Health Officer, Karachi Air Port, with effect from the forenoon of the 18th March, 1938, *vice* Captain C. J. H. Brink, transferred.

Captain J. Brebner, on general duty at the Medical College Hospitals, Calcutta, is appointed to be Civil Surgeon, Chittagong, *vice* Lieutenant-Colonel N. C. Kapur, transferred.

Captain G. F. Harris is appointed to officiate as an Agency Surgeon, with effect from the forenoon of the 14th March, 1938, and is posted to the North-West Frontier Province.

Captain C. J. H. Brink is appointed to officiate as Residency Surgeon, Kashmir, with effect from the forenoon of the 1st April, 1938.

The following appointments are made:—

Short Service Commissions

To be Lieutenants

LEAVE

Major-General H. C. Buckley, K.H.P., Surgeon-General with the Government of Bombay, is granted leave on average pay for 5 months and 19 days followed by leave on half-average pay for 1 month and 12 days, with effect from the 2nd April, 1938, afternoon.

Lieutenant-Colonel N. S. Jatar, D.S.O., Inspector-General of Prisons, C. P. and Berar, is granted leave for 6 months *ex-India*, from the 3rd April, 1938.

Lieutenant-Colonel T. C. Boyd, Principal, Medical College, and Superintendent, Medical College Hospitals, Calcutta, is granted leave for 4 months, with effect from the 12th April, 1938, or from any subsequent date from which the leave is availed of.

Lieutenant-Colonel B. Gale, who was on leave *ex-India* till the 4th April, 1938, has been granted an extension of his leave up to the 8th December, 1938.

Lieutenant-Colonel C. M. Nicol, Director of Public Health, Punjab, proceeded on leave *ex-India* on average pay for 8 months, with effect from the 8th April, 1938.

Lieutenant-Colonel C. J. Lodge Patch, M.C., Medical Superintendent, Punjab Mental Hospital, Lahore, proceeded on leave *ex-India*, with effect from the 19th April, 1938.

Lieutenant-Colonel S. N. Makand, Director of Public Health, C. P. and Berar, is granted leave for 4 months *ex-India*, from 19th April, 1938.

Lieutenant-Colonel K. S. Thakur, Civil Surgeon, 24-Pargannas, is granted leave for 18 months, with effect from the 26th April, 1938, or the date on which he is relieved.

Previous notification is hereby cancelled.

Major D. Kelly, Civil Surgeon, Raipur, is granted leave for 4 months *ex-India*, from the 8th April, 1938.

PROMOTIONS

Majors to be Lieutenant-Colonels

R. C. Wats. Dated 26th March, 1938.

T. H. Thomas. Dated 8th April, 1938.

Captains to be Majors

J. H. Boulbee. Dated 29th April, 1938.

J. P. J. Little. Dated 30th April, 1938.

E. A. O'Connor. Dated 30th April, 1938.

P. L. O'Neill. Dated 30th April, 1938.

Short Service Commissions

Lieutenants to be Captains

M. L. Gujral. Dated 1st October, 1937, with seniority from 19th May, 1935.

B. N. Bhandari. Dated 1st October, 1937, with seniority from 21st May, 1935.

Mohan Singh. Dated 1st October, 1937, with seniority from 21st May, 1935.

B. L. Kapur. Dated 1st October, 1937, with seniority from 22nd May, 1935.

D. R. Sharma. Dated 1st October, 1937, with seniority from 23rd May, 1935.

P. S. Bassalvi. Dated 1st October, 1937, with seniority from 25th May, 1935.

G. N. Ahmadi. Dated 1st October, 1937, with seniority from 25th May, 1935.

P. M. Kaul. Dated 1st October, 1937, with seniority from 26th May, 1935.

A. K. Dev. Dated 1st October, 1937, with seniority from 31st May, 1935.

M. Akram. Dated 1st October, 1937, with seniority from 2nd June, 1935.

D. S. Raju. Dated 1st October, 1937, with seniority from 4th June, 1935.

B. S. Bindra. Dated 1st October, 1937, with seniority from 16th June, 1935.

M. S. Chadha. Dated 1st October, 1937, with seniority from 19th June, 1935.

W. A. Mirza. Dated 1st October, 1937, with seniority from 21st June, 1935.

Indian Land Forces

H. L. Khosla. Dated 1st October, 1937, with seniority from 11th February, 1936.

S. P. Wanchoo. Dated 1st October, 1937, with seniority from 22nd February, 1936.

S. Rameshwar. Dated 1st October, 1937, with seniority from 5th March, 1936.

B. H. Sayed. Dated 1st October, 1937, with seniority from 17th June, 1936.

V. Sivasankaran. Dated 1st October, 1937, with seniority from 24th June, 1936.

J. R. Vaid. Dated 1st October, 1937, with seniority from 24th June, 1936.

K. N. Rao. Dated 1st October, 1937, with seniority from 1st July, 1936.

B. S. Khurana. Dated 1st October, 1937, with seniority from 1st July, 1936.

R. Kasiwal. Dated 1st October, 1937, with seniority from 23rd September, 1936.

T. D. Chablani. Dated 1st October, 1937, with seniority from 30th September, 1936.

S. Sunkavally. Dated 2nd October, 1937, with seniority from 2nd October, 1936.

A. S. Rao. Dated 10th October, 1937, with seniority from 10th October, 1936.

R. L. Soota. Dated 10th October, 1937, with seniority from 10th October, 1936.

M. Shankhla. Dated 11th October, 1937, with seniority from 11th October, 1936.

K. S. Aiyer. Dated 22nd October, 1937, with seniority from 22nd October, 1936.

Ivan H. B. Ghosh. Dated 5th December, 1937, with seniority from 5th December, 1936.

K. S. R. Menon. Dated 13th December, 1937, with seniority from 13th December, 1936.

Indar Singh. Dated 27th December, 1937, with seniority from 27th December, 1936.

Z. H. Khan. Dated 3rd January, 1938, with seniority from 3rd January, 1937.

A. G. Khan. Dated 9th January, 1938, with seniority from 9th January, 1937.

S. A. Mian. Dated 29th October, 1937.

V. P. Gupta. Dated 15th November, 1937.

I. Mallik. Dated 7th December, 1937.

M. S. Rao. Dated 9th December, 1937.

P. Dass. Dated 11th December, 1937.

S. A. Hasan. Dated 22nd December, 1937.

C. Parkash. Dated 7th March, 1938.

V. R. Damle. Dated 29th March, 1938.

The seniority of Lieutenant (on probation) G. B. Jackson is ante-dated to the 1st January, 1937.

RETIREMENTS

Major-General D. P. Goil, K.H.P. Dated 29th March, 1938.

(Previous notification, as it relates to the retirement of this officer, is hereby cancelled.)

Lieutenant-Colonel J. B. deW. Molony, O.B.E. Dated 3rd April, 1938.

Lieutenant-Colonel C. H. Smith, O.B.E. Dated 26th March, 1938.

Notes

NICOTINIC ACID B. D. H.

Nicotinic acid is stated to be a precursor of the 'P.P.' (pellagra-preventing) factor of the vitamin-B complex.

Nicotinic acid has been isolated from active 'anti-neuritic' concentrates, and it has therefore been inferred that it might be related to vitamin B₃. Subsequent investigations, however, have proved that nicotinic acid has no anti-neuritic properties, but it has been shown that it will cure black-tongue in dogs, a disease considered to be in man. The discovery that 'vitamin B₃' actually consists of three fractions (lactoflavine, vitamin B₆ (the rat dermatitis factor) and the pellagra-preventing factor) and that monkeys fed on a diet deficient in the 'P.P.' factor, but not in lactoflavine or B₆, develop 'monkey pellagra', suggested that nicotinic acid might be active in human pellagra, as it had proved to be in black-tongue. Nicotinic acid was therefore tried, first in monkey pellagra and then on human pellagrins. The

conclusion reached was that the administration of nicotinic acid rectifies a deficiency in these pellagra-producing diets. Reference is made also to an investigation carried out in Egypt in which nicotinic acid was administered to two groups of pellagrins (with controls). In one group, on a poor diet, the action of the nicotinic acid was more or less confined to a specific effect on the erythematous lesions. In the second group, on a more balanced diet, both the erythema and the general condition of the patients improved.

It was concluded therefore that the 'P.P.' factor may not be the sole factor concerned in human pellagra. Nevertheless, the results so far obtained appear to justify the use of nicotinic acid in every case of pellagra.

Clinical application

A case of human pellagra is reported in which a dramatic recovery followed the administration of nicotinic acid in doses of 60 mg. daily for twelve days; it was found that no reaction followed the oral administration of nicotinic acid; intramuscular and intravenous injections, however, produced a marked but transient flushing. Pulse, blood pressure and respiration were not affected and the patient complained of no discomfort following intravenous injection. A slight feeling of warmth was produced however. The first signs of improvement were noticed twenty-four hours after the treatment was started in that there was 'a striking improvement in the appetite. . .'. After forty-eight hours, mental confusion began to improve, and rationality returned after six days' treatment. The skin began to improve in three days, and was entirely normal in twelve days. On the seventh day the T waves as shown by the electrocardiogram were normal, and on the twelfth day the abdominal cremasteric reflexes were normal.

Reports of other investigations in which 15 pellagrins were treated with nicotinic acid demonstrated that this substance promptly relieves pellagrous glossitis, stomatitis, ptialism, vaginitis, urethritis and proctitis and appeared to confirm the previous findings, establishing the view that nicotinic acid is an antipellagic factor, the results also being stated to furnish '... evidence that the increased porphyrinuria associated with pellagra disappears on the administration of nicotinic acid'.

In these cases larger doses were given than had been recommended hitherto, and it was tentatively suggested that 100 mg. of nicotinic acid five times daily is safe and effective in the average case of pellagra. Further, it was stated that it is rarely necessary to give nicotinic acid parenterally, but 10 to 20 mg. in sterile physiological saline, injected four times daily, gave remission of symptoms. On the other hand it was concluded that other substances, in addition to nicotinic acid, may be concerned in pellagra, and, accordingly, it was recommended that a well-balanced diet should form part of the treatment. Large quantities of meat, eggs and milk should be eaten by the patient.

Method of administration and dosage

In view of the reactions which follow intravenous and intramuscular injection of this substance it is recommended that nicotinic acid B. D. H. be administered orally. The dose suggested is 30 mg. twice daily after food. This dose may be increased, however, at the discretion of the physician. It has been stated that the maximum and minimum dose of nicotinic acid has not been determined, indeed up to 1,500 mg. have been given daily without producing toxic symptoms.

THE LATE SIR JAMES CRICHTON-BROWNE, LAST ADDRESS

BEFORE proceeding with the business of the forty-first Annual General Meeting of Bovril Limited, held in London on 28th February, 1938, the Lord Luke, K.B.E.,

the chairman, said he would like to speak of the loss the Company, and indeed the country, had sustained in the death of Sir James Crichton-Browne. It would be impossible to exaggerate the value of his services to the Company, or the admiration his qualities of mind and character had inspired in his fellow directors. At the age of 97 Sir James showed very little diminution of his mental powers. The last thing he did, handicapped as he was by illness, was to prepare the address he proposed to deliver to the shareholders. This it would be his (Lord Luke's) privilege to read to the meeting.

In the address he had prepared, Sir James recalled how in 1897 the great Russian physiologist, Pavlov, had shown that the administration of meat extracts to dogs stimulated the mucosa of their stomachs and produced a copious secretion of gastric juice.

Remarkable experiments

It had been inferred that in human beings these extracts similarly increased the gastric flow, but no scientific proof of this had, until quite recently, been adduced. But during last year, by a remarkable series of experiments at King's College, London, Dr. Boon had demonstrated that meat extracts in varying degrees had the same effect in stimulating the gastric secretion in human beings that they had in dogs and other animals. This was a fact of first-rate importance. A wide range of typical food products was investigated, and it was found that of these Bovril was the most potent and rapid stimulant of the gastric mucosa.

By stimulating the mucosa to an increased flow of hydrochloric acid, Bovril restores the gastric juice to normal and assists recovery. That was an important finding, but the clinical significance of Dr. Boon's discovery was, in the opinion of Sir James, wider still. In such a disease of the stomach as gastritis, which was often the precursor of very serious trouble, there was a deficiency and alteration in the character of the secretion of the gastric juice, a deficiency and alteration which Dr. Boon's results suggested might be corrected by the judicious administration of Bovril, which so powerfully stimulated the secretion of gastric juice containing the essential hydrochloric acid.

It would seem prudent, therefore, for people at, or after, middle life, who suffered occasionally from indigestion, not dietetically explicable, or other gastric disorder, to try the effect of Bovril in warding off the often disastrous consequences of reduced gastric activity.

ANTITOXIN THERAPY IN GONORRHOEA

Dr. T. ANWYL-DAVIES reports (*St. Thomas's Hospital Reports*, Vol. II, 1937) the following results in using antitoxin (Parke, Davis and Company) in the treatment of both acute and chronic gonorrhoea.

Dosage.—The average daily dose of this unconcentrated antitoxin was found to be 5 to 20 c.cm. when injected intramuscularly. Even with these small doses caution was necessary, as in some cases severe reactions occurred. The beneficial results, however, were beyond question, and it was found possible, even after severe reactions, to repeat the injection twenty-four or forty-eight hours later.

Following these preliminary trials, clinical work was continued with a concentrated antitoxin which proved to be approximately five times more potent than the unconcentrated product. Thus, it was found that the average dose was 1 c.cm., and that doses over 2 c.cm. caused in many cases a marked systemic disturbance. Because of this a routine procedure was adopted of injecting adrenaline chloride solution 1 : 1,000 at the same time as the antitoxin.

Conclusions.—The results obtained with gonococcus antitoxin have been distinctly encouraging. Acute and chronic cases, complicated and uncomplicated, respond equally well, which is in marked distinction to other biological preparations hitherto available for this

condition. Reactions and results indicate that this antitoxin possesses specific therapeutic properties; properly regulated controls confirm this. The results with the improved unconcentrated product have been quite as satisfactory as with the experimental concentrated antitoxin, and in many cases smaller doses appear to be equally effective. The treatment of gonorrhoea depends largely on obtaining satisfactory drainage and it follows that any adjuvant measures to assist this, such as irrigations, douching, etc., should be employed.

Since the introduction of gonococcus antitoxin, accounts have been published in medical literature relating to sulphanilamide, in the treatment of gonorrhoea. Some report rapid cures in chronic, but not in acute, cases; others are favourably impressed by their results in acute, but not in chronic, cases. In spite of these discrepancies the drug has some action, but a true estimate of its effectiveness in relation to cure has still to be evaluated. Most of the failures occur in acute infections; this suggests that sulphanilamide may restrain the gonococcus but that it is unable to effect a cure until the patient has developed a certain immunity. If the rôle of this immune mechanism can be ascertained and applied in relation to this drug it may be of valuable assistance. Clinical evidence suggests that requisite antibodies can be supplied by the antitoxin and thus provide reinforced immunity which assists the action of the sulphanilamide. Possibly, by using this combination of antitoxin and drug a higher percentage of successful results may be obtained.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ANAHÆMIN IN TROPICAL MACROCYTIC ANÆMIA

By L. EVERARD NAPIER, M.R.C.P. (Lond.)

C. R. DAS GUPTA, M.B., D.T.M.

R. N. CHAUDHURI, M.B.

G. N. SEN, M.B., D.T.M.

M. N. RAI CHAUDHURI, M.B.

P. C. SEN GUPTA, M.B.

and

D. N. MAJUMDER, M.B.

(Calcutta School of Tropical Medicine)

THE necessity for putting together these few notes on the action of anahæmin in tropical macrocytic anæmia was realized by the senior writer whilst he was reading this year's *Medical Annual*. In the section on anæmia, the reviewer, Professor S. Davidson, reporting the work of

However, we used anahæmin in only a very few cases and, although the senior writer mentioned this finding to a few workers in London last year, we did not consider that the few results were worth separate publication. We believe that the therapeutic test will prove a valuable one in classifying the different types of macrocytic anæmia that are encountered in India, and we were waiting until we could collect sufficient data to make an analysis of our cases worth undertaking.

As there is still at least one hæmatologist who questions the limitations of the therapeutic activity of the more refined liver extracts, we consider that we ought perhaps to report our findings to date. We will do this summarily and this paper must be considered as an interim report.

Group A. We used anahæmin in the treatment of six cases of macrocytic anæmia in pregnant women. The initial blood counts and some other relevant details are given in the table below.

TABLE I

Showing initial blood findings in pregnant anæmics treated with anahæmin

Serial number	1	2	3	4	5	6

Dr. Lucy Wills and her co-workers (Wills *et al.*, 1937), says 'the authors believe that there are two factors in the more crude liver extracts which are of value in the treatment of macrocytic anæmias and that the more highly purified liver extracts may be less efficacious, since they only contain one factor'. He adds 'in the reviewer's experience no clinical evidence of this danger is at present available...'

The writers were, of course, aware of this work and early last year took the opportunity of confirming Dr. Wills' suggestion, namely, that the highly-refined anahæmin would probably prove inactive in certain types of macrocytic anæmia as it had done in the macrocytic anæmia of monkeys.

In three cases the results we obtained gave us no information of value.

Case 1.—The patient died soon after child-birth on the 6th day after anahæmin had been given, after a reticulocyte rise from 3.8 to 7.8 per cent.

Case 2.—She had a high reticulocyte count before the anahæmin was given: she received two doses of 200 mgm. each, with a week's interval between them; the red cell count rose from 700,000 to 1,200,000 per c.mm. a week after the first injection but no further, and she left hospital a week later.

Case 3.—This was complicated by parturition on the day after the anahæmin was given and also by the house physician giving campolon as well: she had a reticulocyte response of 24 per cent on the 5th day after 200 mgm. of anahæmin.

In the next case there seems to have been a very definite response to anahæmin.

Case 4.—She received only anahæmin, 200 mgm. on 13th July. On the 19th her reticulocyte count was 21 per cent and red cells had risen to 1,600,000 per c.mm. (see chart 1).

In the next two cases the action of anahæmin was less marked.

Case 5.—She had 200 mgm. of anahæmin on three consecutive days, 25th, 26th and 27th June; on 30th June the reticulocyte count was only 5.8 per cent and it had fallen again two days later. On 3rd July her red cell count had risen to 2,200,000, and a week later further to 2,600,000 per c.mm. She gave birth to a live baby and left the hospital.

Case 6.—One dose of 200 mgm. of anahæmin was given: she had a low reticulocyte response and later a slight rise in red cells. Later, she had two injections of neohepatex to 5 c.cm. each on two consecutive days and while there was only a low reticulocyte response there was a sharp rise in the red count a little later (see chart 1). Fractional gastric analysis showed a normal acid curve.

The information obtained from the treatment with anahæmin in these pregnant women is

In the next case there was some slight response to anahæmin, but the main interest was that within a fortnight of anahæmin administration a macrocytic orthochromic case became a

N (+) = Within normal range, but on the high side 45 to 65 c.cm.

therefore inconclusive. One appears to have responded well, but in two others the response was indifferent, and one of these later responded better to neohepatex.

Group B. These were all Indian males (for initial hæmatological data see table II): The first three we can discuss very rapidly.

Case 1.—This was a case of kala-azar in which the anaemia was definitely macrocytic and rather more profound than usual. There was no response to anahæmin, naturally.

Case 2.—This was a hæmolytic case. Two c.cm. of anahæmin had no effect on the red cell count. Later campolon and ferrous sulphate were equally ineffective. Eventually recovery followed blood transfusion.

Case 3.—This was a case of macrocytic anaemia of an aplastic type, in which sulphanilamide is suspected of being the cause. Sternum puncture showed an aplastic marrow, with the nucleated red cells almost all normoblasts (see table III). Anahæmin, campolon, and other liver preparations completely failed to effect any improvement. After repeated blood transfusions his hæmoglobin was raised to 9.35 g. and when seen a month later there had been a slight further increase.

microcytic hypochromic, the cell volume falling to just half its pre-treatment figure.

Case 4.—Marmite was given for 14 days without effect. Then anahæmin 2 c.cm. was given: there was a rise in red cells from 1,710,000 to 2,640,000 per c.mm. in 14 days, without any reticulocyte response, and accompanied by a slight fall in hæmoglobin.

The blood picture was now microcytic and iron was given: there was a slight reticulocyte response and a rapid rising in hæmoglobin and red cells, ending in a normal picture within a month (see chart 2).

Cases in which there was definite response to anahæmin

The next two cases show the very definite action of anahæmin and we will therefore describe them in a little more detail.

Case 5.—Admitted 2nd February, 1937. A Bengalee Hindu, milkman, aged 28; he complained of weakness and increasing giddiness for three or four months. He had an occasional rise of temperature to 99.5°F. but no malarial parasites were found. He had been treated for kala-azar in our hospital two years previously. Splenic puncture showed no parasites.

His anæmia was macrocytic orthochromic, and he had a large spleen and a strongly positive van den Bergh reaction. Gastric acidity was normal. Sternum puncture showed a marked normoblastic hyperplasia (see table III).

CHART 2

Case 4.—Showing response to anahæmin and later to iron.
AH=Anahæmin 200 mgm.

He had no treatment for three weeks and little change in his count occurred, except that his reticulocytes rose to 15 per cent and remained high for some days. He had three doses of anahæmin, 200 mgm. each, on 20th and 24th February and on 1st March—on 25th February the reticulocyte count was 11.6 per

CHART 3

AH=Anahæmin in 200 mgm. doses.
NH=Neohepatrat intramuscularly for 10 days.

cent, the red cells 1,740,000 and the mean cell volume (MCV) 138 cu. μ . After this the red cell count rose sharply, the reticulocytes fell to 2 per cent, and the MCV fell below 100. Two more doses of anahæmin

were followed by an immediate fall and then a steady rise in the red cell count to 3,700,000 but no reticulocytosis.

Ten daily doses of neohepatrat were followed by a slight fall in red cells and again a slow recovery: iron for three weeks did not appear to have any action except that the red cells again fell to 3,250,000 per c.mm. and after three more anahæmin injections, the count rose to 3,750,000. The last anahæmin injection was followed by a sharp reticulocyte response of 7 per cent. Meanwhile the spleen had become reduced very considerably and was only just palpable on discharge, but the indirect van den Bergh was still positive, 4 units (see chart 3).

In this case there seems to be no possible doubt about the specific action of first doses of anahæmin, as the improvement was immediate. In the next case the action was equally clear, but there was in this case a reticulocytosis.

CHART 4

Case 6.—Showing red cell response to anahæmin (AH), and later hæmoglobin response to iron.

Case 6.—Admitted on 21st June, 1937. He was a hotel guide, aged 40, a Moslem. He had fever running up to 102°F. daily, but no parasites were found and his spleen was not enlarged. The sternum puncture showed a very marked megaloblastic hyperplasia (see table III).

The anæmia was macrocytic hyperchromic, the van den Bergh was 'doubtful', below 1 unit, at the first examination and was subsequently negative. His gastric analysis showed no free acid following the alcohol meal, but there was a good response to histamin.

He received 200 mgm. of anahæmin on 23rd June and 100 mgm. on the 25th. The reticulocytes rose from 0.4 per cent to 7.9 per cent on the 29th and 13.6 per cent on the 30th. The red cell count rose rapidly to 2,900,000 per c.mm. and the MCV fell eventually to 86 cu. μ and the mean corpuscular hæmoglobin (MCH) to 23 $\gamma\gamma$. Another anahæmin injection of 200 mgm. produced no result except a slight reticulocyte rise, and he was put on to iron; ferrous sulphate grs. vi three times a day, for 21 days. The hæmoglobin took a sharp turn upwards but he left hospital before cure was complete. With the improvement in his blood count the temperature fell slowly to normal (see chart 4).

An interesting feature in this case was the improvement, first in the red cell count following anahæmin, and then the response of the hæmoglobin to iron.

In neither of the histories of these cases was there any definite evidence of dietary deficiency: the first was a vegetarian but the second was not.

Cases in which there was no response to anahæmin but response to campolon

There are three cases in which anahæmin was apparently quite inactive, yet in which there was a typical response to campolon.

Case 7.—Admitted on 19th April, 1937, a Hindu, male, aged 37, personal servant. He had a low fever,

CHART 5

Case 7.—Showing failure of response to anahæmin and other substances and response to campolon.

LE = Liver extract intramuscularly.

temperature rising to about 100°F. daily; there was apparently no parasitic cause for this and no splenic enlargement. His tongue was red but not sore. Sternum puncture showed a certain number of megaloblasts and erythroblasts, but the picture was not the typical megaloblastic hyperplasia of pernicious anæmia (see table III). His gastric analysis showed a normal acid curve.

His anæmia was moderate in degree but was apparently progressive: it was macrocytic hyperchromic and the van den Bergh was about 1 unit.

On 3rd May his red blood count was 1,500,000 per c.mm. and reticulocyte percentage 0.6; he was given three doses of anahæmin of 200 mgm. each, on 5th, 7th and 11th May. His red cell count fell to 1,400,000 per c.mm. on 11th May and further to 1,130,000 on 15th May. His reticulocyte percentage never rose above 1 per cent. He was then given 'heparnovina', an ampoule three times a day by mouth for nine days, and his red blood count fell still further to 1,100,000, and there was no reticulocyte response.

On 24th May he was given campolon 4 c.cm. daily for five days: on 28th May his reticulocytes were 5.0 and on 31st May 8.8 per cent; by 7th June the reticulocytes had fallen again to 1.2 per cent, and now

the red cell count was 1,500,000 per c.mm. He was then given liver extract*, 2 c.cm. daily for ten days, but the red cell count fell again to 1,200,000 on 21st June, so ventriculin was given, 20 gm. daily for seven days, but the red cells fell further to 1,110,000 on 28th June, and on the following day campolon was again given, 4 c.cm. daily for five days. Six days later the reticulocytes had again risen to 10.1 per cent and by 12th July, a week later, the red cell count was doubled, 2,220,000 per c.mm., and a fortnight later it was 3,410,000. His MCV which had risen to 165 eu. μ at one time and had now fallen to 105; his van den Bergh increased to 4 units at one stage, but fell and was either 'negative' or one unit after the last course of campolon.

In this case there was no possible doubt about the failure of anahæmin or of the response to campolon, but heparnovina and ventriculin by mouth and parenteral liver extract also failed.

CHART 6

Case 8.—Showing failure of response to anahæmin (AH) and response to campolon (C) 4 c.cm. daily.

It is not clear why there was not a better response to the first course of campolon; there was nothing in his clinical condition which could have accounted for the hæmopoietic response being depressed.

Case 8.—A Hindu, male, motor driver, aged 35; he was admitted for increasing weakness for about a year, looseness of the bowels, and indigestion. His spleen was not palpable and he was afebrile. Gastric analysis showed definite hypochlorhydria; only one sample contained free acid. The sternum puncture showed a typical megaloblastic hyperplasia; the megaloblasts were 26.8 per cent and the erythroblasts 16.8 per cent (see table III).

His anæmia was fairly severe, macrocytic and hyperchromic: the van den Bergh was negative. The red blood count on 28th June was 1,070,000 per c.mm. and the reticulocytes 1.6 per cent. Anahæmin, 200 mgm., was given: the reticulocytes never rose above 2.3 per cent and a week later the red cell count was 1,170,000 per c.mm.

*The liver extract was made by a very well-known firm and is a well-tried preparation. The dosage was that advocated in the treatment of pernicious anæmia: 1 c.cm. was said to be equivalent to 100 to 125 grammes of liver by mouth.

Campolon was then given, 4 c.cm. daily for 5 days. On the 5th day the reticulocytes percentage was 18.4, and the red blood count rose to 1,850,000 in the next two weeks, but in another two weeks it had fallen again to 1,440,000 per c.mm. Campolon was again given and within two weeks the red cell count was 4,000,000 per c.mm. The MCV was as high as 136 cu. μ and fell after the second campolon course to 89 cu. μ .

Again, there can be no doubt about the failure of anahæmin and the response to campolon. The dosage of anahæmin should have been quite sufficient to produce a response, and it is obvious that the response to campolon was a response to the first dose.

Gastric analysis showed a very low gastric acidity—maximum 8 c.cm. N/10 HCl. Sternum puncture showed a marked hyperplasia of the red cell elements (75 per cent of nucleated cells) but only 4 per cent of megaloblasts (*see* table III). The anæmia was of moderate degree, macrocytic and hyperchromic: the van den Bergh was 4 units at the first examination, but subsequently was not higher than 1.5 units. The Price-Jones curve showed the mean diameter as 8.095 μ and the coefficient of variation as 13.01 per cent (*see* chart 8).

Anahæmin, 200 mgm., was given on the 9th day in hospital when the reticulocytes were 4.6 per cent, the last red cell count was 1,330,000 per c.mm. The reticulocytes fell to 1.6 on the 4th day, but were 7.8 on the 5th day and 2.6 per cent on the 7th day. The

or so. Spleen not enlarged: fever up to 102°F., for which no parasitic cause could be found; this came down gradually to normal as the anæmia improved.

red cell count fell to 1,210,000 per c.mm. and campolon, 4 c.cm. daily, was then given. Reticulocytes were 9.2 per cent on the 3rd day, 24 per cent on the 4th, and 21 per cent on the 5th day. On the 7th day the

CHART 8

Showing Price-Jones curve of case 9.

red cell count had risen to 2,300,000 per c.mm. and by the 15th day the red cell had risen to 3,290,000 per c.mm. and the reticulocytes had fallen to 2.8 per cent.

There is in this case just a suggestion that the anahæmin might have stimulated hæmopoiesis, but this seems doubtful, and there is no doubt

about the far greater stimulus given by campolon.

The dietetic history in these three cases was difficult to obtain, but they were all nominally vegetarians and an actual food deficiency cannot be excluded.

Summarizing our experience with anahæmin, we can say that in one case of pregnancy anæmia and in two cases of macrocytic anæmia in men there is evidence of the specific action of anahæmin, and that in three other cases of macrocytic anæmia in men, in which campolon stimulated a very definite hæmopoietic response and eventually brought about cure, anahæmin was inactive.

Discussion and conclusions.—In so-called tropical macrocytic anæmia, marmite, which contains the extrinsic factor, will effect a cure, but so also will the ordinary liver extract, as it contains both extrinsic and intrinsic factors.

Anahæmin, a highly refined liver extract, which is supposed to contain hæmotopietin, the combined extrinsic and intrinsic factor, given alone, is a very efficient therapeutic agent in pernicious anæmia. Anahæmin given in adequate doses will not, however, produce any response in some cases of tropical macrocytic anæmia in which campolon will afterwards effect a cure.

If therefore we assume that anahæmin does contain the extrinsic factor, we must conclude that it is not by virtue of their content of extrinsic factor that marmite and crude liver extract effect a cure in tropical macrocytic anæmia, but on account of the presence of some other hæmotinic agent.

These experiments will require to be repeated on a quantitative basis—as it might be argued that anahæmin whilst containing a full quota of intrinsic factor contains a relatively smaller quantity of extrinsic factor—but as they stand they do seem to indicate that Dr. Lucy Wills' suggestion, based on experiments with monkeys, is correct. It also adds support to the suggestion made by one of us (Napier, 1936) that the 'marmite principle' is an independent principle which is essential to normal hæmopoiesis.

Our experiments suggest that this 'marmite principle' is not present in anahæmin, but is abundant in campolon.

They also support a conclusion arrived at in the above-mentioned paper (Napier, *loc. cit.*), namely, that tropical macrocytic anæmia is not a single entity, that is to say, cases grouped together under this name have not a common ætiology. We hoped, and we still hope, that by the aid of the therapeutic test, it may be possible to arrange this large group of cases into smaller groups with common ætiological, hæmatological, and/or clinical characters; but the results reported are not encouraging. There seem to be no common characters in either group that are peculiar to that group; for example, of the cases

(Continued at foot of next column)

PROTAMINE ZINC INSULIN

By J. P. BOSE, M.B., F.C.S. (Lond.)

Diabetes Research Department, School of Tropical Medicine, Calcutta

Introduction.—One of the main difficulties encountered in the use of insulin in clinical diabetes has been its transient but sometimes severe action causing dangerous oscillations in the blood-sugar level. A fact brought out soon after the discovery of insulin was that, as the methods for purification of insulin were improved upon, the action was intensified but the duration was found to be lessened, and though some of the other disadvantages of insulin, such as the local and general skin reactions, disappeared with increased purity, its intensified but short-lived action constituted a great drawback in that the patients were left to oscillate between hypoglycæmia and hyperglycæmia. It was thus found that, to obtain the most favourable results, insulin had to be administered in small doses but at frequent intervals. This was certainly a very great disadvantage, not only from the point of view of the patient but also from that of the doctor.

To overcome all these drawbacks of 'ordinary' insulin, a search has been going on for some time past to find an insulin compound which will have a slower action, causing a more gradual lowering of blood-sugar over a prolonged period. This would then simulate the normal way in which insulin acts in our system, *i.e.*, by a regulated and almost continuous secretion from the normal pancreas.

(Continued from previous column)

showing a characteristic megaloblastic hyperplasia there is one in each group.

On therapeutic grounds we have evidence of the existence of the following groups:—

- (a) A group in which anahæmin is curative, *i.e.*, in which the deficiency is the same as in pernicious anæmia.
- (b) A group in which marmite or crude liver extract is curative, *i.e.*, in which the 'marmite principle' is deficient.
- (c) A possible third group in which campolon is curative but other liver extracts are not (*e.g.*, our case 7), *i.e.*, in which some principle which is peculiar to campolon is deficient.

The six patients, pregnant women, in group A were examined by Dr. D. N. Majumder, who is a worker under the Indian Research Fund Association, in the course of an enquiry financed by that fund.

These considerations have been in the minds of workers in different parts of the world, who have been trying to find means of retarding the rate of absorption of insulin, so that a more or less continuous and sustained action could be obtained. Various methods to retard insulin action, such as using it as an oily suspension, injecting insulin with some vaso-constrictor substances, preparing an insulin compound sparingly soluble in tissue fluids so as to retard the rate of absorption, etc., have been tried without any final or lasting success till 1936 when Hagedorn and his Danish colleagues at Copenhagen introduced to the world a new insulin compound, 'protamine insulin' or 'insulin retard', which was recognized to have several distinct advantages over the ordinary insulin. This new insulin compound was employed therapeutically in Denmark for a fairly long time before it was put on the market as 'insulin retard'.

When the precipitate in suspension is injected subcutaneously it is deposited in the subcutaneous tissues, and there is a steady and prolonged absorption of insulin liberated from the solid particles, thereby causing a continuous and prolonged action on the blood-sugar.

Hagedorn's discovery naturally stimulated very keen and intensive research and his results were soon confirmed by Joslin and others (1936), and later on at the Mayo Clinic and by the Toronto group of workers. As a result of such extensive research, various modifications of the original method of Hagedorn soon appeared, the most noteworthy amongst these being that of D. A. Scott of the Connaught Laboratories in the University of Toronto. Scott (1934) and Scott and Fisher (1935) working with crystalline insulin of Abel and others (1927) found that the crystallization of insulin was only possible in the presence of certain inorganic salts, notably

CHART 1

Protamine zinc insulin = 30 units.

Food intake = Milk 4 oz. every 4 hours.

Discovery of protamine zinc insulin.—The idea behind Hagedorn's discovery was to produce a compound of insulin with a basic protein substance which would be slowly soluble in the tissue fluids so that the rate of absorption would be slower. The ordinary insulin being highly soluble and acid in reaction was very quickly absorbed. To attain this object, Hagedorn *et al.* (1936) tried to link insulin hydrochloride with the different protamines and found that the mono-protamines were most suitable for the purpose and the best result obtained was from the sperm of *Salmo iridius*, the rainbow trout. Hagedorn also found that when insulin hydrochloride was made to combine with this protamine and was buffered in such a way that the iso-electric zone of the compound was brought near the pH 7.2 (*i.e.*, the pH of the tissue fluids) a fine precipitate of insulin protamate was formed. This finely-divided white precipitate was found to contain the active substance.

zinc, and also that when more zinc was added to the insulin the rate of absorption was prolonged. Fisher and Scott (1935) found that zinc was present in fairly large quantities in the pancreas. Working on this hypothesis, they started mixing zinc in different strengths with protamine insulin and found that the addition of 1 mg. of zinc to 500 units of protamine insulin gave a more definite and prolonged action and enhanced its therapeutic value. Moreover, in addition to causing a greatly improved effect, zinc stabilized the protamine zinc suspension.

This new compound has been called protamine zinc insulin. It has been shown that with one injection of this insulin the blood-sugar control is maintained for nearly 24 hours, as compared to protamine insulin, or insulin retard, the blood-sugar control of which lasts from 12 to 18 hours (chart 1).

After the discovery of protamine zinc insulin, a good deal of controversy arose as to whether

continued injection of zinc into the system was likely to produce toxic effects like those of lead; various other metals such as calcium, nickel, etc., were tried. Incidentally, it might be mentioned that certain other substances, such as ferrous chloride, magnesium and other allied metals and certain lipid substances, were also used in this connection with a view to making new compounds with insulin, but the most important work in this line seems to be that of Bischoff (1936) who prepared an insulin-tannic-acid suspension, which when injected into rabbits produced a delayed absorption of insulin and a prolonged hypoglycæmic effect. The addition of zinc to this insulin-tannic-acid suspension was found to enhance the hypoglycæmic effect still further. The injection of this compound, however, was found to be extremely painful and in most patients erythema and subcutaneous swelling developed.

Rabinowitch and others (1936) raised a very important question as to whether an excess of

the injection, when it begins to fall. The rate of fall of blood-sugar, though much slower than that with ordinary insulin, however, continues for a longer time and if the food-intake is restricted, a maximum fall is obtained in 12 to 16 hours after the injection, sometimes causing symptoms of hypoglycæmia to appear. Thereafter, the blood-sugar rises slowly but does not usually attain the pre-insulin level till about 24 to 36 hours after the injection (chart 2).

The action of protamine insulin differs from that of protamine zinc insulin in that the action of the former begins 3 hours after the injection, the maximum fall of blood-sugar takes place within 6 to 8 hours, and the effects last from 14 to 18 hours.

The action of ordinary insulin on the other hand begins almost at once, the fall of blood-sugar taking place within half an hour after the injection, the maximum fall of blood-sugar takes place within 3 to 6 hours, and the effects usually last from 8 to 10 hours.

CHART 2

zinc would inhibit the action of endogenous or exogenous insulin. Fazekas and Himwich (1936) showed that traces of zinc (0.1 per cent), such as used by Scott, would produce no deleterious effect but if the concentration of zinc was increased to 0.9 per cent, the blood-sugar-lowering effect of insulin could be inhibited altogether. As a matter of fact, Drinker, Thompson and Marsh (1927) produced a general fibrosis of the pancreas in cats by giving excessively large amounts of zinc.

It appears to me that the minute traces of zinc which are present in protamine zinc insulin are not likely to cause much ill effects, local or general. The amount of zinc added is very small, i.e., 1 mg. per 500 units, so that a moderately severe case of diabetes taking an average dose of 30 units daily would receive not more than 0.25 gramme of zinc in 10 years.

Action of protamine zinc insulin.—When a dose of protamine zinc insulin is injected subcutaneously, the blood-sugar usually shows no change until about 3 to 4 hours after

It therefore appears that protamine zinc insulin, owing to its slower and long-continued action, has certain advantages over the protamine insulin, or insulin retard, and certainly many more over the ordinary insulin hydrochloride. One of the immediate advantages of the protamine zinc insulin over the ordinary insulin, especially from the point of view of the patient, is in the reduction of the number of daily injections. Ordinary insulin, with its relatively rapid but transient action, lasting for about 8 hours or so, requires to be given repeatedly to cause an effective control over the blood-sugar throughout the day, in severe cases of diabetes. Protamine zinc insulin on account of its less rapid but more persistent and continuous action is better able to prevent the hyperglycæmia for much longer periods and thus to effect a much better control over the blood-sugar level, often without a repetition of the dose. This appears to be a great boon to severe diabetics who have to be awakened during the night to get their dose of insulin, in order to

prevent the early morning hyperglycæmia, for, as is generally known in severe cases of diabetes, a fairly marked hyperglycæmia usually occurs during the early hours of the morning, and a dose of ordinary insulin given in the evening is insufficient to keep the blood-sugar down during the long interval of 10 to 12 hours during sleep. Protamine zinc insulin, on account of its long-continued slow action, is better able to keep the blood-sugar under control during the night and reduce the early morning hyperglycæmia.

The occurrence of nocturnal hyperglycæmia is even more characteristic in juvenile diabetes, in which there is almost always a peculiar 'W'-shaped blood-sugar curve. The control of blood-sugar in such cases is only possible by giving the patient two injections, one at retiring, say, at 9 p.m., and one in the early morning, say, at about 3 a.m.; but such a procedure, apart from the great discomfort both to the patients and his relatives, is not always free from the danger of

security and on account of the persistence and continuousness of the action he is likely to develop into severe hypoglycæmia without warning even when he is under observation. This, certainly, is a great disadvantage in the use of protamine zinc insulin as distinct from ordinary insulin, the hypoglycæmia of which occurs with almost specific regularity and with specific symptoms.

A second disadvantage of protamine zinc insulin is the uncertainty of its summation or cumulative effect, on account of its action lasting somewhat over 36 hours. Even when the patient receives one injection daily, the residual effect of the insulin given on the previous day, combining with that of the fresh dose, will tend to enhance its action and the continuance of the same large dose for an indefinite period is likely to produce undesirable results.

A third disadvantage is that there is no uniformity of action of protamine zinc insulin, the

CHART 3

Ordinary insulin = 30 units.
Food intake = Milk 4 oz. every 4 hours.

an occasional over-dose. Since the discovery of protamine zinc insulin, however, the treatment of juvenile diabetes has been revolutionized. It has flattened the 'W'-shaped curve considerably, as will appear from the charts.

Disadvantages of protamine zinc insulin.—I have just stated that the maximum fall of blood-sugar takes place within 12 to 16 hours after a dose of protamine zinc insulin is injected, sometimes causing symptoms of hypoglycæmia to appear (chart 1, B). The hypoglycæmia is, however, more subtle in onset and, as the subjective symptoms are less severe than with ordinary insulin, the usual early symptoms such as tremulousness, sweating, palpitation, may be quite unnoticed by the patient even when the blood-sugar is as low as 60 mg. per cent.

The early symptoms of hypoglycæmia, due to protamine zinc insulin being thus unnoticed by the patient, often gives him a false sense of

rate of its absorption from the tissues is not constant, varying according to the state of vascularity of the tissues into which it is injected, and hence the rate of reduction of the sugar content of the blood is often not constant, but variable even with the same dose.

Another disadvantage of protamine zinc insulin is that, owing to its slow absorption, it takes a longer time to come into action. Thus, if it is given before breakfast, as is usually done, it would not be able effectively to control the post-breakfast hyperglycæmia and glycosuria. For the same reason, it does not also effectively control the rapidly increasing hyperglycæmia following a high carbohydrate diet, or in cases of severity with complications such as coma, etc. In such cases the physician is likely to find himself involved in the error of giving very large doses in his effort to reduce the blood-sugar quickly. This, as previously mentioned, will produce, by its cumulative effects, hypoglycæmic

reactions of serious consequence, particularly in advanced heart cases.

Still another disadvantage of protamine zinc insulin that may be mentioned is its uncertain keeping properties. The opinion amongst the various workers is not final yet as to how long this insulin keeps its full potency and at the present moment all manufactured protamine zinc insulin has to be dated. The expiration date, as printed on the bottle, is six months from the date of manufacture.

Advantages of protamine zinc insulin.—The new insulin compound, however, possesses several advantages over the ordinary insulin; one of the greatest has already been mentioned, namely, that owing to the slow action continuing throughout the night, it controls the hyperglycaemia, glycosuria and ketosis during the

of ordinary insulin in a day to keep the blood-sugar under effective control, can now be controlled with one effective dose of protamine zinc insulin. Further, it has been found possible, in a certain number of cases, gradually to reduce the dose of protamine zinc insulin. One of my cases, a severe diabetic, used to be on an average daily dose of ordinary insulin varying from 40 to 50 units (taken in two injections) for the last 14 years. Since the advent of the protamine zinc insulin she was put on one injection daily and it has been possible to reduce the dose to 10 to 15 units only, to keep effective control over the blood and urine sugar.

Selection of cases.—In mild or moderate cases, the ordinary insulin, taken once before breakfast, may be wholly replaced by protamine zinc insulin. In the more severe cases it has been

CHART 4

night, without the patient having to take one or two nocturnal injections. This is certainly a great boon to severe diabetics, more particularly of the juvenile type.

A second advantage is that the high carbohydrate diet can be spread out more evenly over all the meals, instead of being mainly confined to those following the insulin injection, as has hitherto been done.

A third advantage is that, if the dose be carefully regulated, there is less likelihood of sudden reduction of blood-sugar and this obviates the risks of hypoglycaemia during sleep. Another advantage I have noticed is that patients treated with protamine zinc insulin notice a greater sense of well-being.

In my experience with protamine zinc insulin I have found that some of the severe cases of diabetes, which required two or more injections

found more satisfactory to combine ordinary insulin with the protamine zinc insulin during the first few days of treatment and then gradually to eliminate the ordinary insulin. The reason for this procedure is that, as has already been stated, protamine zinc insulin is slow-acting and hence unable to control the post-breakfast hyperglycaemia. If, however, a dose of ordinary insulin is given as usual before breakfast, it will effectively control the hyperglycaemia due to food; protamine zinc insulin can then be given 8 hours later and this will help to check the nocturnal and early morning hyperglycaemia; the dose of the ordinary insulin next morning can then be reduced, and finally it can be replaced wholly by one single dose of protamine zinc insulin. The stabilization of the patient to the proper dose of insulin should preferably be done in an institution.

Regarding the comparative dosage of ordinary insulin and protamine zinc insulin, opinions differ. When replacing ordinary insulin wholly by protamine zinc insulin in mild or moderate cases, I usually start with 75 per cent of the total previous dosage of the ordinary insulin in one injection given before breakfast, increased later on if necessary. In more severe cases, where a combination of both kinds of insulin is necessary, 25 per cent of the total dose should be given in the form of ordinary insulin before breakfast, and the remaining 75 per cent of the dose should be given in the form of protamine zinc insulin in the evening. This usually causes an effective control over the blood-sugar during the night and helps to reduce the early morning hyperglycemia. The dose of ordinary insulin can thus be gradually decreased and subsequently wholly replaced by protamine zinc insulin.

As to what the attitude of the general practitioner should be with regard to changing a patient from ordinary insulin to protamine zinc insulin, my suggestion is that those diabetics who are well-controlled and in good health with the ordinary insulin and do not mind two injections a day should be left alone.

In severe diabetes, where there is much ketosis, the best plan is to treat these cases with either large and repeated doses of ordinary insulin or a combination of ordinary insulin with protamine zinc insulin, as suggested before, until the condition has improved sufficiently, when they can be switched on to protamine zinc insulin.

The question now arises as to what is the exact place of protamine zinc insulin in clinical diabetes. Though it is admitted that protamine zinc insulin has passed through the purely experimental stage and has moved on to clinical trials, yet nobody has gathered sufficient experience to lay down hard and fast rules; moreover this is not possible because of the lack of uniformity of its action, depending no doubt on the rate of absorption from the tissues. Besides, in dealing with new therapeutic preparations one should always be on guard to avoid unwarranted claims and inferences before a proper evaluation of the drug has been satisfactorily established by long clinical and laboratory experience. As it stands at present, there is certainly room for improvement both in the preparation of the drug and in the mode of its administration.

All we can say at present is that protamine zinc insulin is a powerful weapon and is destined to prove a more useful one than the ordinary insulin; its introduction certainly constitutes a step forward in the treatment of clinical diabetes.

A NOTE ON THE THERAPEUTIC EFFICIENCY OF SOLUSEPTASINE IN SIMIAN MALARIA (P. KNOWLES)

By R. N. CHOPRA, C.I.E., M.A., M.D., SC.D. (Cantab.),
F.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to the King,
and

B. M. DAS GUPTA

(From the School of Tropical Medicine, Calcutta)

WHILE discussing with the writers the problem of treatment of leptospiral infection by synthetic drugs, Mr. Harold Walker, representative of Messrs. May and Baker, Ltd., suggested that the effectiveness of soluseptasine, which like other compounds of the sulphonamide group has earned a great reputation for its bactericidal properties, particularly in streptococcal infections, might be tested on this infection as well.

Soluseptasine is a white crystalline powder of well-defined chemical constitution. The chemical formula is as follows:—

Disodium-p (γ-phenyl-propyl-amino) benzene-sulphonamide-α-γ-disulphonate.

It is readily soluble in water to give a solution of approximately neutral reaction. The concentration selected by the manufacturers for clinical use is 5 per cent. A solution of this strength is very nearly isotonic with the blood and is, according to the manufacturers, well tolerated by subcutaneous, intramuscular, or intravenous injection by all the common laboratory animals, and also by man. It is said to be much less toxic in the experimental animals than the other sulphonamide derivatives and no serious untoward effects have been reported following the use of soluseptasine.

With a view to determining the safe maximum dose for guinea-pigs and monkeys we injected these animals with varying amounts of the drug by different routes. One monkey of the series, which received 2 c.cm. of the drug

intravenously, was one of those animals which was suffering from low grade infection with *P. knowlesi* and on the day of injection of soluseptasine it showed a fair number of the parasites (both schizonts and gametocytes) in the blood, but 24 hours after the injection no parasites could be demonstrated even in thick blood films. The question arose whether the disappearance of the parasites was spontaneous as this is not uncommon in monkeys with chronic infection, or whether it was due to the destructive action of the drug on the plasmodium. In order to discover the cause of this disappearance we took a fresh monkey (not used previously for any experimental work), 4.48 kilogrammes in weight, and inoculated it with 3 c.cm. of monkey blood showing a very scanty infection with *P. knowlesi*. On the fourteenth day after inoculation an examination of the thick blood films revealed a few parasites for the first time. The further progress of the infection and its course after the administration of soluseptasine are shown in the graph. When

Symbols—V.S. = Very scanty parasites detected in thick films.

+ = up to 1 per cent red cells parasitised.

++ = " 10 " " "
 +++ = " 30 " " "
 ++++ = " 50 " " "

the parasite count was very high (nearly 40 per cent red cells infected), the monkey developed hæmoglobinuria and looked very ill. At this stage 2 c.cm. of soluseptasine were injected intravenously. Next day the animal looked better. Not only was there a considerable fall in the parasite count but there were also definite degenerative changes in the parasites, characterized by marked chromatolysis and karyorrhexis. The same dose was repeated 24 hours after the initial injection and this was given intramuscularly. No parasites could be found in the blood after the two injections and the monkey soon recovered from the anæmia caused by the severe malarial infection.

Comments.—Napier and Campbell (1932) and Knowles and Das Gupta (1932) have shown that *P. knowlesi* produces a very intense and virulent infection in *rhesus* monkeys, causing death of the animal, if untreated. The control of such an infection in the monkey by a drug is,

SOME OBSERVATIONS CONCERNING THE RECENT TYPHOID EPIDEMIC IN CALCUTTA

By H. E. MURRAY, B.A., M.D., M.Ch., M.C.O.G.
 LIEUTENANT-COLONEL, I.M.S.

Surgeon Superintendent, Presidency General Hospital, Calcutta

WITH A NOTE ON TYPHOID MYOCARDITIS

By GERARD KELLY, F.R.C.S., F.R.C.P.I.
 MAJOR, I.M.S.

First Resident Medical Officer, Presidency General Hospital, Calcutta

Introduction.—An outbreak of enteric fever recently occurred in Calcutta, and it seems to

(Continued from previous column)

therefore, the crucial test of its antimalarial activity. The destructive action of soluseptasine on the plasmodium appears to be exceedingly powerful. One injection was sufficient to check a very severe infection and after the second the parasites disappeared altogether from the peripheral circulation. In their studies on the action of atebirin on *P. knowlesi*, the present authors (Chopra and Das Gupta, 1933) have pointed out that it exerts a very powerful action on the parasite. These observers have also noted that after treatment with atebirin the parasites almost invariably reappeared in 10 to 15 days and multiplied with the same rapidity as in the primary attack, causing the death of the animal, if prompt treatment were not accorded. It is evident from the graph that in the case of soluseptasine the parasites reappeared after 12 days in small numbers, a low grade infection persisted for some time, and eventually disappeared altogether without any treatment. We should not, however, like to attach much importance to this point before we have carried out further experiments. It may be mentioned in this connection that recently Dr. Díaz de León (1937) treated 15 cases of human malaria (benign tertian) with Rubiazol*, with satisfactory results. In view of Dr. León's experience in *P. vivax* infection and our results with monkey malaria it may be stated with certainty that sulphonamide compounds are effective specific drugs for malaria.

us that it will serve a useful purpose if we place on record the clinical picture presented by the patients who were admitted to, and treated in, the Presidency General Hospital.

Let us state at the outset that we are not concerned with the cause of the outbreak, for that has been investigated by the proper authority. However, the great majority of the cases admitted to the Presidency General Hospital came from one building; as the same organism was isolated from nearly all the cases, and as the course of the disease was identical in almost all the cases, it would point to the fact that a carrier was to blame.

The epidemic, if one may call it that, was short but virulent. In all, some 31 cases were admitted to the hospital, and all were of the 'private-room' class of patient. To our minds one of the great lessons to be learned from this outbreak is the value of prophylactic inoculation; only five patients out of the 31 had ever been inoculated. Though the stool, Widal, or other examinations of these five showed that they had been attacked by the same organism as the other cases, yet the course of the disease in these five was short and mildly toxic, severe symptoms did not appear, and convalescence was comparatively rapid.

We would urge all medical men to impress and keep on impressing on their patients the extreme value of prophylactic inoculation in enteric and other diseases, but especially in enteric. If this report should do nothing else but bring this point home, we feel it will have served a purpose.

The clinical picture.—The onset of the disease in the great majority of the cases was strikingly atypical, as it was ushered in with suddenness, a high temperature (103° to 104.8°F.), intense headache, pains in the joints and limbs, and in a few cases with rigors. This onset is misleading and any doctor when called to see such a case would quite naturally consider at the outset that he was dealing with dengue, malaria, or some such condition. As already stated those patients who had been inoculated ran a very mild course, and can now be dismissed from this report, so that the remainder of our observations applies to the non-inoculated cases only.

These cases earlier on displayed an intense degree of toxæmia. Headaches were very severe from the start, as also was sweating. An extreme degree of abdominal distension was a marked feature, and delirium and unconsciousness also made an early appearance and lasted a long while. Some of the patients had meningeal symptoms, and lung complications occurred in others. Bowel hæmorrhages occurred in only two cases and both these patients died. The patients were so ill that special nurses were utilized night and day for every one who could afford them.

The severe symptoms lasted for an average of about 25 days, the shortest being 10 days,

and the longest 5 weeks. Only three patients died, the two bowel hæmorrhage cases mentioned above, and one who developed lung complications.

Bacteriology.—The *Bacillus typhosus* was shown to be the causative organism in nearly every case, either as a result of the Widal test, or isolation from the stools, urine, or blood. It is an interesting point that in two cases *B. typhosus* was grown in blood culture 6 weeks after the commencement of the disease. In three of our cases, however, the Widal was 'negative' throughout and in two others in which it was positive at first to *B. typhosus*, 1 in 83, it showed no rise in titre as the disease progressed; yet all these five were definitely clinically enteric.

Treatment.—In addition to the usual orthodox treatment of enteric, the severe symptoms mentioned had to be dealt with as they arose. It was found that aspirin was not effective in relieving the headaches, and of course it increased the sweating, so novalgin or gardan were used for the headaches and joint pains. A daily enema was administered and in the cases where the abdominal distension was great a flatus tube was passed every evening as well, and more frequently if necessary. In all these cases of severe distension of the gut, pragmolin, 1 c.cm., or acetylcholine was given with the enema or the passing of the flatus tube.

Our observations on this method of treating the distension led us to be emphatic on its very great value. We had not seen this mentioned in the literature on enteric, and it was tried as an experiment. The results exceeded our expectations, and the relief afforded to the patient was great.

Luminal, usually in doses of 1½ grain tablets, was our sheet-anchor in those cases which displayed cerebral irritation, and for these it was used unstintingly.

Stypven, morphia and cotarnine were used in the cases of bowel hæmorrhage, but the bleeding was too severe for any drug to be efficacious. Eight cases developed lung complications with extreme cyanosis. All these cases were very ill indeed and for them the continuous administration of oxygen was begun as soon as the affection of the lungs became apparent. The oxygen was given in most of the cases by means of the nasal catheter which on the whole was well tolerated. For two of the cases, however, a modification of Poulton's oxygen tent was rigged up. From our observations of these cases, as well as previous ones, we are convinced of the great value of continuous oxygen therapy in all cases where lung oxygenation of the blood is lessened, either from a pure pneumonia, or in complications of a toxæmia from other diseases.

In our opinion the giving of continuous oxygen by the in-dwelling nasal catheter is good enough for all practical purposes, at any rate in India where financial stringency prohibits, in the vast majority of hospitals, the

purchase of an oxygen tent. We would stress however that the administration of the oxygen *must be continuous* (there is very little use in giving it for 10 minutes every hour), and a nurse or attendant must be constantly with the patient. Oxygen given by means of a glass funnel held in front of the patient's mouth and nose is completely useless. The various forms of oxygen tents of course give the best treatment, but they are all fairly expensive. Some of them, such as Poulton's, are comparatively simple; others are, in our opinion, too complicated for use in India. We believe that with a little ingenuity it is possible to rig up a satisfactory tent.

Diet.—The dieting of these patients presented no difficulty, for the seriously ill patients were unable to take anything but whey, sips of glucose water, and honey. As they got better the diet was rapidly but gradually increased up to a full 'milk diet' (i.e., milk, milk foods, eggs, puddings, jellies, bread and butter). The first increase from the whey and glucose water was citrated milk, and then a gradual increase up to the full milk diet was permitted, and in some cases this was reached before the temperature settled to normal. All the patients except those with cerebral irritation took their nourishment well.

The writers' enteric patients are all ordered 'milk diet' on admission, and then when seen they may be permitted the 'full milk diet', or a modification of it is made to suit each individual patient according to his condition. Thus, a mild enteric, especially of the *para* group, may be on a full milk diet from the moment of his admission. We have never seen any ill effects from judicious feeding of enterics, but on the contrary are convinced that the feeding is beneficial, and lessens the weakness of convalescence and the risk of complications.

Complications.—One of our cases, a boy 9 years old, was already so ill that it seemed impossible that he could recover, when one morning an ulcer in his gut perforated. The abdomen was opened, and the perforation repaired; the abdomen was partially sutured and a large drainage opening left. However, the toxæmia was so great that, on the fifth morning after operation, the wound completely broke down and most of his intestine came out into the bed. The condition then seemed 'hopeless', especially as the child was suffering from severe shock, and was collapsed and pulseless. The intestine was heaped back into the abdomen, and covered over with a drum towel saturated with normal saline, and the patient was put into a corset and binder. The towel was re-moistened every two hours, and completely changed every 12 hours. The patient was kept quiet. He is now completely well, the wound has healed over, and he is waiting for a metal protector before leaving for his home.

During convalescence we observed that all these patients showed some degree of myocarditis and anæmia. Splenic and liver enlargement were not marked features. Convalescence was treated with strychnine and the other usual tonics, and one or other of the liver extract preparations was extensively used, with, we feel, good results, but not having any control cases we must not be dogmatic.

We have not appended any tables or statistics for the number of our cases is too few, so we have considered that a narrative description would be of more interest.

Our thanks are due to Dr. C. D. Torpy, I.M.D., the Hospital Registrar, for searching through the various history sheets for us.

TYPHOID MYOCARDITIS

European and American authorities nowadays regard circulatory failure in typhoid fever as predominantly of peripheral and not of cardiac origin; otherwise stated by White, 'generally the heart is not affected to any important or appreciable degree in typhoid fever'. Many of us in India, however, in the light of our more frequent experience of the disease, incline to the opinion that the central contribution to circulatory failure afforded by myocardial weakness, and often manifest about the middle course of typhoid fever, is not quite so inconsiderable as our distinguished confrères would have it. We courteously suggest that the myocardial pathology of typhoid fever has been a trifle hastily interpreted by modern thought, which too abruptly dismisses as merely a sign of rapid post-mortem decomposition the toxigenically soft and swollen or flabby heart of the clinical pathologists of former days. Furthermore, it is difficult to conceive any severe grade of peripheral failure without corresponding impairment of the coronary circulation and consequent myocardial weakness. At all events we think that more extensive electrocardiographic study of the heart in typhoid will probably support our more tolerant clinical concept of circulatory failure in this disease.

The difficulties inherent in the discovery and demonstration of typhoid myocarditis by ordinary clinical methods are expectedly manifold. The previous myocardial state is generally an unknown quantity. The complications of typhoid, and more especially those of abdominal origin, focus our attention elsewhere than on the heart. But most disturbing of all is the knowledge that those signs upon which we used to rely so faithfully—namely, feeble pulse, rapid heart rate, distant heart sounds and even fetal heart sounds—may all likewise document circulatory failure of peripheral genesis. Accordingly, although we shall omit the usual description of the changes undergone by the apical first sound and proceed at once to mention some of the more direct bedside evidence of typhoid

(Continued at foot of opposite page)

MALARIA IN RELATION TO THE COASTAL LAGOONS OF BENGAL AND ORISSA

By C. STRICKLAND, M.A., M.D.

*Professor of Medical Entomology, School of Tropical
Medicine, Calcutta*

CHANGES in level of the currents of water that flow on the Earth's surface are of course an everyday phenomenon: the streams at a comparatively high level being described as 'in flood', and the antithetic condition 'low-water', or 'at the ebb'. Now it is well known, at any rate in deltaic lands, that along a certain line between the margin of the flood and that of the stream at low-water—and this is true whether the current be a sea-current or the flow of a river—a relatively high bank of sediment settles down, and it is such banks on either side that confine the river at low-water. The channel so formed by this disposition is ordinarily regarded as all that 'the river' is, whereas it would be more correct to look upon the uttermost and vaguer limits set to the margins of the current while it is in flood as demarcating 'the river', the stream when more clearly limited by the banks of sediment referred to being only its low-water phase.

(Continued from previous page)

myocarditis, we at the same time assert that such heart-sound changes are in part at least early expressions of myocardial failure.

The development of cardiac dilatation during the course of typhoid fever is primary evidence of acute myocarditis. It is displayed by an outward movement beyond the left mid-clavicular line of a wavy cardiac impulse with corresponding shift of the left border of cardiac dullness. Provided, firstly, that the diaphragm is not displaced unduly upwards by the commonly prevailing meteorism and, secondly, that we exclude organic valvular disease, hypertension and coronary disease, the appearance of such dilatation clearly proclaims the presence of acute myocarditis. The most emphatic auscultatory sign is succinctly given by gallop rhythm, which in our experience may often be foretold at an earlier phase by so-called impurity or splitting of the first heart sound. It may be interesting and profitable to note that, quite apart from typhoid myocarditis and circulatory failure in acute infections, gallop rhythm is now recognized as an outstanding, facile and often early sign of the failing arteriosclerotic or hypertensive heart, which is by far the commonest type of failing heart encountered in India. Dilatation of the typhoid heart, however, is most usually announced to the unwary observer by the development of an apical systolic murmur which rarely fails to evoke an immediate diagnosis of some sort of myocarditis or endocarditis, and a suitable sense of auscultatory pride and satisfactory accomplishment.

During this phase, it must now be mentioned, there remains behind the bank a residuum of the flood-level water known as a *lagoon**.

Now whether one be by the sea-coast on the one hand, or by the courses of the rivers in the uplands or paradelta on the other, this moulding of the land may be observed. In the hills, the streams in flood stretch from scarp to scarp of the old rocks that confine them; but at their low-water or 'fair-weather' flow their channels lie between banks of deposit behind which are shallow sheets of water, that are sometimes called 'lateral lakes', and they are *homologous in every respect to the lagoons of shallow water in the delta*.

It is only, however, the formation of the lagoons at or near the sea-coast that will be here considered, and again it must be remarked that they are characteristically shallow expanses of water shut off at times of low-water from the river, or sea-currents, by a bank, while they are flooded over at the times of high-water.

The secular history also of such a lagoon may be here recounted. Originating from an expanse of water which is at no time shut off from the sea or estuary, as far as one can see at the surface, it is only a later circumstance that the bank of sediment, that has been gradually laid down along a wayside current, appears above the surface of the water and separates off what is now the lagoon. Coral growing on a ring bank and an atoll forming is the manifestation of an exactly homologous phenomenon. Gradually the lagoon silts up, relatively to the surrounding land, and so becomes ever shallower and less often or less extensively inundated by the floods. The silt that effects this transformation is carried into the lagoon by the surrounding waters when in flood and it is deposited as the waters recede, as also—and this factor is perhaps not sufficiently appreciated—by wind-blown material, for in the vicinity of the sea-coast it can readily be realized that this is a circumstance to be reckoned with. Meanwhile as the lagoon becomes shallower and shallower it becomes relatively less brackish, and more and more sweet-water plants invade it and cover its surface.

Along a sea-coast the nascent formation of lagoons is represented by the series of parallel gutters and sand-banks between the beach and the open sea. This parallel formation is a consequence of the fact that wind-waves of the open sea, whatever be their direction, gradually become parallel with the coast as they run on shore, owing to the greater drag exercised by the bottom as the water shallows. The water-currents for the same reason assume a direction parallel with the line of the shore, and just as a river-current elevates a bank the summit of

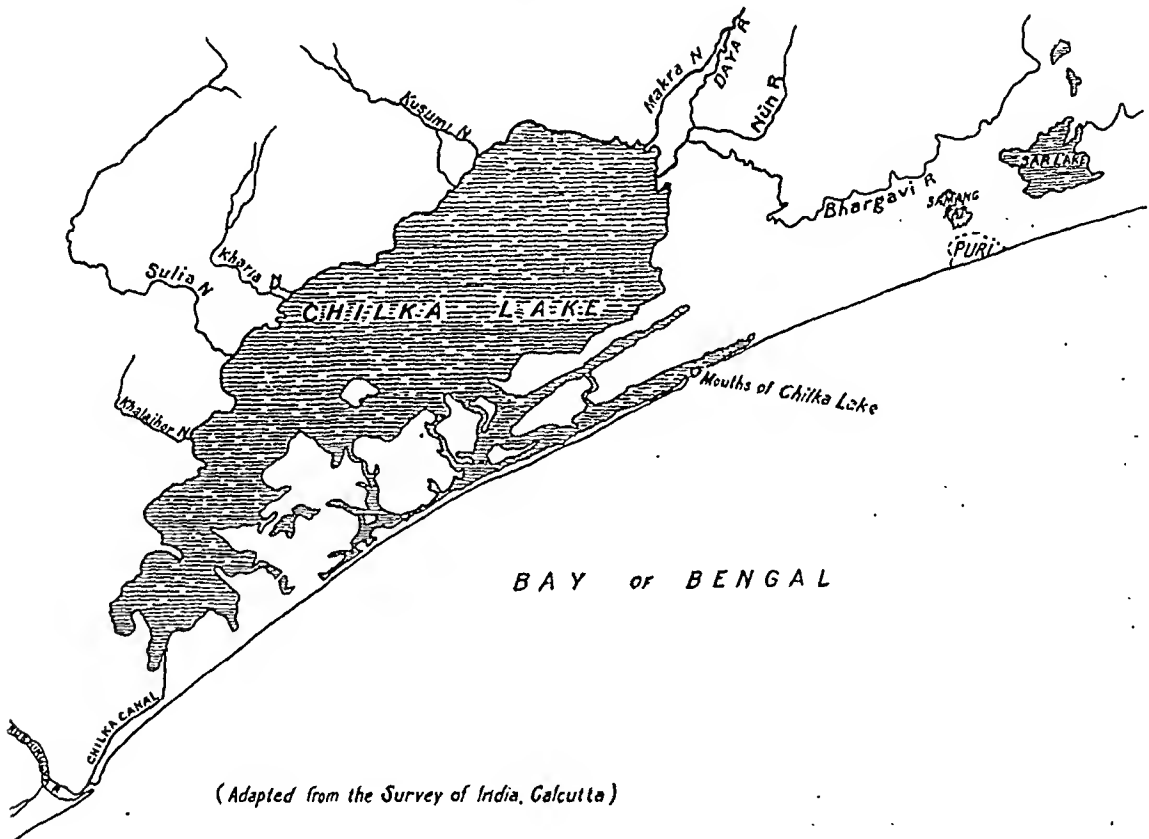

*The reason why there is a residuum of the flood is explained by the writer in a paper *Holland and Bengal*, vide Transactions of the Royal Society of Tropical Medicine and Hygiene, 1938 (in the press).

which follows a line somewhere between its low-water margin and its high-water limits, behind which bank is the lagoon, so do the sea-currents throw down a series of sand-banks between which and the 'sea-beach' are gutters of comparatively placid water, the beginnings of lagoons, which are beautifully shown in map 1. In the course of time such a sea-bank is raised to a level at which it remains above the sea for comparatively long periods and meanwhile it becomes consolidated by the cementing action of the water and by the growth of plants, and derives accession of wind-borne material.

If the sea-waves only should hold sway, the lagoon might be wholly continuous along the sea-coast, and there would not be any cloaca

the sea-currents have laid down a bank of sand that would be completely continuous if it were not that the fresh waters brought into the lake by the Daya, Bhargavi, and other rivers provide a potential head for keeping a small and shallow channel scoured out through the seaward bank. They have not as yet demarcated a channel for themselves thus occluding the rest of the lagoon. The tendency is always for the sea to form a continuous bank and repair any breaches in it, but the opposing rivers must prevail to a greater or less extent—to a greater when they are in flood, to a less in the fair-weather. When the rivers during the rainy season are in flood the waters widen the exit through the sea-wall and then they press back

MAP 1

(Adapted from the Survey of India, Calcutta)

(see map 1) in the seaward sand-bank, but the rivers draining the hinterland and passing through the lagoon have to find an outlet to the sea, and in doing so they build up the inevitable bank of sediment, as described above, and tend to separate off their channels from the lagoon, incidentally retaining a passage through the sea-bank for the passage of their waters. Before, however, the rivers crossing a lagoon demarcate themselves their waters mingle with those of the lagoon, finally finding an outlet through the sea-bank, and when the river has demarcated itself there always remains in the river-bank a passage for flooding the lagoon over a low bank exposed in the fair-weather.

The Chilka Lake in Orissa (see map 1) illustrates these points on a grand scale. Here

the sea and as they prevail the lagoon becomes ever sweeter, whereas when the rivers are at their fair-weather flow the sea prevails and the waters of the lagoon become more brackish, although at the same time the sea-bank is to some extent repaired by the sea.

There is at Chatrapur (see map 2) an example of a lagoon or *tempara*, as in Orissa it is called, shut off nearly completely from a river, the Rushikuliya, that floods and drains the *tempara*, a river that doubtless once flowed through it at all times as does the Bhargavi now through the Chilka Lake. Seaward it is completely limited by a sea-bank or sand dune (see plate VII, figures 1 and 1a).

The persistence of the lagoon-structure continuously right along the coastal belt of Bengal

PLATE VII

Fig. 1.

Fig. 3.

Fig. 4.

Fig. 4a.

and Orissa, of which a section is shown in map 2, indeed made feasible the building of the Orissa Coast Canal, along an endless chain of *temparas*, while their feeders, the great rivers that crossed the lagoons and shut them off, have made water available for the canal.

The *temparas* are not reproduced in any such striking way at the Bengal sea-face, and probably this is due to the fact that here the littoral drift is of a finer material than in Orissa. However, in the Contai sub-division of Midnapore district there are the vestiges of such traets; for instance, there is a small *tempara* at Jinput, and at Fraserganj on the south of the district of the 24-Pergannas there are also some such formations.

With regard to the relationship of the *temparas* with malaria, the writer has elsewhere pointed out that their homologues in the Bengal Sunderbans are non-malarious, but on the coast at Fraserganj (see map) the *rayats** showed a 25 per cent spleen index, and *Anopheles ludlowi* was captured here. This was in marked contrast with the very low spleen index in the immediate hinterland.

In lower Bengal in general one may say that if the basins of the *dwips* that represent the lagoons are protected from the ingress of flood-water from the rivers they are non-malariagenic, while on the sea-coast where grassy sandy maidans abound with intervening swamps that are not bunded, and carry *Anopheles ludlowi*,

MAP 2

(Adapted from the Survey of India, Calcutta)

In the deltaic Bengal Sunderbans the relatively low-lying area in a *dwip*, as the naturally-formed island is named, is called a *bhil* and this is characterized by a comparative lack of tree-growth, so that in the hot weather its surface becomes sun-dried mud. In Malaya, along or near the coast, sand-banks may be found here and there and are called *permatang*, which are usually grassy 'maidans', as in Bengal, while in that country too it is interesting to note that a place called Singarang in Johore State occupies the site of an old *tempara*, and *singaram* is an alternative Kling name for the *tempara* of Orissa. Also at Batu Burok in Tringganu State (see plate VII, figure 2) there is a similar old lagoon silted up and now intensively cultivated.

the people suffer from malaria. At Jinput near Contai outside the great sea-dyke a few poor people living beside a small *tempara* eke out a scanty existence. The children who were available for examination here were only seven in number but every one had splenomegaly, while inside the great sea-dyke where the water is sweet enough for the cultivation of *padi*, the spleen-index was under 5 per cent.

It is exactly the same in Orissa; one has the coastal brackish water *tempara* represented on a great scale by the Chilka Lake, and the sweet-water inland *tempara* now silted up and planted with *dalia padi* as at the Samang Pat (see

* Cultivators.

map 1) behind Puri, the one intensely malarious, the other practically free from malaria.

The indication of these observations would seem to be the closure of the basins as far as possible, only allowing to accumulate the fresh sweet water entering them from the hinterland. In deltaic Bengal, the garden of aquatic vegetation growing on the surface of the waters collecting in the natural basins does not appear to conduce to malaria, and if the *tempara* be closed, it is probable that the shallow sweet water supporting a garden of aquatic vegetation would not breed malaria-carrying mosquitoes as it does now (plate VII, figure 3). It is probable that it is the close embankment of the *dwips* of Bengal that has saved its people from malaria, though of course they would not be there if they had not embanked their land, for it would not have been habitable.

As far as the Chilka Lake is concerned there would be an additional benefit of closing to some extent its existing outlet, in that the feeder rivers would remain under water at a higher level than they do at present, and this might have the added advantage of providing more water for the irrigation of the *rabi* crops. In this case economics and health would seem to be closer bound up than usual. The proposed measure would drown the shallow-water mosquito-breeding places on the foreshore (see plate VII, figures 4 and 4a) and pisciculture as well as agriculture would be benefited. Of course there must be no obstruction to the passage of the rivers through the lake in the rains.

An objection that might be raised from a consideration of the natural régime of a *tempara* is that an artificial head of water in it might set up a stress tending to break down the sea-bank at some weak point, and this might be manifested by its being sapped by seepage on the seaward side. The difficulties, however, cannot be compared with those bound up with the converse measure of attempting better drainage of the country by opening the outlets into the sea, a measure that can only be described as fatuous, because it would be in opposition to forces of Nature that are far too powerful to combat. Such a procedure has been attempted at Lake Sar (see map 1) with ill success.

Apart, however, from any interference with the levels of the waters in the Chilka Lake, or any other *tempara*, the foreshore which is a prolific breeding place of the mosquito might be warped by one method or another. The best would seem to be by the growth of mangroves, or other plant life such as the *nal* reed, both of which have an economic value, and probably have both been cleared away in the past, just as is a corn-field by a swarm of locusts. Otherwise warping should be resorted to by physical means such as groynes or baffles of some sort or other.

To do anything at all to alter the *status quo* is in a sense to combat Nature and her agent

COLOUR PERCEPTION, AND COLOUR-BLINDNESS TESTS

By C. E. R. NORMAN, F.R.F.P. & S., D.P.H.
Chief Medical Officer, South Indian Railway,
Golden Rock

THIS paper is a short study of colour-blind persons, and the relation of their colour perception, as shown by the spectrometer, to the answers given by them when examined by the Edridge Green lantern and Ishihara's tests.

For practical purposes a person may be said to be colour-blind, if he is a trichromic, dichromic, or has a marked shortening of the red end of his spectrum. Persons in these three categories exhibit the following peculiarities:—

(1) Red, green, yellow and white lights owing to their common property of brightness are confused with each other by trichromics and dichromics, if these lights happen to be bright and poorly saturated or dimmer than usual.

(2) Dark red lights are often not seen by those who have marked shortening of their red ends, and will be called black and no light and occasionally whitish.

(3) Persons with a shortened red end will match a dark reddish-brown wool with a darker green and consider a small dark-red light as green and a darker green light (signal green) as red.

(4) With composite colours a person with a shortened red end will often fail to see the colour he is deficient in, i.e., he will consider as blue a pale pink which is a mixture of blue and red, because he fails to see the red in it.

(5) Central vision for colour is more pronounced. Trichromics and dichromics will fail to identify a letter made up, say, of a series of red dots but usually they will have no difficulty in recognizing the colour of any particular dot composing the letter. A normal person at a glance will perceive all the red dots making up the letter and recognize it at once, but the trichromic and dichromic can only make out the colour of the particular dot looked at but not of those next to it or above and below it and hence fails to recognize the letter.

(6) The balance between brightness and saturation, on which the correct interpretation of colour appears to depend, seems to be interfered with, particularly if there is any shortening of the spectrum. If the balance is upset, and the sense of saturation for reds and violets is diminished and they are paler than what appears to the normal person, brightness not saturation gains the upper hand and reds are mistaken for yellows, blues for violets giving

(Continued from previous column)

Man, so one comes down to a choice of the measures that will encounter least opposition and will involve least difficulty. Closing up the *tempara* to a certain extent would seem to be such a measure.

rise to the so-called increased yellow and blue sensation. There is not an actual increase in sensation; these colours merely appear bright. If red, yellow, yellow-green, blue and violet dots are mixed up together figures made of red or green colours are not distinguished from the other colours which form the background, particularly if viewed in a bright natural light, but the figures may be recognized by the same person if the examination is carried out in the subdued light of a room, or if the figures are viewed by artificial light. This points to the influence of brightness over colours and helps to explain the variations which may occur with different examiners.

(7) Colour-blind persons do not guess. They answer strictly in accordance with their colour perception. A couple of examples can prove this point :—

(a) Light red (red B) and orange are frequently called red by dichromics. Add a modifier (neutral one) and they will very often be called green. Remove the modifier and the original answer will be given. This can be repeated over and over again. This is not guessing.

(b) A case of mine, a trichromic, almost a dichromic and with a shortened red end saw light green as red and signal green as green. When a modifier (neutral one) was added and the brightness effect caused by the yellow in the light green was toned down, it was called green, and the signal green (dark blue-green light) was called red, because it now was much darker and he had a shortened red end. When the modifier was removed the original answers were given. This was repeated again and again and for several consecutive days. He was not guessing.

Dr. Edridge Green's spectrometer

This spectrometer is provided with right and left hand shutters. The method of examination is as follows :—

(i) Different regions of the spectrum are exposed between the shutters.

(ii) The red end is ascertained by moving the left hand shutter to the right. If there is a shortening a strip of spectrum distinctly red will be called black or grey.

(iii) The fullest extent of red is now ascertained by moving this shutter to the left, and when orange appears the right hand shutter is slid across to the orange border and the left hand shutter moved to the left until yellow appears. In this way the whole spectrum can be traversed. Both shutters are now drawn to the ends of the spectrum and the following will be noted :—

(a) The number of colours that can be observed: According to Dr. Edridge Green the number of colours to be observed vary from 7 to nil. Both extremes are very rare. More commonly 6 and 5 colours are noticed, red, orange or yellow, green, blue and violet, then 4,

red, yellow, green and violet, 3, red, green and violet, 2, red and violet (or yellow and blue). I believe 10 to 15 per cent of people can see only 3 or 2 colours. A white area in the place where green should be is sometimes seen by dichromics and varies in extent from a strip to nearly the whole length of the spectrum. There is sometimes no white area.

(b) *Brightness of the spectrum.*—The spectrum particularly if very brightly illuminated will appear at first to be uniformly bright but if a moderately bright spectrum is closely observed two areas can be noted, one a very bright area made up chiefly of orange and yellow with narrow strips of pale red and yellow green—this I call the area of most intense brightness; it will be noted that the colours in this area are not very saturated, i.e., are pale reds and greens and the other a larger area of brightness which extends from the junction of the dark and bright red to the blue and contains saturated colours. Now, the reason why colour-blind persons mix up red, green, yellow and white lights with each other is because of their common property of brightness, it will naturally be supposed that this defect should first appear where the brightness in the spectrum is most marked, and this is actually what happens. The trichromic, when mapping out the spectrum in the manner indicated, will map out and call yellow a narrow area more or less corresponding to the area of most intensive brightness and consider this area absolutely monochromatic. He may also call it white. As this area contains poorly saturated pale red, orange (reddish) yellow and yellow-green (greenish) colours, he will with a lantern test mix up pale red, orange (reddish) yellow and yellow-green (greenish) lights, because these colours more or less correspond to the colours in his monochromatic area, but he will not make mistakes with saturated reds or greens (unless modified), because they are not within this area. With the dichromic there is merely an extension of this defect. When mapping out red he will draw the left hand shutter beyond the blue-green junction and declare the whole of this area to be red or yellow. In a very few instances he will call it white or green. This area corresponds to the larger area of brightness and since it contains saturated reds and greens will with a lantern examination mix up these colours. This behaviour to me proves beyond question that differences in brightness are responsible for the mistakes that are made by the colour blind. As regards the zones of brightness, it is a common experience to have trichromics of increasing degrees of trichromatism map out monochromatic areas from just a narrow strip in the orange-yellow area, to an extent which is almost dichromic, and their behaviour with the lantern tests has corresponded. As regards the larger area of brightness it is difficult to define exactly where it shades on the left. The dichromic usually stops at the blue-green junction, I suppose, because he recognizes blue,

but a number of dichromics I have questioned when asked what they consider was the largest area of brightness said it ended at the commencement of blue.

Edridge Green lantern.—The coloured glasses in the Edridge Green lantern are carefully picked and approximate as closely as possible to the colours of the spectrum. The dark red (red A) resembles the dark red of the spectrum and, therefore, if there is a shortened spectrum this red will not be seen nor appear as black or grey, particularly if a modifier is used as well. On the spectrum, dichromics will sometimes see the dark red as green. Therefore they will also sometimes see red A as green, when given a lantern test. The bright red (red B) comes within the greater area of brightness and, hence, will be called either yellow or red and sometimes green or white by dichromics, but trichromics will not make mistakes unless a modifier is used. The orange-yellow and yellow-green colours are similar to the same colours seen on the spectrum, and, as these colours come within the area of most intensive brightness, they are often confused with each other by other trichromics when viewed through the small apertures of the Edridge Green lantern, but generally they are recognized if seen through the large diameters, unless modifiers are used. They are invariably mistaken by dichromics, even when large diameters are used. The yellow-green light is considered to be red because :

(a) it is within the larger area of brightness which is either yellow or red to dichromics, and

(b) the yellow in the green is seen as red. A normal person will call this colour a yellow-green or a greenish-yellow light, because he perceives the yellow in it. It follows that a colour-blind person, who sees no green and to whom yellows are red, will call it red. Orange and yellow lights may be called red or white, but are often called green, particularly if a modifier is used.

The Ishihara test

This embodies more or less all the points observed in colour-blind persons and particularly allows for the altered state of the spectrum with regard to brightness and saturation resulting in monochromatic areas and consequent inability of colour-blind persons to recognize colours which occur in the monochromatic areas of the spectrum and which are therefore liable to be confused with each other. Plates 6, 7, 8 and 9 and the numerals thereon are made up of unsaturated colours which appear in the monochromatic areas and in consequence the red and green numerals are not picked out from the surrounding colours. It should be noted that failure to see the numerals 6 and 2 in figures 12 and 13 is not due to the fact that he cannot see green, but that he has a shortened spectrum, because the lower you go in the scale of colour

AN OBSTETRIC COT

By W. C. SPACKMAN

LIEUTENANT-COLONEL, I.M.S.

Professor of Midwifery and Gynaecology and Senior Specialist in Obstetrics with Gynaecology, Bai Motlibai and Sir D. M. Petit Hospitals, Bombay

THE bed illustrated herein has been designed at the Bai Motlibai Hospital as suitable for labour purposes in hospital and maternity home practice. We had felt the need for an improvement on the type of maternity bed in common use, which was usually a hard plank bed of plain design.

The special features displayed by this bed are—

1. The *med* top or mattress :

- (a) So as to have no obstruction at the foot-end to the surgeon or the nurse; the raising or lowering device for the top is operated from the head-end instead of from the foot-end as in other makes.

(Continued from previous column)

perception, the more frequently do defects in light perception appear, and their presence is only strongly suggestive of dichromatism on account of their frequent association with it. Examinations should be carried out in bright naturally-lighted rooms, otherwise mistakes may be made and variations observed in the same person examined with the same book.

I would like to express my thanks to Dr. Edridge Green for his courtesy and assistance; whatever little I have learnt on the subject of colour perception is due entirely to my using his spectrometer, lantern, beads and book tests, and to the encouragement he gave me.

- (b) In cases of collapse and to facilitate manipulation in the lithotomy position the foot-end can be raised to any desired angle—movements being almost unperceived by the patient.
 - (c) The 'U-shaped' recess at the foot-end assists draining and gives good access when a patient is in the lithotomy position. This also makes application of forceps particularly easy.
 - (d) The top is slightly curved along the central line and slopes towards the foot-end, facilitating easy drainage into the douching shoot at the foot-end.
2. Removal of foot-end bow, which permits full access to patient in lithotomy position by the use of removable side crutches.

- 3. Both the head-rest and the foot-end bow are detachable to form a plain table.
- 4. Detachable tray-stand at foot-end for instruments, cord ligatures, swabs, etc.
- 5. Detachable douche-can carrier.
- 6. Pulley on foot bar for applying weight-traction.
- 7. Tray under the bed (foot-end) for bed-pan, keeping this clear of the floor.
- 8. Tray under the bed, head-end, for container for dressings, pads, etc.

This bed has been made for us by Messrs. Nanus Brass Works, Bombay, and was designed by Dr. K. A. Nulkar, M.D. (Bom.), B.M.S., and myself. Such beds have been in use here for a year and have proved very satisfactory.

VIBRIO CHOLERÆ FROM MATERIAL OBTAINED BY LIVER PUNCTURE DURING LIFE

By C. L. PASRICHA

MAJOR, I.M.S.

A. J. H. DEMONTE, I.M.D.

and

B. C. CHATTERJEE, M.B., D.P.H., D.T.M.

(From the Bowel Disease Research Department, School of Tropical Medicine, Calcutta)

ALTHOUGH *Vibrio cholerae* has been recovered from many organs at post-mortem examination, we are not aware of any records of the finding of this organism from sources other than the stools, vomit, or urine of cholera patients during life. In the case recorded in this paper vibrios were recovered from material obtained by liver puncture performed during the acute stage of the disease. A brief summary of the clinical history of the patient and the characters of the vibrios isolated are given below:—

The patient, a boy aged 7 years, developed cholera with typical symptoms on 30th April, 1938, and was under the care of one of us (B. C. C.). *V. cholerae* was isolated on the first day of the disease. The usual treatment for cholera was given and the patient progressed satisfactorily till the morning of the third day when he complained of pain in the right side of the abdomen. There was an icteroid tinge in the conjunctivæ and on examination there was found a hard tender mass extending to the level of the umbilicus, continuous with the liver dullness. The icterus increased and towards the evening of the same day the jaundice became generalized and the condition of the patient became unsatisfactory. During the next three days the patient's general condition remained unchanged. On the seventh day he became much worse, the jaundice more intense and the liver dullness extended to below the umbilicus. A fine needle was inserted into the enlarged liver below the costal margin in the anterior axillary line and a few drops of blood withdrawn. This was immediately inoculated into peptone water. The next day the patient was much better, the jaundice and pain less and the liver enlargement decreased. Convalescence was slow but uninterrupted. The patient was well in about 14 days.

Typical O-agglutinable vibrios were isolated from the stools collected on the first, second, seventh and ninth days of the disease. The vibrios isolated from the material obtained from the liver puncture were O-agglutinable smooth *V. cholerae*, indistinguishable in their biochemical, serological and bacteriophage reactions from the vibrios isolated from the stools. Vibrios were not found from samples of blood and urine collected from this patient. The van den Bergh's test, done on the ninth day of the disease

CHOLERA EPIDEMICS IN BURMA AND THE TYPE OF VIBRIO ASSOCIATED WITH THEM

By G. C. MAITRA

LIEUTENANT-COLONEL, I.M.S.

P. N. SEN GUPTA, M.Sc.

and

U. THANT, D.T.M.

(From the Pasteur Institute of Burma)

CHOLERA has been known to exist in Burma for many years. Its seasonal prevalence was also recognized, as the Burmese word for it—*Kala-Wun-Yoga* (*Kala* = Time, *Wun* = Intestine, *Yoga* = Disease)—literally means periodical intestinal disease. Beyond this very little is known about its ætiology, spread, and control among practitioners of indigenous medicine. A vague belief, however, exists that the disease was first introduced by Indian labourers who came to build pagodas (Buddhist temples) at Pagan. On the other hand, there is every probability that epidemics occasionally spread from southern China where cholera was described by the very name it now bears, over two thousand years before the Christian era (Maxwell, 1929).

A systematic record showing the mortality rate for cholera in Burma (Bozman, 1937) is only obtainable since 1872 after the country had passed under British control. Rogers (1928) refers to this record and, correlating the mortality rate with figures of absolute humidity deduced from various meteorological data, arrived at the conclusion that Lower Burma is 'a typically endemic' area. But there is still some doubt in certain quarters about accepting this view, as frequent reference to importation of cholera from neighbouring provinces by immigrants is found in annual reports of provincial health authorities.

This confusion has been largely due to lack of facilities for investigating outbreaks by modern scientific methods. In a busy port like Rangoon where such facilities exist, the result is vitiated to a great extent by frequent admission

of persons from hyperendemic areas in India, some of whom are probably 'carriers', and are capable of starting a fresh outbreak if placed in suitable environments. A striking example of this type of epidemic was first described by Greig (1913) in Puri jail. On this occasion the carrier was a convict who had acquired the disease before imprisonment and recovered from it.

About the middle of July 1936 a small and sharp outbreak of cholera occurred in a big jail within easy reach of Rangoon. This afforded us an excellent opportunity to study the epidemic from beginning to end under controlled conditions. The jail being specially set apart for habitual offenders, the inmates were mostly convicts serving long sentences.

The first case was a prisoner who had been in jail for several months past and as such could not have associated with outsiders or obtained food and drink from outside sources. He succumbed to infection within a few hours of onset, and a portion of his small intestine was sent to the Pasteur Institute laboratory for examination. The congestion and inflammation of the mucosa were so great that the tip of the little finger could scarcely be passed into its lumen. A smear from the submucosa showed a large number of 'comma' vibrios and cultures taken from the same situation gave a pure and profuse growth of a vibrio, serologically confirmed as the true cholera vibrio. This was followed by two more cases, of which one was severe and required saline transfusions. Cholera vibrio was isolated from both the cases.

All prisoners employed in the jail kitchen and contacts of actual cases were examined, and two were detected as carriers of true cholera vibrio. They were isolated until declared free by repeated bacteriological examinations. The whole jail population was given protective inoculation, and adequate steps were taken to disinfect fresh faeces and urine by chlorinated lime. These measures completely controlled the epidemic and no more cases occurred. The outbreak is remarkable in that all reasonable possibilities of importation from outside sources were excluded proving that the disease originated locally and quickly showed a tendency to assume epidemic proportions.

Characters of vibrios isolated from cholera cases in Burma

Since 1935, cultures of vibrio recovered from stools of acute cases have been collected for study as to their detailed characters, particularly to help in selecting suitable strains for preparing vaccine used in preventive inoculation in Burma. Though the majority of strains were isolated from patients admitted into the Contagious Diseases Hospital, Rangoon, a few were also recovered from cases which occurred in the delta area, e.g., Pyapon and Twante. In recent years a vast amount of work has been done by Linton and others (1932-1934) on the chemical

(Continued from previous page)

when the jaundice was intense, gave an indirect positive result and a delayed direct result. This suggested that the jaundice was of the hæmolytic type.

Summary

1. A case of cholera, in which on the third day of the disease there occurred an acute enlargement of the liver with the development of jaundice, is recorded.

2. From the material obtained by puncture of the enlarged liver *Vibrio cholerae* was isolated. This strain was indistinguishable in its biochemical, serological and bacteriophagic reactions from the vibrios found in the patient's stools.

composition of vibrios, especially with regard to their protein and carbohydrate contents. Owing to obvious limitations in this laboratory we could not go into these details. We concentrated mostly on the biochemical reactions described by Heiberg (1934) and serological reactions with sera raised against stable 'O' antigens of 'Inaba' and 'Ogawa' type cultures. Altogether 56 strains were studied and most of them, when freshly isolated, agglutinated well with 'HO' serum prepared in our laboratory against type cholera vibrios received from the National Collection of Type Cultures. Four were inagglutinable or reacted partially (20 to 25 per cent of the full titre) with the 'HO' serum. All 56 were further titrated with pure 'O' sera. The results of agglutination tests, nitroso-indol reaction and hæmolsin production for sheep cells have been summarized in the following table :—

before the results were noted, and they may be summarized as follows :—

TABLE II

	Saccharose	Mannose	Arabinose	Heiberg's group
Agglutinable 52.	+	+	—	I
Inagglutinable 4.	+	—	—	II

+ Acid production. — No acid production.

The type of reaction obtained in sugar media is clear-cut and brings out that all sero-positive strains come under Heiberg's group I. The association of this serological type with a spring disease culminating in epidemics was observed and recorded by Maitra (1925) and Tomb and

TABLE I

* Supply received by courtesy of the Director, Central Research Institute, Kasauli, India.

(1) Rough.

It will be seen that all 'HO'-agglutinable strains, except one, reacted with the Inaba 'O' serum. The non-reactor on further test was found to have become rough. Of the Inaba-serum reactors, only one strain gave a positive reaction with the Ogawa 'O' serum. Owing to the rarity of this type in India and Burma a brief history of the case in which the strain was isolated is given below :—

One Mr. W., an employee of the British India Steam Navigation Company, was on his way to Rangoon. After a long voyage from Mauritius his boat touched at Colombo for a short time, but he did not go ashore. From Colombo he travelled to Calcutta by boat in a week. In Calcutta, though he remained on board for two days, he had occasion to land for taking meals in restaurants. He then transferred himself to another boat plying between Calcutta and Rangoon. On the second day of the voyage from Calcutta the usual symptoms of cholera developed and on arrival at Rangoon he had to be sent to the Contagious Diseases Hospital for treatment. From his stool collected in the acute stage the 'Ogawa' strain was isolated.

Biochemical reactions studied were based on observations recorded by Heiberg. The inoculated sugar tubes had been incubated for a day

Maitra (1927) in their observations in the Bihar and Bengal coal-fields.

Summary

1. An autochthonous epidemic of cholera confirmed by bacteriological study has been described.

2. The prevailing type of cholera vibrio isolated from acute cases in Burma has been recorded.

3. A case of cholera due to the 'Ogawa' type of vibrio has been detected in the course of routine examinations.

OBSERVATIONS ON THE MOTTLED CONDITION OF HUMAN TEETH ENDEMIC IN A CERTAIN LOCALITY OF NAGERCOIL IN TRAVANCORE, S. INDIA

By S. C. PILLAI, B.A.

(Department of Biochemistry, Indian Institute of
Science, Bangalore)

It has been observed that a section of the people residing at one end of the town of Nagercoil in South Travancore is afflicted with

members of the community, would appear to have been subjected to a sort of corrosion followed by pigmentation (figure 1).

In addition to the pigmented condition and the consequent disfigured appearance, the mottled teeth have also been found to be defective in structure and strength.

It has also been found that almost the entire population in that locality (consisting of about a hundred families), irrespective of sex, has this dental defect, although its degree of severity varies with age and other conditions.

A comparative study of the conditions in that place and those in the adjoining areas would show that the sectional incidence of mottled enamel can be correlated with the occurrence of fluorides in the drinking water supplies. Thus, the analysis of the drinking water supply of the afflicted persons shows the presence of 0.4 to 0.5 parts (per 100,000) of fluorine, whereas the water supplies for the other sections of people contain practically no fluorides (table I).

It may be observed from the results that the presence of fluorine is the distinctive character of the water used by those having mottled

A RAT-FLEA SURVEY OF MATTANCHERY (COCHIN) (1937)

By P. MOHAMED ALI, M.B., B.S.

Medical Officer for Epidemics (Cochin State) and
Special Plague Officer, Mattanchery

FROM the peculiar history of plague in Mattanchery, a study of the bionomics of its rat-flea population should be as interesting from a scientific as it should be useful from a practical point of view. As far as records are available, Mattanchery had, besides the present one, three outbreaks of plague during the last 50 years; the first one was in 1919 and accounted for 19 attacks and 15 deaths; the second one was in 1928 and was responsible for 14 attacks and 14 deaths during a period of seven months; and the third outbreak which lasted for four months resulted in 6 attacks and 4 deaths. The relation between the epidemic and the epizootic in all these outbreaks is rather interesting. The positive rat-falls were quite out of proportion to the number of human attacks. There used to be heavy rat-falls for months together without any human case. This unusual occurrence

(Continued from previous page)

teeth. In other respects, the composition of the water is similar to those from adjoining areas.

The harmful effects of fluorides on the general health and development, particularly on the bone formation and tooth structure, have been increasingly recognized in recent years, but the exact nature of the toxic action of fluorides occurring in drinking water and the related mechanism of the mottling of human teeth are still obscure.

Further work in this direction is in progress and will form the subject of further communications.

I wish to thank Prof. V. Subrahmanyam for his kind interest in the work. My thanks are also due to Mr. N. K. B. Kurup, Nagercoil, for having sent me samples of water from time to time.

[Note.—Attention was drawn to this very important observation regarding the fluorine content of certain water supplies in Southern India by an article in the July issue of this journal last year (Shortt, Pandit and Raghavachari, 1937). In the same number we reprinted a note from the *Lancet* referring to work in Europe on fluorine poisoning. Since this date a fuller account of the symptomatology and pathology of this condition has appeared in the *Indian Journal of Medical Research*. Further information on this important subject is welcomed.

is all the more baffling in view of the facts that Mattanchery is one of the most thickly populated towns in the world and that the general sanitation of the place leaves much to be desired. In contradistinction to this state of affairs in Mattanchery, the conditions are reversed in the case of Kunnamkulam, a small town in the interior of Cochin State, which had a visitation of plague early in 1935. Here the number of human attacks was more and the positive rat-falls few. A rat-flea survey of Kunnamkulam will, therefore, provide interesting data which will serve illuminating comparison with those obtained in the present survey of Mattanchery town.

Previous survey.—A rat-flea survey of Mattanchery and British Cochin in January 1930 formed part of an extensive survey of the Madras Presidency conducted under the auspices of the Public Health Department of the Government of Madras. The following is the summary of the report:—

(1) The rat-density was low in all areas except Mattanchery bazaar.

(2) The flea-indices were very low in all areas.

(3) The epidemic of plague in the past was probably caused by *X. braziliensis* or *X. astia* or by both. (It is mentioned in the report that *X. cheopis* was totally absent in Mattanchery.)

(4) The rat-epizootic prevalent needs further investigation. (The officer who did the survey was inclined to doubt whether the cause of the epizootic was really plague.)

The present survey.—Since the previous report much water has flown under the bridge. Cochin port has since been declared a major port and its maritime trade has assumed enormous proportions. It has become the only safe and sheltered harbour on the west coast south of Bombay. Apart from being the nerve-centre of commerce in the State, it promises to be the emporium of trade for the whole of South India, thereby easily entitling it to be christened the "Queen of the Arabian Sea". But, unhappily, the growing prosperity of the town is not an unmixed blessing. On account of the maritime connections that Cochin port has with important ports in the world, the chances of importing infection to Mattanchery are great and will continue to be so as the volume of trade increases; and the conditions in crowded Mattanchery, where there are a large number of rat-infested, grain godowns, which do not easily admit of rendering rat-proof, make the town dangerous alike to health and trade.

Thus, further information regarding this all-important question of plague in Mattanchery is required so as to organize and systematize more effective measures to prevent an outbreak of this serious disease. Hence the present survey.

Physical features of the town.—Situated between the Arabian Sea on the west and the back waters in the east, and contiguous with British Cochin in the north, Mattanchery forms an important boundary to the Cochin harbour. Into an area of 3 square miles is crowded

a population of wellnigh 50,000. There is hardly any demarkation or differentiation between residential quarters, shops and godowns in the bazaar area. The climate is hot and humid, as the place is low and swampy. The mean annual temperature is a little over 81°F., variation ranging from 75°F. in December to 86°F. in May. The average annual rainfall in 1937 was 123½ inches as against 116¼ inches in 1936; the major portion of the rainfall is generally during the south-west monsoon (June to September). The following are the meteorological conditions as observed during the survey:—

Mean maximum temperature 85.23°F.

„ minimum temperature 76.38°F.

„ dry bulb thermometer at 9 a.m. 80°F.

„ wet bulb thermometer at 9 a.m. 77°F.

„ relative humidity 86.24 per cent.

„ saturation deficiency 0.1425 inch.

Chief imports and exports.—Cochin imports rice from Akyab, Bankok, Bassein, Bombay, Calcutta, Coconada, Moulmein and Rangoon, and paddy from Akyab, Bankok and Saigon. From Bombay and Karachi are imported large quantities of other grains and pulses. Of late there has been noticed a regular decline in the imports of rice and paddy, a welcome feature from the point of view of plague. The chief exports are copra, coco-nut oil, rubber, coir and cashew-nut kernels.

The survey.—The rat-flea survey commenced on the 18th November and ended on the 18th December, 1937. Twenty-four modified elongated 'wonder' traps were set daily in representative localities in all the 19 wards in the municipal area. Traps were conveyed to the laboratory in canvas bags made to fit each trap lest the fleas should escape during transit. The rats and fleas were killed by cyano-gassing in

a small wooden chamber. Traps containing more than one species of rat were discarded to avoid variation of results in calculating specific flea-indices. The rat-density, as generally calculated, is, in my opinion, scientifically incorrect besides being of doubtful significance. Hence no attempt is made to give such figures. All the rats were autopsied, and none of the smears taken from them show *Bacillus pestis*. As the survey extended only for a month seasonal variation in rats and fleas could not be given. The grain-godowns are mostly situated in wards I and II and the remaining wards consist of residential quarters. Hence figures are not given for individual wards, and the whole area has been arbitrarily divided into godown area and residential quarters.

Rats.—Table I gives the different species of rats trapped. *Rattus rattus* forms the majority of them and they are predominantly from the residential area. As many *Rattus norvegicus* were obtained from the residential quarters as from the godowns. Bandicoots and musk rats mostly favour residential quarters. No *Gunomys*, *Gerbilles* or *Mus musculus* were obtained, perhaps on account of the smallness of the total number of rodents trapped for the survey.

Fleas.—Table II gives the varieties of fleas obtained and their relative numbers. The most noteworthy feature here is the presence of *Xenopsylla cheopis* which were reported to be absent in Mattanchery during the previous survey. They seem to be present in both the residential and godown areas, though it is noteworthy that there is a preponderance in the latter. However, their comparative scarcity is of some epidemiological importance as far as plague in Mattanchery is concerned. *Xenopsylla braziliensis* are also found in residential

TABLE I

Species	NUMBER IN DIFFERENT AREAS		PERCENTAGE IN DIFFERENT AREAS		Percentage of all rats
	Residential area	Godown area	Residential area	Godown area	
<i>R. rattus</i> ..	198	69	74.2	25.8	91.7
<i>R. norvegicus</i> ..	7	7	50	50	4.8
Bandicoots ..	6	1	85.7	14.3	2.4
Musk rat ..	3	0	100	0	1.1

TABLE II

Species	NUMBER IN DIFFERENT AREAS		PERCENTAGE IN DIFFERENT AREAS		Percentage of all fleas
	Residential	Godown	Residential	Godown	
<i>X. astia</i> ..	544	136	71.7	28.3	68
<i>X. cheopis</i> ..	21	25	45.7	54.3	6.5
<i>X. braziliensis</i> ..	87	92	48.2	51.8	25.5

as well as godown quarters. This is also against the findings in the previous survey in which it is said that they are conspicuous by their presence in Mattanchery bazaar alone where the grain-godowns are situated. *Xenopsylla astia* abound in residential quarters. They are by far the largest single species that is present in Mattanchery.

Flea-indices.—Table III gives the various flea-indices. The total flea-index is low. As would be expected from table II, *astia* index is the highest and *cheopis* index the lowest. The *astia* index for *Rattus norvegicus* is slightly higher than that for *Rattus rattus*. But it is worth noting that the *cheopis* index is the lowest for the *Rattus norvegicus* while the *braziliensis* index for the same rat is comparatively very high. The total flea-index and the specific flea-indices for the godown area are higher than the corresponding figures for the residential areas. The high *cheopis* index in the godown area is significant.

present outbreak have proved beyond doubt that there is plague among rats in Mattanchery.

Two very significant facts were noticed by me in the present outbreak: one is that 72 per cent. of the positive rats obtained were of the *norvegicus* species; and the other is that *X. cheopis* were found in comparatively large numbers on *R. rattus* trapped from two houses where human attacks had occurred. To me these two facts appear to have important bearings on the peculiar relationship observed in Mattanchery between epizootics and epidemics.

It is admitted on all hands that *X. cheopis* is a far more efficient carrier of plague than the other two closely allied species. It attacks man very readily; *X. astia* does so with reluctance especially above 80°F., while *X. braziliensis* hardly bites him at all (Hirst and Goyle). Chitre and Tailor have, however, found that *X. astia* can transmit infection in guinea-pigs, and that it could be got to bite man at temperatures from 76° to 84°F. Hirst has found in Colombo

Plague in Mattanchery.—As I have mentioned in the opening paragraph of this report, the relation between the epizootic and the epidemic that has been noticed in all the outbreaks in Mattanchery is anomalous. There used to be heavy rat-falls for long periods with few or no human attacks. This phenomenon is not peculiar to Mattanchery alone. Workers in this field have met with similar conditions elsewhere in India. Many hypotheses have been advanced to explain this seeming incongruity. The absence of intimate association between human beings and the particular species of rats which are found to be the greatest sufferers from plague in an epidemic is mentioned by some as a cause for paucity of human cases. G. D. Chitre does not fully concur with this view. The relative number of the different species of fleas in a particular place is also spoken of as an influential factor. Baffled with the conditions in Mattanchery, the officer who did the previous survey even went to the length of doubting the genuineness of plague as a cause of the rat-epizootic in the town. As to this there is no doubt, as culturing and animal experiments carried out in the course of the

that *X. cheopis* formed less than 1 per cent. in non-plague areas while in plague areas this species formed 17 to 46 per cent. of the fleas. My observation in the present epidemic lends colour to this view. Hirst has also found that it was impossible or very difficult to transmit plague from rat to rat through the bites of *X. astia*.

So, the comparative scarcity of *X. cheopis* in Mattanchery, as the present survey shows, may be one of the main causes for the paucity of human attacks. The fact that *R. norvegicus*, which are found to be the most vulnerable victims to plague at present in Mattanchery, do not so freely associate with man as *R. rattus*, and that the *cheopis* index is the lowest for them (*R. norvegicus*) also points to the same conclusion. The high *braziliensis* index for *R. norvegicus* must, if we are to give credence to the views of Hirst, further support this view.

It has been observed by some workers on plague that saturation deficiency and mean temperature help to determine the incidence of human plague in a locality. According to St. John Brooks and Rogers, a mean temperature over 80°F. when accompanied by a saturation

deficiency of over 0.03 of an inch has a tendency to check the disease. Dold in Shanghai and Heggs in Baghdad arrived at the same conclusion. Mattanchery satisfies both these conditions. Thus the saturation deficiency of much over 0.03 of an inch coupled with the almost uniform mean temperature of over 80°F. might also be one of the causes why plague has not got a firm footing in Mattanchery.*

Summary.

(1) Out of the 291 rats 267 were *R. rattus*, 14 *R. norvegicus*, 7 bandicoots and 3 musk rats.

(2) Of the 705 fleas, 480 were *X. astia*, 46 *X. cheopis* and 179 *X. braziliensis*.

(3) Two facts which were noticed during the present outbreak of plague and which are believed to have some importance in the epidemiology of plague in Mattanchery are mentioned.

4. The comparative scarcity of *X. cheopis* is suggested to be an important cause for the absence of many human attacks of plague despite heavy positive rat-falls.

5. The mean temperature and the saturation deficiency are also suggested as contributory factors in checking the disease.

6. For further elucidation of plague in Cochin, a rat-flea survey of other important towns in the State, especially Kunnankulam where there was an outbreak of plague in 1935, is suggested.

7. Since the chances of importation of all varieties of fleas and infection to Mattanchery are becoming greater and greater proportionately with the growing importance of the town, permanent plague-preventive measures, such as making the godowns rat-proof, improved sanitation and sustained rat-destruction, are indicated.

Before concluding this report I should mention, with gratitude, that the services of Dr. N. S. Sankaranarayanan, M.B., B.S. (Madras), D.P.H. (Calcutta), Health Officer, Mattanchery Municipality, in conducting the survey, were of great help to me.

[*Note.—St. John Brooks pointed out that a high temperature is detrimental to plague transmission, but that in a dry climate, one in which the saturation deficiency is above 0.300 of an inch, transmission may be checked, even when the mean temperature is below 80°F. On the other hand, when the atmosphere is humid, and the saturation deficiency below 0.300 of an inch, plague transmission occurs, even if the temperature is a little above 80°F.

In Mattanchery the temperature is usually above 80°F.; this would tend to check the spread of plague. But the climate is also very humid, and the saturation deficiency is usually below 0.300; this, according to Brooks, would make transmission possible, even with the temperature above 80°F. A saturation deficiency of 0.030 at 80°F. means almost complete saturation, about 97 per cent relative humidity, and naturally the saturation deficiency at Mattanchery is usually more

EXPERIMENTS ON THE STABILITY OF SEMINAL STAINS FROM A MEDICO-LEGAL STANDPOINT

By S. N. CHAKRAVARTI, M.Sc., D.Phil. (Oxon.),
F.C.S., F.N.I.

Chemical Examiner to Government, United Provinces
and Central Provinces, Agra

and

S. N. ROY

DURING the course of examination of thousands of articles for presence of spermatozoa, it has been found that a much larger proportion of negative results is obtained in cases of mixed blood and seminal stains (and in very old stains) than in cases of seminal stains alone. To throw light on the underlying causes of this, the following experiments were instituted. A piece of semen-stained cloth was cut into four pieces. Two of these pieces were covered with blood. One of these pieces and one piece containing semen only were kept in two separate dishes in the dry state. The remaining two pieces, one containing semen alone and the other both semen and blood, were moistened with water and kept exposed to the atmosphere in open dishes. These pieces were examined for spermatozoa and subjected to other tests every 7 or 10 days at the beginning and at larger intervals after a month. The result of these experiments is outlined in the following table. At the beginning, all the four pieces of cloth contained a larger number of complete spermatozoa and gave the Florence test for semen.

It will be seen from the table that complete spermatozoa could be detected on the dry pieces even after 100 days, although the Florence test was not given by the piece containing blood and semen after 44 days. In the case of the wet stains, the tails begin to disappear after 10 days and are unrecognizable after 75 days, while clear heads can be detected even after 100 days. *The Florence test was negative even after 48 hours.*

These results are very important as they show that too much importance should not be attached to the Florence test (even as a negative test), particularly in case of old stains [cf., Bagchi (1937), Chakravarti (1937), and Thomas (1937)]. These experiments also show that search for complete spermatozoa is not likely to give any results in case of old, wet stains and in these cases it would be justifiable to declare a positive result if a number of good heads were found.

(Continued from previous column)

than this, but not, we imagine, more than 0.300 of an inch which corresponds to a relative humidity of about 71 per cent at 80°F. We do not know from where the writer got this figure 0.030 of an inch; it is not apparently a clerical error as we have written to him on the subject and he has repeated this figure.—Editor, I. M. G.]

TABLE

Time of examination	Semen stains containing blood kept in a dry state	Semen stains containing blood kept in a wet state	Semen stains kept in a wet state	Semen stains kept in a dry state
10 days after.		The stains were found to be of green colour and decomposition had set in. Fungus growth was found on the stains. Spermatozoa with short tails were detected. Florence test was negative. Spectroscopic test for blood was positive.	Fungus growth on the stains were found and a decomposing odour was also noticed. Spermatozoa with short tails were detected. Florence test was negative.	
17 days after.	No change of colour of the stain and no decomposing odour could be found. Spermatozoa with long tails were detected. Florence test was positive. Spectroscopic test for blood was positive.	The decomposing odour was still present. The colour of the stain was green. Short-tailed spermatozoa were detected. Florence test was negative. Spectroscopic test for blood was positive.	A decomposing odour was again noticed. Spermatozoa with short tails were detected. Florence test was negative.	
24 days after.	Complete spermatozoa were detected. Florence semen test and spectroscopic test for blood were positive.	Mainly heads of spermatozoa were detected. Few had short tails. Florence test was negative. Spectroscopic test for blood was positive.	A few spermatozoa with short tails were detected but mostly heads only were found. Florence test was negative.	
After 31 days.	Complete spermatozoa were detected. Florence semen test and spectroscopic test for blood were positive.	Very few spermatozoa with very short tails were detected. Florence test was negative. Spectroscopic test for blood was positive.	Only sperm heads could be seen. The tails had all disappeared. Florence test was negative.	
44 days after.	Several complete spermatozoa were detected. Florence test for semen was negative. Spectroscopic test for blood was positive.	Only heads of spermatozoa could be detected. A few had very short stump-like tails. Florence test was negative. Spectroscopic test for blood was positive.	Only sperm heads could be detected. Florence test was negative.	Large numbers of complete spermatozoa were detected. Florence test was positive.
75 days after.	Complete spermatozoa were detected. Florence test was negative. Spectroscopic test for blood was positive.	Only heads of spermatozoa could be detected. Tails were found to be absent in all. Florence test was negative. Spectroscopic test for blood was positive.	Only heads of spermatozoa could be detected. No tails could be found. Florence test was negative.	
100 days after.	Complete spermatozoa were detected. Florence semen test was negative. Spectroscopic test for blood was positive.	Only heads of spermatozoa could be detected. No tails were found in any. Florence test was negative. Spectroscopic test for blood was positive.	Only heads of spermatozoa could be detected. No tails could be seen. Florence test was negative.	Large numbers of complete spermatozoa were detected. Florence test was positive.

These experiments afford a scientific basis for the rule that articles of clothing, etc., having suspected blood or seminal stains should be thoroughly dried before being sent for examination—a rule which is often unthinkingly disregarded by the authorities who forward the articles.

For detecting spermatozoa, a method developed in this laboratory involving the use of two stains (erythrosine and malachite green) and

sulphuric acid, which preferentially destroys any foreign matter present, was used throughout (Ganguly, 1936). This method has been found to be superior to all other known methods of detecting spermatozoa.

Summary.—During the course of examination of thousands of articles for spermatozoa, it has been found that an unusually large proportion of negative results is obtained in cases of mixed blood and seminal stains and in very old stain.

cases. To throw light on the underlying causes of this, a series of experiments were instituted which show that while Florence test is given by dry seminal stains even after 100 days, in the case of mixed stains the Florence test is not given after 44 days, although complete spermatozoa can be detected. In the case of wet stains, the Florence test is not given even after 24 hours, and tails begin to disappear after 10 days and are undetectable after 75 days. These results are very important and show that too much importance should not be attached to Florence test even as a negative test. These experiments further show that it would be justifi-

able to declare a positive result if a number of good heads are found.

[Note.—Whether a positive result should be returned on finding heads alone is a question; many medical jurists will not agree with the writer on this point.—*EDITOR, I. M. G.*]

A Mirror of Hospital Practice

A CASE OF HYPERNEPHROMA OF THE KIDNEY WITH SECONDARIES IN THE OS CALCIS AND THE BRAIN

By C. D. TORPY, M.M.F. (B.), I.M.D.

House Surgeon, Presidency General Hospital, Calcutta

HYPERNEPHROMATA constitute, it is stated, about 60 per cent of all renal tumours. One can hardly therefore offer rarity as the reason

one child, who, presenting many features of kidney disease two months after birth, succumbed seven months later to a cerebral tumour which, unfortunately, was not proven by a post-mortem examination.

Previous history.—In April 1936, he developed a small 'boil' over his left groin, which with the usual household remedies soon subsided. A few days later, however, he noticed pain and tenderness in his left heel, which interfered with

Fig. 1.—Skiagram of left os calcis shows an irregular area of bone absorption with some feathery reaction at the upper surface of the bone posterior to the astragalo-calcaneal joint.

for the publication of this case. There are, however, more important reasons, as the case presents several unusual features.

The patient, H. V. D., male, tea-planter, born and lived almost continuously in India, married, was admitted into the hospital for the investigation of a 'painful left heel' and bouts of painless hæmaturia, which he stated followed the treatment given him for the painful heel. He had

walking. He attributed this to the inflammatory condition in his groin, from which he had just recovered. With the passage of time, however, there was no improvement in the condition; in fact, it became more acute and painful, finally restricting his walking, or even applying any pressure on the heel. There was no obvious swelling or inflammation at the time. He then consulted his doctor who thought that gout or

a strained ligament might explain the case and prescribed accordingly. Finding that the patient did not improve, he sent him down to Calcutta for an x-ray examination.

This was carried out, and a skiagram of the left heel revealed an irregular area of bone absorption with some feathery reaction at the upper surface of the os calcis, posterior to the astragalo-calcaneal joint. It was suggested by the radiologist that the appearances may be due to a specific osteitis but that, on the other hand, an osteogenic neoplasm could not be excluded. The Wassermann reaction was negative, but in the course of an investigation for the presence of a toxic factor, a streptococcus was isolated in pure culture from the patient's throat, from which an autogenous vaccine was prepared. The left heel was put up in a plaster-of-paris cast and the patient returned to the tea-garden to have his course of autogenous vaccine. It was now thought that the cause of the trouble had been

Fig. 2.—Right kidney showing tumour.

found in the streptococcus from the patient's throat. Three injections were given uneventfully, but a couple of hours after the fourth injection, the patient developed a sudden and severe painless hæmaturia. Being a chronic malarial subject he thought an attack of black-water fever had added to his troubles, but with the arrival of his doctor, his fears were allayed. As soon as the hæmaturia was over, and patient was fit to travel, he returned to Calcutta to have this new feature of the case investigated radiologically and biochemically.

With perabrodil, an intravenous descending pyelography was carried out. The control picture showed the right kidney shadow to be definitely larger than the left. Excretion of the dye, as seen in the pyelograms, took place on the left side, the outlines of the pelvis and calyces appearing normal, but on the right side only the very faintest suggestion of traces of excretion could be seen. The radiologist suggested that the appearances might be due to an inflammatory condition of the kidney, and that

a retrograde pyelography and further investigation of kidney function should be undertaken. At this juncture, the patient was admitted to hospital, and came under our care.

The patient was an elderly man, very sparely built, of poor physique, bright eyed, thick eyebrows, hectic flush of both cheeks, presenting a typical tuberculous diathesis. No active signs of tuberculosis could, however, be elicited in the lungs; this was confirmed by radiological findings which showed only a small round patch, the size of a pea, an old fibrosed focus of infiltration.

Abdomen, soft and lax; spleen and liver, not palpated; colon, not thickened or tender. There was definite tenderness over the right post-renal area and the kidney appeared to be enlarged. No burning or scalding on passing urine, but patient gave a history of attacks of painless hæmaturia, which he stated cleared up rapidly and uneventfully. Blood urea, 46.6 mg. per 100 c.cm.; non-protein nitrogen, 40.15 mg. per 100 c.cm. Urea concentration test showed very poor excretion, concentration varying from 0.5 to 1.4 per cent. The hæmogram revealed nothing of note, except a moderately severe lymphocytosis (45 per cent).

Fig. 3.—Brain showing secondary tumour.

Very soon after admission to hospital, patient had another bout of painless hæmaturia which cleared up rapidly without any treatment.

A cystoscopy and retrograde pyelography were later carried out. The bladder appeared perfectly normal. The right ureteric orifice was seen to be injected, swollen, and oedematous; the left was fairly normal.

Chromo-cystoscopy showed that the right kidney excreted in 9 minutes, and the left in 6½ minutes.

The pyelographic appearances confirmed the provisional diagnosis of a hypernephroma in the right kidney with a metastasis in the left os calcis.

A suspicion that the condition might after all be tuberculous in origin, for which clinical evidence was not wanting, and not malignant was settled by cutting down on the tumour in the os calcis and submitting sections for the pathologist's opinion.

On cutting down, an irregular area of bone absorption filled with a highly vascular, bluish tumour, soft and cyst-like, was found at the upper surface of the os calcis, posterior to the astragalo-calcaneal ligament. Sections of the bone and tumour were submitted for examination, and reported on by the pathologist as being typical of a hypernephroma.

The night after the operation, the patient suddenly became worse, complained of severe headache, and became restless, had a large vomit at midnight, followed six hours later by another copious one; pulse feeble and irregular. The speech became affected, blurred and inarticulate. It was also noted that there was some paresis of the limbs on the right side. In a couple of days' time the condition appeared to improve, the speech becoming more distinct, and the weakness on the right side less apparent. When he started to speak, he spoke fairly clearly for a few seconds only, but soon became difficult to understand, though one left him feeling that he knew what he wanted to say, but could not put it into spoken words. As the co-operation of the patient could not be obtained, no tests for hemianopia were done.

Soon the patient presented the clinical picture of a cerebral tumour; marked headache, and symptoms referable to the sensorium, and psychical centres. With

dormant, showing no clinical signs of its presence.

2. The administration of an autogenous vaccine appeared to have provoked a bout of hæmaturia, the cause of which is not clear.

3. The radiological findings of the left heel and the kidneys at first suggested an inflammatory cause, and the diagnosis was for a little time completely missed, though in retrospect, when the hæmaturia set in, a diagnosis of hypernephromata could have been the only one likely.

4. In spite of the marked infiltration present in the right kidney, as seen at the post mortem, the function appeared to be quite good, by the indigo-carmin test, which suggests this test is not altogether reliable.

Fig. 4.—Photomicrograph of tumour from left heel.

sudden temporary increase in pressure, attacks of more marked loss of consciousness not infrequently took place, and he became gradually exhausted taking a critical turn on the night of the 6th October, 1936, ushered in by a copious vomitus, slowing of the pulse rate, and loss of consciousness, and on the next day the patient died after an illness spread over a period of six months.

A post-mortem examination was carried out. A large hypernephroma of the right kidney was present, the left kidney appeared normal. Lungs, normal, no secondaries present. Brain—small secondary tumour in left occipital lobe, another small one in frontal lobe.

Points of interest

1. A painful left heel, the site of the secondary tumour was the first indication of any disease being present, though the primary lesion was in the right kidney, until then it lay

5. Secondaries in the brain are not usual in hypernephromata, whereas their absence in the lungs is rare.

6. The painless hæmaturia rather added to the difficulty in arriving at a correct diagnosis, this being a feature of both tuberculous disease of the kidneys and of hypernephroma.

My thanks are due to Lieut.-Colonel H. E. Murray, I.M.S., Surgeon Superintendent, Presidency General Hospital, Calcutta, for his permission to publish this case, and also to Professor M. N. De of the Calcutta Medical College for the pathological findings, the microphotograph, and the other photographs, and to Lieut.-Colonel J. A. Shorten, I.M.S. (retd.), for the skiagrams.

JULY

WORLD DISTRIBUTION OF DISEASE : THE CHANGING PICTURE

THE division of diseases into two arbitrary groups, those of tropical and those of temperate climates, is a convenient one and to a certain extent a sound one, especially regarding tropical diseases, many of which are strictly limited to the tropics or even to certain parts of the tropics, by the distribution of the insect or other carriers necessary for their propagation. Possibly as an offset to this allocation of certain diseases definitely to the tropics there has grown up in the minds of medical men in general, the idea that many of the diseases common in temperate climates do not exist among natives of tropical countries.

Twenty years ago it was confidently stated, particularly with regard to tropical Africa, that African natives never suffered from cancer. Such statements were made by doctors who had often spent many years in the countries concerned, so they carried the weight of authority with the professions as a whole. This is easily understood because in those days properly equipped research and pathological laboratories, where carefully conducted investigations could be carried on, were practically non-existent in the tropics, and further, at that time it was not customary to apply statistical methods to the examination of data on the incidence of disease, so it was common for inexact or insufficiently numerous observations to be accepted as statements of fact. The result was that many erroneous ideas were, and to some extent still are, held on the prevalence of this and other common diseases. It is now generally accepted that natives of all tropical countries, living a simple life, are just as liable to malignant disease as are the inhabitants of highly civilized countries, and it is not as was once widely taught, a disease to which civilized man is particularly liable on account of his highly complicated and more or less artificial life under the conditions of modern civilization.

Acute rheumatism is a disease the existence of which in India was for a long time denied, or if the fact or its presence were admitted it was considered to be extremely rare. A considerable amount of evidence has now been accumulated, notably in a series of articles recently published in this journal, to show that it is probably a fairly common source of heart disease in this country. It is true that most of the data have been collected in the northern part of India which in the strictest sense is not tropical, as the district where the work was done is about four degrees north of

the Tropic of Cancer. An artificial line such as this is of no importance in the present instance, as the United Provinces, where most of these observations were made, is a typical, comparatively dry, inland tropical climate of the plains.

Still another important group of diseases, the gastric and duodenal ulcers, were once considered almost non-existent in India. The reason given for this supposed state of affairs being that the simple diet of the majority of the inhabitants and the different amount of hydrochloric acid in the gastric juice of Indians from that of Europeans, which was caused by the differences in the dietetic habits, reduced the liability to ulceration in this part of the gastro-intestinal tract. These assumptions have now been shown to be incorrect for there is found to be no essential difference between the gastric juice of Indians and Europeans no matter what the principal constituents of their diets may be, and the incidence of peptic ulceration is found to be relatively high throughout India. At first its presence was only recognized in the north and north-west and it was said to be absent in the south and truly tropical parts of the country, but now it is becoming clear that it is a common disease all over the country, and evidence is rapidly accumulating that peptic ulceration, and its not uncommon sequel malignant disease of the stomach, are probably more common in South India than they are elsewhere.

Certain skin diseases that are common in colder countries are said to be non-existent in the tropics. One of the best examples is psoriasis, and in books on skin diseases this supposed effect of climate on its distribution is regularly referred to. In a recent lecture on psoriasis delivered in England by an experienced dermatologist, it was stated that one of the most satisfactory methods of bringing about improvement in psoriasis was to send the patient to a warm climate. This may be true for some cases acquired in England, but it cannot apply to those which arise in India, for a Calcutta dermatologist would be hard put to it to find a warmer climate than Calcutta is for the greater part of the year, to which he might send the many cases of psoriasis that arise and flourish in its warmth. It is frequently seen in Calcutta that some cases improve in the cold weather and show an exacerbation in the hot weather, while others, conforming with the above statement, are worse in the cold weather and better in the heat, therefore climate probably has little to do with the incidence of psoriasis. This is not the point under discussion, however; the fact it is wished to emphasize is that psoriasis is common in India, and that because psoriasis arising in cold climates may be benefited by going to the tropics, this is not evidence that the disease cannot arise there.

Leprosy is a disease which was widespread in colder climates a few generations ago but it has practically disappeared from there and is now almost wholly confined to the tropics.

Evidence is accumulating that tuberculosis appears to be following the same course and is dying out in temperate climates while becoming more frequent in the tropics. The altered and altering distribution of these two diseases, however, is mainly because social, hygienic and dietetic improvements have been more rapid in the temperate zones than in the tropics.

The above are a few of the most striking examples of what adequate observation and careful work have done in recent years in correcting our views on the distribution of some diseases, and it indicates that the inhabitants of the tropics are not exempt from the major

diseases of colder climates. The reverse is not true, however, because there are a number of serious and widespread diseases which can be rightly termed tropical and tropical only, and which must remain confined to this part of the world because their transmission is not possible in cold climates, as the necessary vectors cannot live there. In other words, climate *per se* has not nearly as much influence on disease incidence as has been supposed, and as further careful work is done, especially in tropical countries, we may anticipate a smoothing rather than an accentuation of the differences between disease distribution in temperate and tropical climates.

PRESENT POSITION OF ANTI-MALARIAL DRUG THERAPY IN INDIA

By R. N. CHOPRA, C.I.E., M.D., Sc.D. (Cantab.),
F.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to the King

ANTI-MALARIAL drugs may be divided into two main groups :—

- (I) The cinchona derivatives.
- (II) Other anti-malarial remedies; this group includes most of the synthetic drugs.

(I) CINCHONA DERIVATIVES

(A) *Cinchona* alkaloids

It is well known that as many as 20 alkaloids, and probably more, are present in the cinchona bark, all of which are chemically closely allied to each other. These alkaloids have been divided into (i) crystallizable alkaloids, and (ii) amorphous alkaloids. The former group only, have anti-malarial properties; the amorphous alkaloids have been shown to be inactive in this respect. Of the crystallizable alkaloids present, four occur in large quantities; these are quinine, quinidine, cinchonine and cinchonidine. Till recent years these alkaloids were the only drugs available which had specific action on the malarial parasites. If given in suitable doses and under proper conditions their action in controlling malarial paroxysms is certain. Of the four alkaloids, quinine still holds the foremost position in the treatment of malaria, though the anti-malarial value of the other three alkaloids has been fully established. From the data now available there is no room for doubt that quinidine, cinchonine and cinchonidine, in similar doses to quinine, are equally, or very nearly as effective in the treatment of malaria. In considering the relative therapeutic value of different alkaloids, it is of importance to take into account their effect in causing harm or inconvenience to the patient. It may be said in favour of quinine, that it can as a rule be given in sufficient doses and for sufficiently long periods without danger to the patient. Cinchonine is more nauseating than quinine and is liable

to produce blurring of vision. Quinidine is also more nauseating and has a powerful depressant action on the heart. Cinchonidine is neither toxic nor irritant, but is distinctly the weakest of the four alkaloids.

The importance of the fact that all alkaloids have marked anti-malarial properties is very great to India, where the economic condition of the people is low and purified quinine preparations, on account of their high price, are beyond the means of ordinary people. The reasons why quinine is more expensive than the total alkaloids of the bark is:—(i) that its proportion in the bark usually is a little more than half of the total alkaloids. *Cinchona succirubra* and *Cinchona officinalis* barks, for example, contain about 5 to 6 per cent of total alkaloids of which only 3 per cent is quinine. *Cinchona ledgeriana* contains somewhat higher proportions. (ii) The cost of its separation from other alkaloids and purification further adds to its price. It would follow, therefore, that if the total alkaloids are used they will be cheaper than if only quinine by itself is used. It was for this reason that 'cinchona febrifuge' has been used in India, and the League of Nations have introduced *totaquina* which contains 70 per cent of the total alkaloids of which 15 per cent must be quinine. By this means it is hoped that the treatment can be made less expensive and extended among the masses.

Some of the other alkaloids of cinchona bark which occur in smaller quantities than the four alkaloids stated above, for example, cupreine and cupreidine compounds have also anti-malarial properties. Cupreine sulphate in doses of 1 gm. was found by Giemsa and Werner to be a good substitute for quinine in human malaria, but it is much more expensive and toxic. These observers also obtained good results with quin-ethyline and quin-propyline in doses of 0.3 to 0.4 gm. in human malaria and with these compounds and quinamyline in bird malaria. Ethyl-hydrocupreine or optochin has been tried in malaria but it is a toxic compound.

The hydro-alkaloids are said by some to be more effective than ordinary salts. Giemsa and Werner, Baerman, MacGilchrist, Morgenroth, Goodson and many others have proved that hydroquinine, as regards both its tolerability by the human subject and its parasitocidal action is superior to quinine. Rabe and his co-workers have been successful in preparing hydroquinine and hydroquinidine synthetically, but the process is so costly that there is no likelihood of possible competition between the artificial and natural products.

The disadvantages of the cinchona alkaloids are:—(1) They have no action on the sporozoites injected by the mosquitoes, and therefore they cannot have any really prophylactic action in this disease. This was demonstrated by Yorke and Macfie who showed that 18 grains of quinine for 5 days before and 7 days after the mosquito bite failed to avert an attack of malaria, but if the drug was continued for 10 days, the disease did not develop. This shows that these alkaloids have little effect on the injected sporozoites but act on the asexual forms liberated from the infected red blood corpuscles.

(2) Cinchona alkaloids have little effect on the sexual forms of malignant tertian parasites. They however impede the formation of the pre-gametocytes of *P. falciparum* and may thus be regarded as directly schizonticidal and indirectly gametocidal.

(3) They do not prevent relapses.

(4) These alkaloids do not act uniformly on all strains of malaria.

After the Great War there was a feeling against the use of cinchona alkaloids, especially quinine, and it was said that this drug was not effective against certain forms of malaria. Further investigation, however, showed that this was not due to any fault of the drug but due to its improper use.

It has been proved by hæmatological and other evidence that the best method of administration of these alkaloids is by the mouth. It is advisable to give them in solution, but owing to their bitter taste they may produce vomiting. They can be given in the form of tablets so long as these are easily disintegrable. Subcutaneous injection finds few advocates. Intramuscular injection should only be resorted to in those cases where administration by the mouth is not desirable or possible, as it is liable to produce serious local disturbances, such as necrosis of muscles and involvement of nerves. The intravenous method should only be used for severe and urgent cases, where the patient is comatose, or very gravely ill, and an immediate response is necessary. These parenteral methods should not be used for routine administration of these drugs, but any evidence of impending cerebral malaria is an imperative indication for treatment by a parenteral route.

On the acute symptoms of the primary infection, quinine has a definite action, from the third

day onwards (second paroxysm of fever) in benign tertian, but in malignant tertian malaria its action is less rapid, and in the case of some strains symptoms may continue until the fifth dose (third or fourth paroxysm).

As regards the time of administration of these alkaloids by the oral route, it is advisable to give them $2\frac{1}{2}$ to 3 hours after the meal when the gastric contents are acid, the digestion has been completed, and the stomach is nearly empty. If given at this time they rapidly mix with the contents of the stomach and pass into the small intestine from where they are quickly absorbed into the circulation. There is less liability of their irritating the stomach if administered in this way.

Dosage.—Experience shows that in the case of Indian strains of malaria, a 5 to 7 days' course of treatment with 20 to 25 grains of the alkaloids daily is effective. Larger doses are not only wasteful, but may be harmful. According to the Fourth General Report of the League of Nations, 0.5 gramme of quinine hydrochloride sometimes causes a temporary disappearance of trophozoites of benign tertian and quartan infection, but a mean daily dosage of 1 gramme for 5 to 7 days is often necessary to cause the trophozoites to disappear, and not to make their reappearance in the peripheral blood after a latent period of varying lengths. In malignant tertian malaria 1.3 gramme produces analogous results. It is also agreed that definite advantage is obtained by combining them with alkalis.

(B) Preparations containing cinchona derivatives

During recent years a number of cinchona derivatives have been used in the form of proprietary remedies whose composition is secret. Various claims have been made for these, amongst others, that they have destructive action on both the sexual and asexual forms of all species of plasmodium, that they prevent relapses, and that they have prophylactic value. A number of preparations are on the market and we have tested some of these. Our observations show that their action is practically the same as that of cinchona alkaloids, they have no direct action on the gametocytes of malignant tertian, they do not prevent relapses, and have no effect on the sporozoites. Being proprietary remedies they are more expensive than the non-proprietary preparations of the cinchona alkaloids.

The following are some of the preparations in use:—

Malarcan.—Malarcan is said to be a compound of a stereo-isomeric base of methyl-acridinium chloride and hydrocholic acid. It is thus probably a derivative of quinine or quinidine.

Tebetren.—Tebetren is described as methyl hydro-cupreine-methyl-acridine-dihydrocholate, i.e., a compound in which quinine is combined with acridine (from which atebren is derived).

Paludex is a complex organo-metallic preparation containing copper joined to an oxy-quinoline group. Chemically paludex is cupro-oxy-quinolin sodium sulphonate, and contains 8.37 per cent of metallic copper. It is a greenish amorphous powder, readily soluble in water, forming a solution which is neutral in reaction and stable under ordinary conditions.

Plasmodex is a similar compound, containing copper in a larger proportion.

Esanofele.—This is a proprietary preparation containing 0.1 gm. of quinine bisulphate, 0.001 gm. of arsenious acid, 0.3 gm. of iron citrate, and some bitter principles. If given as recommended, it contains less quinine than the usual minimum dose for effective therapy, specially against malignant tertian infection.

(II) OTHER ANTI-MALARIAL REMEDIES

Other anti-malarial remedies, which include the synthetic anti-malarial drugs.

These compounds can be divided into two groups:—(1) those that act like the cinchona alkaloids on the asexual cycle, e.g., atabrin, and (2) those whose main action is on the sexual cycle, particularly of the malignant tertian species, e.g., plasmochin.

Neither of these compounds acts on the sporozoites injected by the mosquito and therefore they have no true prophylactic value. They do not prevent relapses though their action in this respect is said to be more powerful than that of the cinchona alkaloids.

Their dosage as compared with the cinchona alkaloids is much smaller, but they are considerably more toxic.

(1) *Plasmochin*.—The shortage of quinine supply during the war led to experiments at Bayer-Meister-Lucius Research Laboratory at Elberfeld with the object of finding a synthetic drug which could be used in its place. Schulemann and his colleagues chose methylene blue for investigation; they prepared a large number of compounds which were tested on canaries infected with *Plasmodium relictum*. Among these compounds they found one which was particularly effective, and this was an amino-quinoline derivative in which a basic aliphatic radicle was united to a quinoline nucleus by a connecting link of nitrogen. This compound was modified in many ways, and eventually the compound, first known as 'beprochin' and afterwards as plasmoquin, or *plasmochin*, was produced. It was at first thought to have a definite curative effect in the treatment of all forms of malaria, but later experience showed, that while it was effective in comparatively large doses (which often produce toxic effects) in curing the benign tertian and quartan malaria, in sub-tertian malaria it was of no therapeutic value because it had no action on the schizonts, and some observers went so far as to say that it had a provocative action. It, however, possesses the remarkable and unique property

of destroying the crescents in the peripheral blood.

On account of this peculiar property of damaging the gametocytes it renders them non-infectious to mosquitoes. Even such small doses as 0.01 or 0.02 gramme of plasmochin daily are effective in this respect. This remarkable effect against the more resistant form of the parasites is the greatest virtue of the drug.

It should be fully appreciated that plasmochin is a drug which is likely to give rise to toxic effects and it should not be used for routine treatment of malaria. It can be given in combination with quinine, and it is claimed that this combination is more effective than quinine and the number of relapses is decreased. Prolonged administration of this combination in therapeutic doses is likely to produce toxic effects, but these are not so marked as when plasmochin is given with atabrin. Thus, plasmochin by itself holds a minor place in the symptomatic treatment of malaria.

Cilional.—The toxic effects produced by plasmochin have been fully appreciated by the workers of Bayer's Scientific Laboratories and they have been busy in producing less toxic compounds. Cilional is one of these compounds, which has been recently introduced, and which according to preliminary experiments was not only more effective than plasmochin but was considerably less toxic. Trials on human beings show that this compound is certainly less toxic than plasmochin, but it is not so effective unless larger doses are given. The work at the Calcutta School of Tropical Medicine has shown that this certainly is the case with the gametocytes of the Indian strains of *P. falciparum*.

Atabrin.—The work of Schulemann and his colleagues at Elberfeld, which culminated in the synthesis of plasmochin, was continued by Mietzsch and Maus. More than 1,200 compounds were prepared and eventually the drug, originally called 'erion' and now known as 'atabrin', was produced. Chemically it is the di-hydrochloride of an alkyl-amino-acridine derivative, and is a yellow powder with a bitter taste. Its solubility in water is 1 in 14 and it forms a neutral fluorescent solution. The action of atabrin is very similar to that of quinine, but according to some workers it is more effective than quinine in reducing the number of relapses. None of these drugs by themselves or in combination (e.g., atabrin and plasmochin, or quinine and plasmochin) represents a *therapia magna sterilisans*. Chopra and his co-workers (1933) tested this drug on the Indian strains of malaria and have come to the following conclusions:—

(1) Atabrin is an effective drug in the treatment of Indian strains of malaria. Its destructive action on the asexual forms of benign tertian, malignant tertian and quartan types of malaria is about equal, the schizonts disappearing from the peripheral circulation after 0.6 to 0.9 gramme of the drug.

(2) The sexual forms or gametocytes are more slowly acted upon than the asexual forms. The gametocytes of the benign tertian and quartan types are readily destroyed. The gametocytes of the malignant tertian type are not affected at all.

(3) The drug is effective in doses of 0.1 gramme three times a day, the course lasting for five days, making a total of 1.5 gramme of the drug for the cure. The drug can be given intravenously in doses of 0.1 gm. to 0.3 gm. dissolved in 1 to 2 c.cm. of distilled water, when the number of parasites in the peripheral blood is large.

(4) In chronic types of malaria the drug is effective and produces a rapid reduction in the size of the spleen.

(5) Atebrin has earned a great reputation as a powerful remedy in preventing relapses in all species of human malaria. In view of clinical evidence, the drug would appear to be more powerful than quinine in curing malaria, but so far as prevention of relapses is concerned this is not our experience with Indian strains of malaria.

Atebrin musonate.—This form of atebrin has come into prominence through trials made during the recent epidemic in Ceylon. It is simply an improved form of a soluble atebrin salt suitable for injection, 0.3 gramme of atebrin being contained in 0.375 of the musonate. Hecht has shown that when atebrin is administered by mouth much of it is retained in the upper intestine, liver and bile, and only the overflow goes to the peripheral circulation after these organs are saturated. This exceptionally high concentration of atebrin is responsible for the manifestation of toxic symptoms. By means of injection the drug gets into the circulation quicker and gives a response earlier. Doses from 0.1 to 0.375 gramme are given and a single injection often produces remarkable effects on the clinical symptoms, but recrudescence usually occurs in a few days. Two injections on successive days, however, usually prove sufficient to control the temperature within 48 hours, and in four days all forms of benign tertian parasites and the ring forms of malignant tertian are destroyed. Crescents are not affected and must be destroyed by plasmochin. The intravenous route can be used, but this method apparently produces no quicker response than does the intramuscular, and by some is not considered free from risk. The drug though quickly absorbed is quickly excreted, and relapses are said to be more frequent with intravenous injections.

It has been reported that some cases of malaria fail to respond to quinine and are controlled by atebrin and *vice versa*. This may be due to a number of factors which interfere with the proper absorption of these drugs. The parasitocidal effect of neither of these drugs is immediate and takes a certain time to manifest itself.

Toxic effects of atebrin.—Atebrin, even in therapeutic doses, produces yellow staining of the skin which may take weeks to disappear. It may also occasionally produce headache, abdominal discomfort or colic, but cyanosis that may follow plasmochin administration is not seen. There appears to be no doubt that cases of psychoses of various forms and other cerebral complications have been associated with its use.

Relapses and prophylaxis.—Quite a large number of malarial patients get relapses, which occur within a few weeks to a few months after treatment, whether quinine or atebrin is used. Relapses are said to be less common with the synthetic drugs than with the cinchona alkaloids; but neither of these drugs completely eradicates the infection. Although they have remarkable parasitocidal powers over the asexual forms, the forms that produce clinical manifestations of the disease, their action on the gametocytes is much feebler, and on the sporozoites negligible. As regards sporozoites there is evidence to suggest, in bird malaria, that there may even be a further cycle in the vertebrate host, and that sporozoites may not all directly give rise to asexual forms in the blood, but may undergo a schizogonic cycle of their own in the cells of the reticulo-endothelial system. In this form, unharmed by drugs, they may exist as a reservoir from which the blood may get subsequently re-infected and produce clinical relapse. This has not yet been demonstrated in the case of human malaria.

The reason why a daily dose of quinine is often suggested as a prophylactic, when its action on the sporozoites is negligible, is that although quinine and atebrin may not be lethal to sporozoites, their presence in the blood tends to suppress the multiplication of asexual forms and so inhibits clinical manifestations. For prophylaxis 5-grain doses of quinine daily, or larger doses at correspondingly longer intervals, have been used. Some use 0.3 gm. of atebrin weekly, but with this drug it is difficult to strike a balance with a dose which is effective and yet which is free from undesirable effects.

Atebrin and plasmochin combination.—As atebrin only acts on the asexual forms of the malignant tertian parasite, it has been combined with plasmochin. A comparative study of the action of atebrin and an atebrin-plasmochin combination on Indian strains of malaria by Chopra and co-workers (1936) showed that, (1) in cases of benign tertian and quartan malaria the combination of the two drugs is not more effective than atebrin alone in so far as the time of disappearance of the parasites from the blood is concerned, (2) in case of malignant tertian infection, however, the combination appears to be more effective and the parasites disappear more rapidly from the peripheral circulation, (3) with regard to the relationship between the number of parasites and their disappearance from the peripheral circulation, atebrin alone and atebrin-plasmochin combination behave in the same way, (4) the relapse rate

is definitely lower when the combination of the two drugs is used, and (5) the combination of the two drugs is more toxic.

It is therefore recommended that in those cases where crescents are present a 3 days' course of plasmochin 0.01 gramme, twice daily, be given after the course of atebirin is completed. The toxic effects are thus eliminated.

Anti-malarial drugs in ape malaria

A few words may be said about the action of these drugs on ape malaria. It has been shown that *P. knowlesi* produces a very intense and virulent infection in *Silenus rhesus*, causing death of the animal if untreated. This plasmodium appears to be more closely related to that occurring in man than plasmodia occurring in birds, which are usually used for testing anti-malarial drugs. The results obtained should therefore be more readily applicable to man. Chopra and Das Gupta (1933) showed that the destructive action of atebirin on *P. knowlesi* was exceptionally powerful. Usually two doses of 0.025 gramme of the drug given intramuscularly or intravenously are sufficient to control a very heavy infection, which may amount to a million parasites per c.mm. of blood. The drug affected equally the schizogony and the gametogony. Owing to its slow excretion, atebirin appears to exert a more prolonged action than quinine, and atebirin is successful in checking a heavy infection whereas quinine may not be. It was, however, shown that even after 5 days' intensive treatment with atebirin, the parasites invariably reappeared in the monkeys in 10 to 15 days and multiplied with the same rapidity as in the previous attack, causing death of the animal if prompt treatment was not given. The recrudescence can, however, be checked more easily, one dose sufficing to control the multiplication of the parasites. After this a low grade of infection persists for long periods, the parasites losing their virulence. Compared with atebirin, quinine, according to Chopra and Das Gupta (1934), has a much less powerful immediate effect on these parasites. When the parasite count is low, i.e., below 100,000 per c.mm., one dose (intramuscular or intravenous) may be effective in controlling the infection, but, when the parasite count is higher, 2 or 3 injections are necessary to control the infection. Further, the first effect of injection may be an actual increase in the number of the parasites. The advantage of quinine is that relapses rarely occur after the treatment of the primary infection, and, even when they do occur, they are not often fatal. The action of quinine thus appears to be slower, and if the treatment is started at a time when the infection is moderately heavy, the infection does not seem to be affected, in most cases, in 24 hours or even longer with quinine, whereas with atebirin, even if treatment is started late, i.e., when the count exceeds half a million parasites per c.mm., this invariably falls to a negligible number.

Stimulated by the results of these experiments, further work has been carried out on the concentration attained by these drugs in the circulating blood at different intervals of time in relation to the parasite count. With regard to quinine, Chopra, Ganguly and Roy (1935) have shown that there is no direct relationship between the concentration of quinine in the blood and the parasite count at any particular time. The highest concentration of the alkaloid attainable without producing toxic effects caused no apparent reduction in the number of parasites nor degenerative changes in them. The action of quinine thus appears to be synergistic to other defensive mechanisms set up in the body. In therapeutic doses quinine augments these processes, or possibly it acts on the parasites in such a way as to render them more vulnerable or unable to propagate. Studies on the concentration of atebirin in the blood by Chopra, Ganguly and Roy (1936) show that the highest concentration of atebirin occurs between half an hour and six hours after the injection of atebirin. The number of parasites per c.mm. of blood distinctly diminishes in the majority of cases in the first 6 hours when the concentration of atebirin in the blood is highest. Within 24 hours the parasites are reduced to a negligible number, in spite of the rapid falling off in the concentration of atebirin. It is, therefore, reasonable to state that atebirin, unlike quinine, has probably some direct lethal action on *P. knowlesi* *in vivo*. This has been further confirmed by Chopra, Das Gupta and Roy (1936), who showed that atebirin solution in a dilution of 1 in 50,000 *in vitro* is capable of destroying the parasites even when the infection is heavy. The smears of blood, which were kept in contact with atebirin, showed degenerative changes in the parasites. This work is being further elaborated.

Three important points which have come out of this work are :—

(1) Atebrin has a more powerful and more rapid effect on *P. knowlesi*. Whereas quinine takes 24 hours to produce its effect, atebirin is effective in 6 hours and concentration of this drug runs parallel with the decrease in the number of the parasites.

(2) Atebrin has some direct action on *P. knowlesi* (in 1 in 50,000 concentration), quinine has not. In fact the first effect of quinine administration may be actual stimulation of multiplication of parasites.

(3) A fatal relapse is more common after atebirin than after quinine. The action of quinine, though less powerful and less rapid, appears to be more prolonged and lasting.

Whether all these facts are applicable to human malaria remains to be seen.

Cinchona alkaloids versus synthetic anti-malarial drugs

What is going to be the effect of the introduction of these powerful synthetic anti-malarial drugs on the cinchona alkaloids? Are these

veterans going to be entirely replaced by the new-comers? The Malaria Commission of the League of Nations has rightly pointed out that neither of the two groups is the *therapia magna sterilisans*, and that their effect in preventing relapses is not marked. They have also no true prophylactic action. The synthetic drugs, according to the Commission, are not to be regarded as 'substitutes for quinine but as additional weapons for use in particular circumstances and for special purposes'.

This, I have no doubt, is the correct point of view. The cinchona alkaloids have a very low degree of toxicity, and can be used with impunity in the mass treatment of malaria, even for self-medication, without any danger. The same cannot be said about the synthetic anti-malarial drugs. They have a high degree of efficacy combined with some toxicity and should always be used under proper medical supervision. Even under such conditions, toxic effects are sometimes met with. Unless further researches produce less toxic drugs—and I may say that efforts are being made in this direction—cinchona alkaloids will hold the field for treatment of malaria generally.

During the last few years, it has been debated whether the cinchona plantations in this country should be extended. One of the arguments brought forward against their extension is that in view of the rapid development of synthetic anti-malarial drugs there will be no further necessity for cinchona alkaloids. I personally feel no hesitation in saying that unless something extraordinary happens, for the next 15 to 20 years we shall have to use the cinchona alkaloids in our struggle against malaria in India. The cinchona plantations take 7 to 8 years to mature and if we wish to extend the treatment of malaria among the masses, which is one of the chief methods of eliminating this disease, it is very desirable that cinchona plantations should be extended till such time as an effective and harmless synthetic drug is available, which can be used for mass treatment of malaria without any special supervision.

In Formosa large areas have been put under cinchona plantations, and in a few years' time Japan will be able to meet all her own requirements. In India large scale and economic production should be taken in hand, now that information is available regarding the species of cinchona which yield the highest percentage of the alkaloids, and the best soil for cultivation. It may be ten years before India, even if she starts work at once, can hope to produce all cinchona alkaloids her population needs, but in the meantime it should be possible to overhaul the existing resources. It is a health rather than a fiscal problem.

EARLY OPHTHALMOLOGISTS IN CALCUTTA*

By E. O'G. KIRWAN, F.R.C.S.I.
LIEUTENANT-COLONEL, I.M.S.

Professor of Ophthalmology, Medical College Hospitals, Calcutta

DURING the regime of the Honourable East India Company the first properly organized hospital, the Calcutta General Hospital, was established in 1790 in Calcutta. This was followed in 1792 by the opening of the Calcutta Native Hospital. The former is now represented by the present Presidency General Hospital, the latter was rebuilt and re-named and is now the present Mayo Hospital which was opened in 1874. The Calcutta Native Hospital appears to have been the first institution to provide scientific treatment for diseases of the eye, and even to this day, in spite of many other hospitals for the treatment of eye diseases, the Mayo Hospital still has the reputation among the inhabitants of Bengal as a place from which blind persons return with their sight restored.

Dr. John Shoolbred was the first surgeon and superintendent of the Calcutta Native Hospital and remained in charge of that institution from 1792-1816. In the year 1798 he published, in the annual transactions of the hospital, the treatment of two cases of cataract, twenty cases of phlegmon of the eyes and thirty cases of ophthalmia. He does not, however, give an account of the details of treatment. The number of eye cases reported in the annual hospital transactions steadily increased from year to year. He held the appointment of superintendent and surgeon to the Calcutta Native Hospital through his whole service, till he went on furlough in 1818 prior to retirement, with two intervals, one of furlough and the other when he acted as superintendent general of vaccination in 1806-1807.

Dr. Shoolbred obtained the Certificate of Surgeons in 1785, and served as surgeon of the Indian 'General Goddard' in 1789-90. He was commissioned as assistant surgeon in 1794, became surgeon in 1807, retired in 1821 and died in 1831.

Official records dated October 1816 show that operations for the relief of blindness, including cataract, were first done in Calcutta by Surgeon Thomas Luxmore. He applied to the Right Hon'ble the Governor-General in Council for a grant and an allowance for the upkeep of the small hospital he established in Chowringhee in 1816, and pointed out that the various opportunities he had in performing the operation of cataract had afforded him the pleasing gratification of rendering the operation so successful as generally to restore the sight of those who were blind from any species of cataract, from the infant born in that state to the adult in the advanced period of life, provided there was no other defect in the organs of sight. He mentions that

Drs. Cochrane and Leny, of the Medical Board, Bengal, inspected minutely the cases of cataract in his hospital and were pleased with the results of the new mode of treatment. The Governor-General in Council, the Right Hon'ble Francis, Earl of Moira, K.G., sent in the application of Dr. Luxmore to the Medical Board in Calcutta asking if an institution could be established for boys from the Orphan and Free Schools to be instructed by Dr. Luxmore in the mode of extracting cataracts, and in the treatment of other diseases of the eye. Dr. R. Leny, secretary of the Medical Board, replied that the Medical Board was of the opinion that no advantage could be gained from instructing young men from the Orphan and Free Schools in the mode of performing the operation for the cure of cataract and for the treatment of other diseases of the eye. From the delicacy as well as the complicated structure of the organ not only are the operations to be performed on it of a fine and difficult nature, but the proper treatment of its diseases requires an extreme range of knowledge. It appears, therefore, more necessary in respect to the eye, more than perhaps any other organ of the human body, that its professional management should be confined to persons better informed and more skilful than boys from the Orphan and Free Schools. It is likewise proper to remark that boys could not at present be furnished for such a purpose by these establishments, for a number of boys, not less than fifty, is now required for completing the new hospital establishment and a very small proportion of them can be supplied.

The matter was referred to Dr. John Shoolbred, the surgeon superintendent of the Calcutta Native Hospital, as to whether he considered a ward contiguous to the Native Hospital, could with advantage be constructed for the reception of natives affected with cataract and other diseases of the eye. He replied that, as there were prejudices amongst many patients remaining as indoor patients, there was no necessity at present, as cases of cataract and other chronic affections of the eye requiring operation, so long as they were not contagious and could remain in the common ward without danger to anyone, could be accommodated in some of the spare cots which were always available in the hospital. He also was of the opinion that before the new ward was erected exclusively for diseases of the eye the necessity for it should be satisfactorily established by experience, and this could easily be done if the surgeon in charge of the hospital were directed to keep a register of eye patients for 12 months, separate from that of other patients, and to ascertain by this means how many cases of diseased eyes in that period would require or derive benefit from such separate accommodation, and how many would avail themselves of it were it offered to them. If the number of the latter were sufficient to warrant the expense of an additional ward, it would then be time enough to erect it. If not, eye cases would, of course, continue to be received as they have hitherto been as house or out patients at their own option, when not improper to mix with others, for any idea of compelling them to remain in hospital contrary to their own wish would be the certain means of deterring many from applying for relief at the hospital, who might otherwise have derived benefit from it, both in these and other complaints. The first separate account of eye patients submitted was from 1st September, 1816 to 31st August, 1817. In the Government Gazette dated 19th December, 1816, the following appears: 'A person blind received sight by the means of a surgical operation performed by Dr. Luxmore, who removed a cataract which was the cause of blindness'.

Dr. Thomas Luxmore was born 13th March, 1774. Assistant Surgeon 8th September, 1815, M.R.C.S., 1820, surgeon, 23rd May, 1825. Died at Lucknow, 2nd October, 1828.

In 1825, Mr. Surgeon Breton, superintendent of the Calcutta Medical Institution, presented to the governors of the Native Hospital a tract on the eye and its appendages and another on cataract, for the use of the assistants at the Native Hospital and its subsidiary

dispensaries. These were written in Hindustani, in the Persian and Nagree characters and were intended for the use of the students of the Native Medical Institution in Calcutta. These tracts were printed in lithography. The Calcutta Medical Institution was founded in 1822 and Surgeon Breton was the second superintendent. As superintendent of the Native Medical Institution he taught the senior students the native mode of operating for cataract, as he was convinced by positive proof that this method, on account of its extraordinary simplicity and efficacy, was the safest for the students to adopt. It is on record that a Mussalman practitioner operated successfully on eleven patients in his presence. In 1826 he wrote an article on the native method of couching. He was an author of repute. In the annual records of the Calcutta Native Hospital from 1816 onwards mention is made of cases of cataract admitted for treatment. Eye diseases were classified under four headings, *viz*, nyctalopia, cataract, phlegmon of the eyes and ophthalmia.

Dr. Peter Breton was appointed assistant surgeon on 27th August, 1801, and surgeon on 22nd August, 1814. He gave up promotion to superintending surgeon to retain his appointment of superintendent of the Native Medical Institution in 1826. He died in Calcutta on 18th November, 1830.

When Dr. John Shoolbred resigned the post of surgeon and superintendent of the Calcutta Native Hospital in 1816 he was succeeded by Dr. Simon Nicolson. Crawford says of Nicolson, he was the best known medical man of his time in Calcutta, perhaps, he might say, of any time. He was born on 5th July, 1779, in the Manse of Kiltarlity, Inverness, Scotland, of which parish his father was minister, and he was educated at St. George's Hospital, London, where he was house surgeon in 1801, and M.R.C.S. in 1802. He was assistant to Sir Everard Home in private practice until 1805 and was succeeded in that post by Sir Benjamin Brodie, when the post fell vacant through Nicolson's acceptance of an appointment in India. He was appointed to the Madras Medical Service in 1806, but never joined that Presidency, being gazetted to the Bengal Medical Service as Assistant Surgeon in the Calcutta General Hospital. Except for one period of leave to the Cape, he spent the rest of his service and life in Calcutta. From 1807 to 1816 he served in the Calcutta General Hospital and in 1816 he succeeded Dr. John Shoolbred as superintendent and surgeon of the Calcutta Native Hospital, and during his time the number of eye cases treated in the Calcutta Native Hospital steadily increased from year to year. Unfortunately the annual reports show no details of treatment. In the records his name appears frequently as being associated with the teaching of students in the diseases of the eye. He and Dr. James Randal Martin were amongst other examiners in the first final examination for the diploma issued by the Medical College, Calcutta, in 1838. At this examination eleven students presented themselves and four passed. He retired from the post of surgeon and superintendent of the Calcutta Native Hospital in 1830 on the grounds of ill health, and was appointed a Governor of this Hospital by the Governor-General in Council, on the recommendation of the Board of Governors of the Calcutta Native Hospital in appreciation of his work for that institution. Early in 1833 he went on two years' leave to the Cape. On his return in 1835 he was posted as surgeon to the Calcutta European Hospital and held that post till he died twenty years later. In 1839 he was gazetted superintendent surgeon but was allowed to decline promotion and to retain his appointment in Calcutta. He retired on 1st August, 1855, and died in Calcutta a week later on 8th August, 1855, at the age of 76 years.

It was Nicolson who first brought James Randal Martin into notice, recommending him in 1823 to the Governor-General, Lord Amherst, to be sent to Hyderabad to treat Sir Charles Metcalfe, the Resident there, who was seriously ill. In 1830 Martin succeeded Nicolson as superintendent and surgeon of the Calcutta Native Hospital. He also took charge of Nicolson's practice while he was at the Cape.

Dr. Simon Nicolson, 1779-1855.

Dr. C. C. Egerton. 1798-1885.

James Ranald Martin, Surgeon, Governor-General's
Bodyguard, 1821

Sir James Ranald Martin. 1870

Nicolson left no published works and nowadays he is almost forgotten, a mere name, but no officer in the Indian Medical Service ever stood higher in the public and private estimation of his contemporaries. Sir John Kaye has described him under the name of Nicholas Fitzsimon in a long-forgotten novel 'Peregrine Pulteney'. A retired Bengal civilian in the novel speaks of him as follows: 'Nicholas Fitzsimon, everybody knows him in India—finest fellow in the world—kind, generous, trump of a fellow. Now I'll tell you, go to him—give you breakfast, tiffin, dinner, shelter, advice, everything. If you are sick, go to him, sure to cure you—sure to be kind to you—saved more lives than the invention of the lifeboat—a most excellent fellow—good Samaritan—sure to love him'.

A picture of Nicolson, seated in a chair, hangs in the rooms of the Calcutta Asiatic Society and a photograph of this painting is published with this article.

The late C. R. Wilson, in his *Descriptive Catalogue of Paintings in the Possession of the Asiatic Society of Bengal*, quotes two other references to Nicolson, which should be reproduced here. 'His practice was only limited by the impossibility of performing more than a certain amount of work within a certain space of time. One carriage was always kept waiting, day and night, to enable him to attend to any call without delay.'

In accepting his resignation, the Governor-General, Lord Dalhousie, wrote to him as having long possessed: 'In a measure rarely equalled, the confidence and reverence of your professional brethren, the universal respect and esteem of the community amongst whom you have passed your days and the approbation and gratitude of the Government, to whose service you devoted a long course of valuable labours'.

Dr. Simon Nicolson was succeeded in 1830 as surgeon and superintendent of the Calcutta Native Hospital by Dr. James Ranald Martin, one of the greatest medical men of his time in India, and in the annual records of the Mayo Hospital mention is made of large numbers of eye cases that were treated during his time as surgeon and superintendent, and it is of interest to know that the earliest official records of glaucoma in Calcutta are found in the old records of that Native Hospital in 1830, in the year that Martin succeeded as surgeon and superintendent of that institution. In that year James Ranald Martin records the treatment of four cases of sudden acute inflammation of the eyes with widely dilated pupils and included these in a list of 113 cases of ophthalmia, as at that time all inflammatory diseases of the eye were still classified under the general heading of ophthalmia. Definite mention of glaucoma treated by operation is found in the records of the department of ophthalmology of the Calcutta Medical College when Dr. Archer was the surgeon in charge, 1858-1870. The number of eye cases coming for surgical relief for glaucoma in those days was few, and the popular belief was that operation on a glaucomatous eye was of no benefit except perhaps to allay pain. In the year 1835 the Calcutta Medical College with its associated hospitals was established and in the records of these institutions the earliest eye work mentioned was in 1840 and the name of Dr. Martin is associated with it. He was the first part-time professor of ophthalmology at the Medical College, Calcutta. He was the first to practise injections of iodine in the cure of hydrocele. A ward in the original Medical College Hospital, which was erected in 1848, was called the Martin Ward, to commemorate his services to humanity in Calcutta.

In 1839 he resigned the office of surgeon and superintendent to the Calcutta Native Hospital and the Governors of that institution expressed themselves as follows: 'The Governors feel great regret at being called upon to accept your resignation, and particularly at the cause which has led to your retirement; at the same time they feel deeply sensible of the valuable services you have rendered to the institution

over which they preside, of the great professional skill which for a period of more than nine years you have displayed in attendance on the native sick entrusted to your care, and of the zeal and ability you have constantly shown in offering numerous and important suggestions for the improvement of the institution over which you were placed'.

To the Governor of Bengal they wrote: 'We take leave on this occasion to lay before you, Honourable Sir, copies of our correspondence with Mr. Martin, in the belief that it will be a source of satisfaction to the Government, contributing as it does largely to this charitable institution, that it should be informed how very highly we appreciate the past services of Mr. Martin'.

His friends and patients, at a meeting presided over by Sir John Peter Grant in the Town Hall, presented him with an address signed by over one hundred of the leading inhabitants, European and native, of Calcutta, and a gift of plate to the value of four hundred guineas.

On retirement from India in 1842 James Ranald Martin rapidly became a prominent figure in the medical world in England. He was appointed a member of the Health of Towns Commission, and to him is due one of the most valuable appointments that was ever made in England, that of medical officer of health. He sat on the Royal Commission to enquire into the conditions of the Royal Army Medical Department and was instrumental in founding the Army Medical School at Netley. His labours so benefited the Army that James Ranald Martin was widely spoken of as the soldiers' friend. His whole life was one of activity and usefulness and, whether in his public capacity or later in life in the private exercise of his profession, he was noted for the wisdom and judgment which he manifested and for the influence for good which he exercised on all with whom he was brought into contact. The Martin Memorial Gold Medal, presented to the surgeon on probation who takes the highest place in military medicine at the Royal Army School at Millbank, London, at the close of each session, was created to commemorate his memory in advancing the science of tropical medicine and sanitation in India and at Home, with the inestimable result of improving the health and diminishing the death rate of the Army in India.

James Ranald Martin was born on 12th May, 1796, and was a pupil of Sir Everard Home, as well as of Sir Benjamin Brodie at St. George's Hospital, London. He was appointed assistant surgeon, Indian Medical Service, Bengal establishment, on 5th September, 1821-1826. Surgeon to the Bodyguard of the Governor-General, 1821-1826. Surgeon to the Governor-General, 1817. Appointed Surgeon of the Calcutta Native Hospital, 1830. Retired, 1842. Elected F.R.C.S., 1843. F.R.S., 1845. Appointed examining Physician to the Secretary of State for India, 1859-1864. C.B., 1860. Knighthood, 1860. President, Medical Board, India Office, 1864 (when the Board was first formed) to 1874. Died in London on the 27th November, 1874. Author of 'Medical Topography of Calcutta', 1830. Article on 'Hospitals in Holmes' System of Surgery', 1864.

In the *History and Traditions of the Moorfields Hospital* by Treacher Collins, mention is made that in 1824 Mr. C. J. Egerton, who had studied ophthalmology under Travers in the London Eye Infirmary, was sent to Calcutta, where he founded an Eye Hospital. This must be Charles Chandler Egerton, who was appointed to the I.M.S. as Assistant Surgeon in 1823. The eye hospital which was formerly situated at the junction of Wood Street and Theatre Road, Calcutta, on the present site of the Saturday Club and mentioned in old records, was probably started by him, but his name does not appear as holding a prominent position in ophthalmology. Bengal Civil Order No. 33 of 1st February, 1837, shows that Assistant Surgeon C. C. Egerton was appointed Professor of Surgery and Clinical Surgery to the Calcutta Medical College. He held that

position until he went on furlough in 1842 and was succeeded by Surgeon E. W. W. Raleigh.

Charles Chandler Egerton was born in April 1798. Studied at Guy's and St. Thomas' Hospitals. M.R.C.S., 1819. Appointed Surgeon 1st August, 1837. F.R.C.S. (elected), 1844. Retired 31st January, 1847, and died in England on 4th May, 1885.

COLLEGE OF PHYSICIANS AND SURGEONS OF BOMBAY

REGULATIONS RELATING TO THE EXAMINATION* FOR THE DIPLOMA IN OBSTETRICS AND GYNÆCOLOGY.

1. The College of Physicians and Surgeons of Bombay shall grant a diploma in Obstetrics and Gynæcology† (D. G. O.).

2. The seal of the College shall be affixed to every diploma.

3. The examination shall be open to all those registered with the Bombay Medical Council‡.

4. No candidate will be admitted to the examination unless he produces the certificates of having attended the following courses:—

For candidates who have passed the M.C.P.S. examination of this college or the M.B.B.S. examination of a statutory Indian University

Of having held, for a period of twelve months, a resident appointment in obstetrics and gynæcology, where appointments are combined; or

Of having held, for a period of six months, a resident appointment in obstetrics followed or preceded by six months in gynæcology, either resident or post-graduate, where appointments are separate.

The above appointments to include attendance at ante-natal and post-natal clinics.

For candidates who have passed the L.C.P.S. examination of this college or the licentiate examination of any faculty or board in India

(a) Of having held, for a period of six months, a resident appointment in either medicine or surgery, at a recognized hospital attached to an affiliated institution; or

Of having attended, for a period of twelve months, a post-graduate course in medicine and/or surgery, at a recognized hospital attached to an affiliated institution;

(b) Of having held, for a period of twelve months, a resident appointment in obstetrics and gynæcology, where appointments are combined, or

Of having held, for a period of six months, a resident appointment in obstetrics followed or preceded by six months in gynæcology, either resident or post-graduate, where appointments are separate.

The above appointments to include attendance at ante-natal and post-natal clinics.

5. The examination shall be written, practical, clinical and oral. There shall be two papers, each of

three hours' duration, and each carrying 100 marks, in each of the following subjects:—

(a) Midwifery,

(b) Gynæcology and diseases of the newborn*.

There shall be practical and oral examination, including obstetrical operations on phantoms, carrying 100 marks, and clinical examination carrying 100 marks.

The examination will be very largely practical and is intended to test the student's knowledge of the practical side of obstetrics and gynæcology.

6. To pass the examination, the candidate must obtain 40 per cent of the full marks in each paper, 50 per cent of the full marks in practical, clinical and oral tests taken together, and 50 per cent of the full marks in the written, practical, clinical and oral tests taken together.

7. The examination shall be held annually in Bombay on the last Monday in August.

8. Candidates must apply to the Secretary of the College for permission to appear at the examination at least three weeks before the date of the commencement of the examination, and shall at the same time pay a fee of Rs. 100. Fees once paid shall not be refunded, but may be reserved for the subsequent examination only, at the discretion of the College Council, provided that the application for such reservation is made at least seven days before the date of the commencement of the examination, and good and sufficient reason is shown for the same. A candidate who fails to pass or to present himself at an examination may be admitted to one or more subsequent examinations on a fresh application being made and a fresh fee being paid.

9. The following hospitals are recognized for the D. G. O. course:—

Motilbai and Petit Hospitals, Bombay; Cama and Alibless Hospitals, Bombay; Nowrosjee Wadia Maternity Hospital, Bombay, for midwifery only; King Edward VII Memorial Hospital, Bombay, for gynæcology only; Sassoon Hospital, Poona; King Edward Memorial Hospital, Poona, for midwifery only; St. Margaret Hospital, Poona; Canada Hospital, Nasik; State General Hospital, Baroda; Civil Hospital, Ahmedabad; Wadilal Sarabhai and Chinai Maternity Home, Ahmedabad; Jammagar State Hospital, Jammagar; and Lady Dufferin Hospital, Karachi.

SWINEY PRIZE FOR A WORK ON MEDICAL JURISPRUDENCE

THE council give notice that the next award of the Swiney Prize will be made in January 1939, the ninety-fifth anniversary of the testator's death. Dr. Swiney died in 1844, and in his will he left a sum of money to the Royal Society of Arts for the purpose of presenting a prize, on every fifth anniversary of his death, to the author of the best published work on jurisprudence. The prize is a cup, of a value of £100 and money to the same amount.

*The first examination under these regulations will be held in August 1939.

†Gynæcology will be included in the examination, only in so far as it is related to common diseases and to the complications arising from child bearing. Experience in, or a knowledge of, major gynæcological operations will not be required.

‡Candidates shall at the time of applying for permission to appear at the examination produce a certificate stating that he is registered with the Bombay Medical Council.

*The paper in gynæcology and diseases of the newborn shall include questions in diseases of the newborn, carrying 40 marks.

The award is made by a joint committee of the Royal Society of Arts and the Royal College of Physicians, which appoints special adjudicators.

The prize is offered alternately for medical and general jurisprudence, but if at any time the committee is unable to find a work of sufficient merit in the class whose turn it is to receive the award, it is at liberty to recommend a book belonging to the other class. On the last occasion of the award (1934) the prize was awarded for general jurisprudence. It will, therefore, be offered on the present occasion for medical jurisprudence.

Any person desiring to submit a work in competition, or to recommend any work for the consideration of the Judges, should do so by letter, addressed to the secretary of the Society, not later than 30th November, 1938.

K. W. LUCKHURST,
Secretary, Royal Society of Arts.

JOHN STREET,
ADELPHI, LONDON, W.C.2.

BOMBAY MEDICAL COUNCIL

THE following extracts from a summary of the proceedings of the meeting of the Bombay Medical Council held on 14th February, 1938, are published for information:—

The council proceeded to consider further the application of Mr. G. S. Kasyapi, L.M.&S., for the restoration of his name to the Bombay Medical Register and resolved that his request be refused.

The council proceeded to consider the application of Mr. V. R. Kulkarni, L.C.P.S., for the restoration of his name to the Bombay Medical Register and resolved that his name be restored to the Register.

The council proceeded to consider the reply received from the Medical Council of India stating (1) that the suggestion made to them by the Bombay Medical Council, viz., that the Medical Council of India might request the Government of Portuguese India to allow all medical practitioners registered under the Bombay Medical Act, 1912, to practise in Portuguese India, related to a matter outside the scope of the Medical Council of India and (2) that any extension of local reciprocity should be negotiated by and at the discretion of the Bombay Medical Council, and it was resolved that the Government of Bombay be addressed with a request to reopen the question and press on the Government of Portuguese India to consider the advisability of permitting all medical practitioners registered under the Bombay Medical Act, 1912, to practise medicine in their territories on a reciprocal basis.

The council resolved that Government be requested to add the following proviso to clause (1) of section 3 of the Bombay Medical Act, 1912:—

'subject to the proviso that a member shall hold office for the term of five years from the date of his nomination or election or until his successor shall have been duly nominated or elected, whichever is longer'.

The council proceeded to consider the draft bill for the Registration of Dental Practitioners, together with the draft Bombay Presidency Dental Act prepared by the Bombay Presidency Dental Association, and decided that the matter be referred back to the Executive Committee for further consideration and with due regard to the decisions already taken by the council on certain points in respect of the former bill.

The council proceeded to consider an application received for the inclusion of the D.O.M.S. of the College of Physicians and Surgeons of Bombay in table (G) printed in the Bombay Medical Register—showing the qualifications registrable as additional qualifications—and it was decided to call for further information from the executive committee before disposing of the application.

The council proceeded to consider an application from the Registrar, Andhra University, for the recognition

of the medical degrees of the Andhra University for registration under the Bombay Medical Act and resolved that Government be requested to add the degrees in question to paragraph 1 of the Schedule to the Act.

The council proceeded to consider further the draft bill to Prohibit the Conferment of Unauthorised Medical Degrees, etc., and Assumption thereof, and resolved that Government be informed that the council is in favour of the bill—which is practically on the lines of the draft bill to amend the Indian Medical Degrees Act, 1916, framed in 1927—subject to certain alterations suggested by them.

The council proceeded to consider further the proposal made by Mr. U. B. Narayanrao, L.C.P.S., and seconded by Mr. V. D. Sathaye, B.Sc., L.C.P.S., for the amendment of section 2 of the Bombay Medical Act in respect of the number of members of the council to be nominated and elected and it was resolved to refer the matter back to the executive committee for further consideration and report on a point raised at the meeting re the reservation of seats for Sind.

The council proceeded to consider further the proposal made by Mr. U. B. Narayanrao, L.C.P.S., and seconded by Mr. V. D. Sathaye, B.Sc., L.C.P.S., for the circulation of the draft revised Code of Medical Ethics to the medical press and medical associations in the Presidency with a view to obtain the views of the registered medical practitioners thereon and it was resolved that a short notice be published in the *Times of India*, the *Bombay Chronicle* and the *Sind Observer* and also the medical journals, if they will publish the notice free, stating that the Bombay Medical Council will welcome suggestions, etc., regarding the revision of the Code of Medical Ethics.

The council proceeded to consider further the proposal made by Dr. Jivraj N. Mehta, M.D. (Lond.), etc., and seconded by Dr. P. T. Patel, M.D. (Lond.), etc., suggesting certain alterations in the Bombay Telephone Directory and it was decided that Dr. Jivraj Mehta and the Registrar should discuss the matter further with the manager of the Telephone Company.

The council proceeded to consider and approved of a suggestion received by them that the names in the Bombay Medical Register should in future be shown together and not in two parts as at present.

The council proceeded to ballot for the election of an executive committee for the year and, in accordance with the result of the ballot, declared the following six members as duly elected:—

Lieut.-Colonel S. L. Bhatia.

Mrs. Cecilia D'Monte.

Dr. B. G. Vad.

Dr. P. T. Patel.

Mr. C. A. Amesur.

Mr. V. D. Sathaye.

The council proceeded to consider a motion made by Mr. C. A. Amesur, M.S. (Lond.), and seconded by Dr. P. T. Patel, M.D. (Lond.), etc., that 'the Bombay Government be moved to amend the Bombay Medical Act VI of 1912, empowering the Bombay Medical Council to register Indian and British Nationals by birth, who possess reputable qualifications which are not in the Schedule', and it was resolved that the matter be referred to the executive committee for consideration in the first instance.

The council proceeded to consider a motion made by Mr. U. B. Narayanrao, L.C.P.S., and seconded by Mr. V. D. Sathaye, B.Sc., L.C.P.S., that in view of the desirability of having one uniform standard of medical education in India as accepted by the Health Ministers' Conference recently held at Madras, etc., the council should request Government to abolish 'Licentiate' course altogether, and it was resolved that the matter be referred to the executive committee with a request to examine it in all its aspects.

PUNJAB MEDICAL COUNCIL

ABSTRACT of proceedings of a meeting of the Punjab Medical Council held in the Committee Room of the

Office of the Inspector-General of Civil Hospitals, Punjab, Lahore, at 11 a.m., on Saturday, the 9th April, 1938.

Proceedings

Notifications regarding the nomination of Col. G. G. Jolly, C.I.E., V.H.S., I.M.S., as president, and nomination of Dr. Hakim Din as a member, were read and recorded.

Notification regarding the election of Dr. Vishwa Nath, M.A., M.D., as a member of the Punjab Medical Council, was read and recorded.

Decided that Lieut.-Col. Amir Chand, I.M.S., be nominated to represent the Punjab Medical Council at the Conference called by the Director-General, Indian Medical Service in India, in November 1938.

Decided that the Sub-Committee appointed by the Punjab Medical Council at their meeting held on the 13th November, 1937, to revise the syllabus of the L.S.M.F. examinations, should function after the Conference in Delhi to be held in November 1938.

(i) Resolved that an Inspection Committee be appointed to inspect the Punjab Medical School for Women, Ludhiana, and to submit its report to the next meeting.

Resolved that (i) foreign nationals whose country of origin possesses no reciprocity relations with India on the basis of the Schedule of the Medical Council in the matter of medical registration, should be debarred from being registered as medical practitioners in the Punjab under the provisions of Section 13, proviso II (a) of the Punjab Medical Registration Act.

(ii) Foreign nationals whose country of origin possesses no reciprocity relations with India on the basis of the Schedule of the Medical Council of India in the matter of medical registration, should be debarred from being registered as medical practitioners in the Punjab under the provisions of Section 13 (a) of the Punjab Medical Registration Act.

Resolved that Government be requested to so amend the Indian Medical Degrees Act of 1916, as to make it more effective against the assumption and use of medical degrees, licences, etc., by unqualified persons.

Resolved that the registration fee charged by the Punjab Medical Council be reduced from Rs. 32 to Rs. 15.

Resolved that the Punjab Medical Council views with disfavour the practice of a registered medical practitioner associating with professions other than his profession as a medical practitioner.

Resolved that the recommendations of the Registration Sub-Committee be accepted with the following amendments:—

Applications of the following American doctors be not approved as their qualifications are not borne on the Schedule of the Punjab Medical Council:—

Dr. E. S. Kirkman.

Dr. E. F. Farra.

Dr. Rose A. Riste.

Dr. S. Bergasma.

Following portion be deleted:—

Recommended also that the Punjab Medical Council should consider the advisability of specifying a maximum size for a Sign-board.

The name of Dr. Bakhtawar Singh Jain be removed from the Punjab Medical Register.

THIRD UNITED INTERNATIONAL CONGRESS OF TROPICAL MEDICINE AND MALARIA

AMSTERDAM/ROTTERDAM, 24TH SEPTEMBER TO 1ST OCTOBER, 1938

Patroness: Her Majesty the Queen of the Netherlands

The third international congress of tropical medicine intended to meet in 1932 at Amsterdam, but it was put off because of the unfavourable times. The third international malaria congress was to take place at Madrid in 1935, but after being put off it had to be definitely given up.

The Netherlands Society of Tropical Medicine has now taken the initiative to organize a combined congress for both, in the last week of September 1938.

All who have sent in their names as entrants to the secretary's office, Instituut Voor Tropische Hygiene, Mauritskade 57, Amsterdam O and have paid the appointed fee of £1 are admitted to the congress.

Members of the congress may give the names of their families as associated members of the congress, after payment of the fee appointed for such, of 10 shillings.

Ordinary members receive the printed reports of the congress. They have the right to attend all the meetings of the congress sections, and to take part in the discussions, the various festivities, receptions and excursions.

Associate members may not take part in the discussions and do not receive the printed reports.

There is a reduction on travelling expenses and hotel prices.

TENTH INTERNATIONAL MEDICAL CONGRESS FOR PSYCHOTHERAPY

THE CONGRESS WILL BE HELD AT BALLIOL COLLEGE, OXFORD, ENGLAND, FROM FRIDAY, 29TH JULY, TO TUESDAY, 2ND AUGUST, 1938

The International Medical Society for Psychotherapy, under whose auspices the congress is being held, has been in existence for some fifteen years. The first President was Professor Kretschmer; recently that position has been taken over by Professor Jung.

The objects of the society are:—(1) To establish, so far as possible, basic principles common to all those working in the same field. (2) To provide a platform where workers in every branch and school of psychotherapy can bring their best contributions and listen to those of leading men and women from other countries. (3) To foster international contacts within a scientific fraternity. (4) To publish original work of merit.

Previous to 1937, when the congress was in Copenhagen, meetings had taken place in various towns in Germany. This is the first occasion that the congress has taken place in an English-speaking country.

TUBERCULOSIS NEWS FOR THE MONTH OF MAY 1938

Carlo Forlanini Institute Scholarships.—The International Union against Tuberculosis, on which India is represented through the King George Thanksgiving (Anti-Tuberculosis) Fund, has informed the Central Fund Committee that the Italian Fascist National Federation has placed at the disposal of the union six scholarships at the Carlo Forlanini Institute, Rome.

These competitive scholarships, of a value of 2,000 liras each plus board and lodging, are intended to enable foreign medical practitioners to stay at the Carlo Forlanini Institute, Rome, for a period of eight months (15th November, 1938, to 15th July, 1939).

The scholarships will preferably be awarded to young physicians who are already familiar with tuberculosis problems and who wish to improve their knowledge of this branch of medicine. The kind of work undertaken at the Institute shall be subject to an agreement between the Director of the Institute and the candidates.

The Central Fund Committee has asked its provincial committees and principals of the medical colleges in India to recommend suitable names for the consideration of the Fund Committee. Names of selected candidates will be forwarded to the executive committee of the union, which will meet on 11th July, 1938.

National Association for the Prevention of Tuberculosis, London.—The 24th Annual Conference of the Association, included in which is the annual meeting of the Care Committee as already announced, will be held in the Great Hall, British Medical Association.

Tavistock Square, London, W.C.1, on 29th and 30th June and 1st and 2nd July, 1938.

The subjects for discussion at the conference are:—

1. The development and organization of anti-tuberculosis activities in rural areas.
2. The family and tuberculosis—the discovery and protection of contacts in a tuberculous household.
3. The control of tuberculosis in tropical and sub-tropical regions.
4. The mental aspects of tuberculosis:—

(a) How tuberculosis affects the mental life of the normal person.

(b) How the mentally disturbed patient is affected by tuberculosis.

Major-General E. W. C. Bradfield, Major-General H. C. Buckley and Lieut.-Colonel C. M. Nicol have been appointed official delegates on behalf of the King George Thanksgiving (Anti-Tuberculosis) Fund.

The council are, however, most anxious to include in the conference private persons, who are interested in tuberculosis and its allied problems. Fee for membership for the conference is fixed at one guinea.

Her Excellency the Marchioness of Linlithgow's Appeal for the King-Emperor's Anti-Tuberculosis Fund.

The total collections actually received by the Honorary Treasurer on the 23rd May came to Rs. 39,99,575-9-2. Collections are going on steadily throughout the country although in some provinces appeal committees were not formed until as late as the middle of April.

In the course of a speech made in Bombay on the 10th May Mr. Subhas Chandra Bose, the President of the Indian National Congress, made an appeal to his countrymen to open wide their purses in aid of the Anti-Tuberculosis Fund.

An appeal committee has been formed in England and sums are being contributed by private individuals and by firms that have dealings with India. It is hoped also that those who are studying or on any other business in England from this country will also contribute.

INDIAN MEDICAL BIRTHDAY HONOURS, 1938

The following are the names of medical men and others, associated with medical institutions, in the Indian Honours List of date 9th June, 1938. We offer them our congratulations:—

C.I.E.

Lieutenant-Colonel N. S. Jafar, Inspector-General of Prisons, Central Provinces and Berar.

Lieutenant-Colonel E. H. Vere Hodge, Professor of Medicine, Medical College, Calcutta, and First Physician to the College Hospital, Bengal.

O.B.E.

Lieutenant-Colonel A. N. Bose, Professor of Pathology, Prince of Wales' Medical College, Patna, Bihar.

Lieutenant-Colonel L. K. Ledger, Civil Surgeon, Peshawar, North-West Frontier Province.

M.B.E.

Captain E. Benjamin, Assistant Director of Public Health, Sind.

J. E. R. Heppollette, Clinical Assistant to the Professor of Midwifery, King Edward Medical College, Lahore, Punjab.

Lieutenant R. Holmes, Quarantine Medical Officer, Bahrain, and Medical Officer-in-Charge, Victoria Memorial Hospital, Bahrain, Persian Gulf.

T. Jadwiga, Mrs. Subramania Iyer, Director, Maternity and Child Welfare Section of the United Provinces Branch of the Indian Red Cross Society.

L. A. Marion, Mrs. Macgregor, Matron, Irwin Hospital, Amraoti, Central Provinces and Berar.

Kaisar-i-Hind Medal (First Class)

Miss C. Tyzack, Matron, Medical College Hospital, Patna, Bihar.

Kaisar-i-Hind Medal (Second Class)

Miss C. B. M. Adderly, Missionary Doctor, Society for the Propagation of the Gospel, St. Catherine's Hospital, Cawnpore, United Provinces.

Miss P. K. Chaudhuri, Lady Doctor, Female Out-door Department, Howrah General Hospital, Bengal.

Miss E. Paterson, Nursing Superintendent, Dow Memorial Hospital for Women, Gujerat, Punjab.

Miss E. E. Tucker, lately Medical Superintendent, Methodist Mission Hospital, Ikkadu, Chingleput District, Madras.

H. H. Keswani, Private Medical Practitioner, Sind. S. Noronha, Honorary Secretary, Bombay Social Hygiene Council, Bombay.

Kaisar-i-Hind Medal (Third Class)

Miss E. France, Nursing Sister, Afghan Mission Hospital, Peshawar, North-West Frontier Province.

A. R. D. Dalvi, Inspector of Sanitation and Vaccination, Thana S. D., Thana, Bombay.

B. B. Deshpande, Inspector of Sanitation and Vaccination, Ahmednagar District, Bombay.

Sardar Bahadur

Sardar Sahib Sardar Sohan Singh, Punjab, Civil Medical Service, Amritsar, Punjab.

Khan Bahadur

Mr. Fazlur Raschid, Superintendent and Medical Officer, Edulji Framjee Allbless Leper Home, Trombay, Bombay.

Rai Bahadur

Rai Sahib Jasoda Nand Srivastab, Civil Surgeon, Ghazipur, United Provinces.

Pandit Bhuvan Chandra Pant, Civil Surgeon, Budaun, United Provinces.

Rao Bahadur

Mandalam Subramania Ayyar Avargal, Honorary Surgeon (Retired), Government Hospital for Women and Children, Madras.

Rao Sahib Vidya Sankar, Chief Medical Officer, Kotah State, Rajputana.

Khan Sahib

Mr. Abdul Kahir, Medical Practitioner, Calcutta, Bengal.

Muhammad Hafizul Haqq, Civil Assistant Surgeon, Subdivisional Hospital, Barh, Patna, Bihar.

Rai Sahib

Mr. Mahadev Ganguli, Medical Practitioner, Calcutta, Bengal.

Mr. Satyendra Kumar Sarker, District Health Officer, Rangpur, Bengal.

Pandit Lakshman Prasad Misra, Honorary Medical Officer, Sardar Hospital, Etawah, United Provinces.

Mr. Lakshmi Narain Mathur, Honorary Dental Surgeon, Benares, United Provinces.

Mr. Sashi Mohan Rudra, Selection Grade Sub-Assistant Surgeon, Civil Hospital, Kalaw, Burma.

Babu Radhika Prasad Ghosh, Civil Assistant Surgeon, Patna City Hospital, Patna, Bihar.

Mr. Chhotubhai Shankarbhai, Sub-Assistant Surgeon, Ajmer-Merwara Medical Department, Ajmer-Merwara.

Jemadar Lala Ruplal Kohli, in Sub-Charge, Cantonment Hospital, Mhow, Central India.

Mr. Isaac Santra, Propaganda Officer, British Empire Leprosy Relief Association (Indian Council), New Delhi.

Rao Sahib

Mr. Walajapet Vijayaraghavan Perumal Avargal, District Health Officer, Madras.

Mr. Kashinath Vishnu Chipkar, Civil Surgeon (Officiating), East Khandesh, Jalgaon, Bombay.

Mr. Mysore Gaikawad, Chief Medical and Sanitary Officer, Avargal, Madras States.

Current Topics

Difficulties in the Use of Protamine Zinc Insulin

By ELLIOTT P. JOSLIN, M.D.

(From the *Journal of the American Medical Association*, Vol. CX, 1938, p. 90.)

THE advantages of protamine zinc insulin are so marked that one is loath to lay undue emphasis on difficulties in its use which have been great enough to lead a few patients to return to regular insulin. I have encountered thirty-eight of these and will now briefly describe them, because in general such a return was unnecessary. This is plainly evident because already eight of the thirty-eight have resumed protamine zinc insulin. The temporary omission of protamine zinc insulin was due in five cases to lack of knowledge of its use on the part of the patient, which resulted in reactions and in one case to lack of confidence in it because the preliminary period of instruction had been too short. Another patient gave it up because of a projective trip, quite rightly believing that on a journey long acquaintance with regular insulin would make its employment safer than protamine zinc insulin, with which she had slight experience. The final patient of this group had simply been given protamine zinc insulin in a series of test experiments for which he deliberately came into the hospital.

Experience in the treatment of patients with protamine insulin or, as now employed, protamine zinc insulin certainly does help in transferring patients on regular insulin to protamine zinc insulin. Thus before 1st October, 1936, 64 per cent of our patients taking protamine insulin alone or combined with calcium or zinc could be classified as showing either excellent or good results, whereas since 1st October, the percentage has risen to 73. Confidence in the use of protamine zinc insulin on the part of the physician also is an important factor. Now we know from the statistical summaries made that our patients taking protamine zinc insulin or even combined regular and protamine zinc insulin do better than those on the former plan of treatment.

There is no gainsaying the fact that eight patients of the remaining thirty returned to regular insulin because they were convinced that the protamine insulin did not control the diabetes. Such a condition could have been avoided in two instances if the physician had not raised the carbohydrate in the diet during the transfer. These patients had been on a fairly low carbohydrate diet, and so seldom do we use so low carbohydrate values to-day that thoughtlessly we increased the same too much or too rapidly. The duration of the diabetes in one of these cases was eighteen years, and the other began in childhood and already was over twelve years. Three other persons who were living very useful and active lives and had survived diabetes by fifteen years did not get as good control of the disease with protamine zinc insulin as with regular insulin, even though they tried both protamine and protamine zinc insulin. They had been accustomed to regular insulin in two or three doses and in this manner could live so efficiently and with such freedom from glycosuria or reactions that they felt happier returning to the regular insulin even with its multiple doses. It is my personal belief that if these three patients cared to take the time to learn how to use regular and protamine zinc insulin together, because they undoubtedly would require combined doses, their diabetes would be far better controlled and they could live quite as efficiently. It is true that to do so it would be necessary that the old idea of changing the dosage of insulin from day to day would be replaced with the increase or decrease of diet to attain results. Two of these patients did not feel as well generally,

and although they were not showing reactions I suspect that the fact that their blood sugar tests were on a much lower level than on which they had lived for years may have been a factor in this disability. Such patients should be changed to protamine zinc insulin very gradually. Furthermore, physicians and patients too should realize that protamine zinc insulin acts for such a long period that there is no use in altering doses daily, but one should be guided by the result of tests over a period of days.

It is true that with protamine zinc insulin occasionally one has a day of unexplained heavy glycosuria even though apparently conditions are identical. I myself do not believe that the conditions have been identical in such cases but rather that without recognition on the part of the patient more food may have been taken quite honestly; in the second place, less exercise in one form or another or more exercise may have been introduced. Then the insulin may not have been injected in quite the same manner. I grant that such days were not as commonly encountered with regular insulin, but there is no use denying the fact that protamine insulin may not be as uniformly absorbed as the regular insulin. I do not think that this irregularity often occurs, and I have less inclination to think so, because with U-80 protamine zinc insulin the results are quite equivalent to a dose obtained with U-40 insulin and such an action one would not expect if the protamine zinc insulin was absorbed very irregularly.

Habit plays a great factor and involuntarily an intelligent patient learns how to live after fifteen years of experience with diabetes. For one who suddenly takes up new methods, life cannot be expected to run as smooth a course.

Of this group of eight, one was notable because severe neurologic symptoms occurred following reaction with protamine zinc insulin. Whether these had any connection with the actual reactions I am in doubt, because this patient had had reactions before with regular insulin and they might have been related to these. Furthermore, it is very questionable, in my mind, whether the neurologic symptoms were not from some other cause. One neurologist interpreted them as multiple sclerosis and another considered that they were part of an organic lesion in the brain. At first we supposed that they were simply manifestations of neuritis so frequent in diabetes and that they had no connection with the reaction. When I last saw the patient a cerebral accident appealed to me most as the etiologic factor for the symptoms, and it is true that in a young man without other cause suspicion falls on the type of insulin which chanced to have been used. No similar instance has been encountered in the 1,250 and more patients taking protamine zinc insulin.

Consideration of the three patients who in the past habitually took liberties with their diet and adjusted their insulin for this purpose calls for a more careful discussion. They found it more difficult to follow such practices with protamine zinc insulin than with regular insulin, although I think they could have done so provided they had added a little regular insulin as a second dose later in the day. Thus Wilder with patients in coma and I with surgical patients and with patients with infectious diseases have used protamine zinc insulin as a basic treatment, and in addition regular insulin has supplemented it depending on the condition of the urine collected at intervals of from four to six hours. Before protamine zinc insulin came in we were accustomed to recommend the fraction according to the result of Benedict's test

red	orange	yellow	green	blue
20	15	10	5	0

units at the respective intervals of four, six or eight hours. With the use of protamine zinc insulin the figures would drop approximately one half.

The five patients who gave up protamine zinc insulin permanently because of reactions were led to do this largely because of reactions developing during exercise. There is no doubt that with protamine zinc insulin

carbohydrate is better utilized and there is less available for use during muscular exertion unless the supply is increased. The patients who are trained first with protamine zinc insulin learn this readily, but other patients who have been habituated to regular insulin have great difficulty in acquiring this knowledge and utilizing it as a routine technique during exercise. Diabetic patients to-day follow such active lives that I believe that, if there is any tendency in any given patient to a reaction, the patient must be brought up to take carbohydrate between meals and on retiring. It simply will not do for the diabetic patient to develop the reputation that he is liable to become unconscious or to have convulsions at any odd moments.

The type of reaction that the protamine zinc insulin patient endures is distinctly uncomfortable. The headache lasts a long time and is not promptly relieved with carbohydrate. The nausea may be very annoying. There are other reasons than protamine zinc insulin, however, for headache and for nausea and these must be sought before laying the blame on protamine zinc insulin. Nevertheless, it is a fact that the headache is depleting and that the nausea is dangerous because it confuses the diagnosis with appendicitis and diabetic coma.

The occupations of three patients were of so varied and changing types that to-day I would hesitate to recommend protamine zinc insulin as the chief basis for their treatment. These were well-trained diabetic patients; they had had their disease for years, had worked and laboured to secure these special occupations and to their precious jobs they had adjusted their entire lives; years of trial and error had been devoted to this object, and a week or two or even a month or two of trial with protamine zinc insulin could not equal what they had accomplished with years of use of regular insulin.

The remaining ten cases of the series in which protamine zinc insulin was given up can be placed in a miscellaneous group. Again here one encounters two instances in which the intelligence of the patient was not equal to the use of the combined regular and protamine zinc insulin, although with a milder type of diabetes the patients could have been brought up to live on protamine zinc insulin alone. There was another patient, a problem child, and still another with encephalitis and one with unusual oedema of doubtful origin. The three patients had been confused because in the early days of protamine insulin we had been obliged to transfer from one preparation to another as new varieties appeared, and in two others we simply did not insist on a long enough period of treatment before discharging the patient.

A hospital stay is not always necessary for a diabetic patient who is to use protamine zinc insulin, but I do think that a hospital stay is very essential if one is to attempt to change a patient who has lived for years successfully on regular insulin over to the combined regular plus protamine zinc insulin. These patients simply must see others going through the process so as to learn the mistakes that can occur. They think they know all about the management of their diabetes, and it is only by having them under observation, where they can watch others as well as themselves, that one can secure the best results. When I see Mrs. St. C., who for months was compelled to take nearly 500 units of regular insulin daily, now living comfortably on regular insulin 100 units and protamine zinc insulin 300 units, each given before breakfast, it makes me confident that any case needing far smaller quantities of insulin could be adjusted satisfactorily. The patient in question has gained from 87 pounds (39.5 kg.) up to 111 pounds (50 kg.). The cause of her insulin resistance need not be discussed here, because eventually a more extensive report will be made; but her case is cited as showing what one can do with protamine zinc insulin and as a hint that other cases far less severe, when the conditions are right, can be managed as well. The number of cases of considerable severity managed satisfactorily on combined regular and protamine zinc insulin almost daily convinces me how

satisfactorily protamine zinc insulin can act. Furthermore, the fact that not one patient who has started his treatment with protamine zinc insulin has been changed to regular insulin in the course of twenty-two months is another argument for the efficiency of protamine zinc insulin. Patience, time and the will on the part of both patient and physician to secure the full benefit which protamine zinc insulin can confer, in my opinion, will surmount any temporary difficulties.

Nutrition and Diet in Northern India : A Comparative Dietary Survey

By DAGMAR CURJEL WILSON, M.D. (Glas.),
M.R.C.P. (Lond.), M.C.O.G., D.P.H.

Women's Medical Service, India (Retd.)

and

E. M. WIDDOWSON, Ph.D.

(From the *Lancet*, Vol. II, 18th December, 1937,
p. 1445)

THE survey is of the diet of 120 families, Hindu, Indian, and Sikh, and it records the nutritional state of 6,000 children belonging to these wheat-eating races. The purpose of the investigation was to correlate diet and stature, and to ascertain whether differences occur in the incidence of disease among the different races, and whether diet influences susceptibility to certain infectious diseases. The method chosen was to study the food as eaten in a sampling of the homes, and to make measurements and observations on the children deriving from such homes. The communities studied are of rather special interest because they include the Sikh community with whose diet McCarrison made his well-known demonstration with rats (1926-27, 1932). When fed from youth throughout the growing period on a reproduction of the Sikh diet these young rats grew far better and were far freer from disease than their fellows, reared on a reproduction of a poor Western European diet or of inferior Indian diets, particularly those of rice-eating peoples.

Hindus, Muslims, and Sikhs living in Northern India are acclimatized to both heat and cold. Many are virile folk known to be physically strong, among whom, when not otherwise occupied, family feuds are not uncommon; from amongst these races many military recruits are obtained. Girls in Northern India are well cared for, and the age of marriage is usually higher than in other parts of the country. The staple crop in the north is wheat which is eaten by all, usually in the form of whole wheat flour, coarsely ground and baked, of which McCay has shown 80 per cent of the protein to be absorbed. There are certain racial differences in the diet. *Hindus*, except among the lower castes, do not usually include flesh in their dietary. They use a variety of pulses and vegetables and fruits, and as much cow's milk and clarified butter as they can afford. *Muslims* eat meat, but usually not in any large amount. They tend to cook their vegetables together with meat, and to use more rice and less milk and clarified butter than *Hindus*. *Sikhs*, where economically possible, combine the best of Hindu and Muslim diets, and are partial to the use of buffalo milk with its high fat content in preference to cow's milk.

DIETARY SURVEY

The dietary survey was supervised personally by the author speaking the vernacular. A period of ten consecutive days in the winter season was chosen for observation. In Northern India, except for any untoward incident such as the failure of crops, the amount and character of the diet is fairly constant throughout the year, save that during the hot season diluted buttermilk is generally drunk.

Records were obtained from 120 families containing 730 persons; this total was made up of equal numbers of Hindu, Muslim, and Sikh families, of which half in each case were urban and half rural, in the relatively

prosperous district of Sialkot in the Punjab. Families were chosen of different economic and social status, to represent the different types of homes from which school-children were drawn. The homes were visited twice daily before the cooking of the principal meals, and the foodstuffs were weighed on a portable balance. In an Indian household there is little waste; it is customary to cook the amount of food that will be used. Allowance was made for guests, and for food given in charity and to animals. As far as possible only the actual parts of food to be cooked were weighed. To handle food after cooking was not allowed, and estimates regarding the effects of cooking are not available.

The social and economic status of the family and its consequent purchasing power were checked by inquiries as to sources of income, but calculations as to net income were not reliable, and the profession of the principal breadwinner was judged to be a more satisfactory indication of family status. From such data and from personal inquiries in bazaars, and from the study of the accounts of boarding-schools and institutions, it is concluded that for an expenditure of 4 annas (about 4d.) per head daily on foodstuffs an adequate, balanced diet can be easily obtained. The age and sex composition of each family were recorded, with the total intake of the various food constituents. The analysis of foodstuffs was carried out at the Nutritional Research Laboratory, Coonoor.

NUTRITIONAL STATE OF THE CHILDREN

Examinations of the nutritional state of 6,000 children, Hindu, Muslim, and Sikh, in approximately equal numbers, were carried out in the winter season by the same observer. All the children were between the ages of 5 and 14 years. The children were living at their homes, where the investigation was made, and consuming the racial diets, indicated in the previous section. Proportionate numbers were examined from the different social classes served by primary, middle, and high schools. About one-quarter were at rural schools, and more than half the total number were girls.

INCIDENCE OF DISEASE IN RELATION TO NUTRITION

Inquiries were made about the clinical incidence of disease, hospital records being supplemented by personal inquiries from medical practitioners, and by visits to hospitals. Not many generalizations emerged suitable for inclusion within the scope of this summary. The large number of children who suffered from greatly enlarged tonsils in all classes of schools housed in insanitary quarters within ancient walled cities was noteworthy. Of girls between 4 and 14 years of age, 1,348 were examined in urban areas, and 771, more than half, showed diseased tonsils. In rural areas the figures were somewhat less bad; of 731 examined about one-quarter (176) had this defect.

The relation of diet to malaria was studied in villages round Delhi where the investigation of the Malarial Survey of India has shown malaria to be endemic and a very high rate of infection to exist. Very many children showed signs of anæmia and debility, and few had access to quinine.

DEFICIENCY DISEASES AND CONDITIONS ASSOCIATED WITH DIETARY FACTORS

Signs of deficiency disease were remarkably infrequent; 3,985 children between 5 and 14 years old were examined from this point of view, and, of these, 107 showed follicular hyperkeratosis (phrynoderma), 24 had angular stomatitis, none buccal stomatitis, 6 had Bitôt's spots, and 43 had rickets. There was thus some slight evidence of vitamin-A deficiency but it did not appear to be widespread.

Conditions frequently met with in certain other parts of India are uncommon among these northern races. Leprosy occurs in the submontane regions of the north, the infection being carried down the passes by wandering tribes from the Central Asian highlands, but leprosy is rare in the plains of Northern India. Spastic paraplegia is rare and peptic ulcer relatively uncommon.

In pregnancy the numbers of cases of anæmia and of eclampsia are small compared with those seen in women's hospitals in other parts of India, and peripheral neuritis associated with pregnancy is very rare. Statistics about maternal mortality in India are often misleading, but such information as is available suggests a lower mortality in the north. The occurrence of late rickets and osteomalacia, often an important contributory cause of high maternal mortality, among certain other northern peoples living under conditions of deficiency of food or sunlight or both, has already been described.

On the other hand, vesical calculus occurs frequently and has a definite 'social incidence', being commoner among the poorer classes. Its association with the wheat diet and hot summers of Northern India has been noted by McCarrison and others.

HEMOGLOBIN ESTIMATIONS

Records were obtained of 166 children from more educated families who volunteered to be 'pricked'; these were boys and girls between the ages of 5 and 15 years attending three large northern public schools. The average percentage hæmoglobin was 83.7 ± 0.5 (S.D. ± 6.3) with a Dare hæmoglobinometer standardized so that 100 per cent equals 16 g. hæmoglobin. Many children stated that they had attacks of fever in the autumn, and this was confirmed by the guardians, but all were in a position to cut short an attack of malaria with quinine.

SUMMARY AND CONCLUSIONS

The dietary intake of 120 families containing 730 persons of the wheat-eating communities, Hindu, Muslim, and Sikh, in a relatively prosperous region of Northern India was recorded, and the nutritional adequacy of the diets was assessed by a physical examination of 6,000 children consuming them. The dietary records are analyzed by Dr. E. M. Widdowson, who reports that the intake of calories, proximate principles, calcium, phosphorus, and iron are adequate when calculations are based on the international scale of consumption units, but that when the Stiebling scale is applied the calcium appears to be slightly deficient in all the diets. The results of the physical survey of the children are analyzed statistically by Mr. Carl Wait, who reports that the amount of subnormality is slight, about one-fourteenth of the children on the Sikh diet, about one-sixth on the Hindu, and about one-fourth on the Muslim being assessed as somewhat subnormal. Only one child in the whole series was actually classed as 'bad'.

It can therefore be concluded that the diets studied and the physical condition of those consuming them are by no means unsatisfactory, and that McCarrison's experimental demonstration with rats of the excellence of the Sikh's wheat-containing diet is fully borne out.

The table shows the average intakes of calories, proximate principles, calcium, phosphorus, and iron, per consumption unit per day, for the six different groups studied. It is apparent from this table that in many respects the average results for the various groups are similar to one another, so that certain generalizations may be made.

The calories lie between 2,300 and 2,900, lower than the figure 3,000 suggested as desirable by most authorities but probably not inadequate. The protein intake, 70 to 90 g. a day, compares well with the commonly accepted figure of 70 to 100 g. for a man's protein requirement. The intake of animal protein, on the other hand, is always very low when judged by European and American standards, all but one group having less than 20 g. a day. Little or no meat is eaten, and almost all the protein is derived from cereals. Milk and milk products provide the small supply of animal protein. The fat consumption is also low in comparison with this country, but no optimum or minimum requirement for fat has been suggested, so there is no evidence that the intake is inadequate. The fat is derived mainly from milk products. The amount of carbohydrate is high, because of the large quantity of cereals eaten.

TABLE

AVERAGE INTAKE OF CALORIES, PROTEIN, FAT, CARBOHYDRATE, CALCIUM, PHOSPHORUS, AND IRON
per consumption unit (international values) per day

Group	Total number of persons	Total number of consumption units	Calories	Animal protein (g.)	Protein (g.)	Fat (g.)	Carbohydrate (g.)	Calcium (mg.)	Phosphorus (mg.)	Iron (mg.)
Hindu urban	94	72.9	2,319	9.9	69.8	49.2	382.9	773	1,654	30.4
Hindu rural	121	92.0	2,720	8.5	81.4	53.1	459.7	813	2,047	39.2
Muslim urban	121	84.8	2,485	26.8	84.2	57.0	397.9	826	1,874	31.6
Muslim rural	158	110.0	2,506	9.4	75.3	39.2	445.8	609	1,854	34.7
Sikh urban	116	86.4	2,776	16.0	87.9	59.2	454.7	1,005	2,118	36.3
Sikh rural	125	94.7	2,908	13.0	89.4	58.6	487.5	987	2,207	40.2

In summer especially, diluted buttermilk in varying amount may be drunk and this has not been included in the records. Amounts of 3 oz. or less of undiluted buttermilk will make no appreciable difference to the protein, fat, carbohydrate, or iron, but the calcium and phosphorus may be increased by 25 mg. a day.

In considering mineral intakes, it is usual in investigations of this sort to take the figures suggested by Sherman, 0.68 g. of calcium, 1.32 g. of phosphorus, and 12 to 15 mg. of iron a day, as standards for adult requirements of these elements, and to compare the findings with them. Actually, Sherman's values were never intended to be used as absolute standards, but only as a rough guide to requirements. Since, however, no other standards for mineral requirements are in existence, Sherman's figures have been adopted, but with full realization of their limitations.

When calculated on the international consumption unit basis, the average intakes of calcium, phosphorus, and iron may be considered adequate in all groups, and the iron intake is remarkably high. This iron is obtained mainly from whole wheat.

A comparison of the results for Hindus, Muslims, and Sikhs shows that, although there are no great differences, and Sikhs have the best diet throughout, their consumption of every constituent is higher than that of either of the other two groups. There is little to choose between the results for the Hindus and the Muslims. A further point of interest is the difference between the diets of urban and rural communities. The rural diets are in all cases higher in calories than the corresponding urban diets, owing to a greater consumption of cereals and hence of carbohydrate in the country. The town-dwellers, on the other hand, tend to have more animal protein, and this is especially noticeable in the case of the Muslims who eat a small quantity of meat.

The results shown in table are average results for 20 families in each group. There is considerable variation from family to family in the intake of all constituents. With calories, for example, there are one or more families in each group having more than 4,000 calories per consumption unit per day, and there are usually several having only 1,000 to 1,500. A number of families have no animal protein at all, while one Muslim urban family had 146 g. per consumption unit per day.

Oxygen Want and Oxygen Therapy

(From the *British Medical Journal*, Vol. I,
29th January, 1938, p. 235)

ALTHOUGH a great deal of information was to hand, from the Haldane and Bancroft schools of research, regarding the effects of oxygen want on respiration and blood gases respectively, what was actually happening in the cells and tissues was not so clear.

This required more direct study of gas pressures in the tissues themselves. Normally in the resting subject the oxygen pressure in the extracellular fluids—for example, serous fluid, lymph, urine—and probably in the cells themselves, is certainly not zero, but varies for different regions between 20 and 40 mm. Hg. or 3 to 6 per cent atmosphere, while the carbon dioxide pressures are about 40 to 60 mm. Hg. or 6 to 8 per cent. As might be expected, these figures, which apply to man and all laboratory mammals tested, resemble the pressures usually given for gases in venous blood. Effects of oxygen want and oxygen therapy upon tissue gas pressures may be easily tested with experimental animals. Thus acute oxygen want, apart from the histotoxic variety—for example, poisoning with cyanide, which affects the ferment system—always lowers the oxygen pressures in the tissues considerably, and if the fall is much below 40 per cent of the normal death results. Life is not possible with a tissue oxygen pressure in general anywhere near zero. Locally a zero oxygen pressure is approached only where there is pus, necrosis, and stasis of circulation—for example, in pyopneumothorax or in the large intestine with food present and fermentation proceeding.

As regards acclimatization to the more severe degrees of oxygen want, the oxygen pressure in the tissues is not raised to normal again even when there is increase both in volume breathed and in red cell count. Such increases seem to be used not to raise the tissue oxygen pressure to normal again but to relieve the work of the heart that is to limit the minute output. Acclimatization is due to the vital organs becoming accustomed to function under the lowered tissue oxygen pressure. Possibly there are changes in the cells concerning such substances as the glutathione of Sir Frederick Gowland Hopkins and the reactions described by Professors Warburg and Keilin. Oxygen secretion, if it does occur in the lungs, is—like any other factor in the body—not capable of keeping the oxygen pressure in the tissues at a normal level during severe degrees of oxygen want. Another important result is that administration of oxygen—even in only double the normal (21) percentage—definitely raises the oxygen pressure in the tissues in a normal animal. This affords the scientific basis for oxygen therapy.

Concerning the powers of endurance, it is found that mammals cannot live continuously in regions where there is only 10 per cent or less of oxygen in the atmosphere; this is equivalent to an altitude of about 20,000 feet. Such degrees of oxygen want cause atrophy, degeneration, and even necrosis in the liver,

heart, brain, and other organs. This limit of 10 per cent was first established with laboratory mammals, and has recently been confirmed for a highly selected community in the South American Andes, as recorded by Dr. Ross McFarland. Some sulphur miners there work at a slow pace at 19,000 feet, but find that they cannot continue in health if they sleep and live continuously above 17,500 feet. Their camp at 17,500 feet is claimed to be the highest permanent village in existence. The miners descend to 12,000 feet for a proper game of football and also send their wives to this level for confinement, though fertility appears to be maintained at 17,500 feet, where the arterial blood saturation with oxygen is about three-quarters of normal. It is obvious that the Everest climbers should not spend too long camping above 18,000 feet. Some of these climbers, like the experimental animals, have exhibited some *temporary* resistance, but, since at 27,000 to 28,000 feet the climbers are reported to have suffered from delusions and to require ten breaths for each step forward, oxygen should be at hand to prevent further calamity in these very high regions.

That mammals cannot live continuously in an atmosphere containing only 10 per cent of oxygen leads to interesting conjectures. Some authorities hold that at one early period of the earth's existence there was not free oxygen in its atmosphere and life was anaerobic; the oxygen now present was freed, under the influence of the sun, by that green plant life which laid down enormous deposits of coal. Dr. W. M. Clark, who has carried out important researches on oxidation-reduction potential, considers that oxygen is a scavenger clearing up the waste products of cell metabolism by combustion. From the above it might be tentatively suggested that when mammals were first sprouting from the tree of life the oxygen present in the surrounding atmosphere had risen above 10 per cent, and that is why mammals cannot now become acclimatized to lower oxygen pressures. When the condition of a patient with oxygen want resembles that of an individual forced to breathe less than 10 per cent of oxygen continuously recovery is impossible.

Turning to modern oxygen therapy, the late J. S. Haldane and others—including Professor Dutrebande—have much improved the mask method employed by Beddoes (1760 to 1808) at Bristol; he and Chaussier (1780) appear to be among the first to administer oxygen to patients. Some of the present forms of mask apparatus are too heavy for weak patients but are inexpensive to run and of service for the stronger patients. Sir Leonard Hill introduced the recent chamber and tent methods, but the first comfortable chamber was that of Sir Joseph Barcroft at Cambridge, while tents have been much improved by Dr. A. L. Barach and others. The chamber, or room, methods are the most comfortable, but running expenses are high. Even the simplest tents—for example, the Guy's Hospital tent and the open-top tent of St. George's Hospital—though cheaper than oxygen chambers, cost up to about thirty to forty shillings a day to run, and often demand constant skilled attention. Still cheaper and simpler methods for nurses are the twin catheter method, the forked nasal tube, and the box mask or face tent; the nasal methods cannot be used with blocked nasal passages. Tents seem valuable for children and for the more restless patients.

Oxygen therapy should of course be used in all cases of excessive dyspnoea and asphyxia as emergency treatment. Also in diseases with cardio-respiratory embarrassment it may certainly keep a patient alive and enable other therapy—for example, serum in pneumonia—and natural processes to produce a favourable result. Pneumonia, the disease most frequently treated with the aid of oxygen, is responsible for about 500,000 patients, with 100,000 deaths, a year in the United States, where much research is being directed towards reducing this incidence and mortality. With less than half the population of the United States, England and Wales (1936) had 46,000 cases, with over 30,000 deaths. The value of early treatment with oxygen—within the first six hours of onset—in lessening

serious complications seems to have been proved in America. Pure oxygen should be used for short periods only—a few hours—the limit recommended for prolonged treatment being 60 per cent, since with higher percentages the late Lorrain Smith found evidence of damage to lung tissue.

Professor Yandell Henderson's advocacy of carbon dioxide as a respiratory stimulant is justified; for carbon monoxide poisoning 7 per cent carbon dioxide with 93 per cent oxygen gives the best results, according to a prolonged test in the New York emergency service. In anaesthesia and asphyxia neonatorum 5 per cent carbon dioxide with 95 per cent oxygen is useful. Dame Louise McIlroy's apparatus is simple and efficient with the newborn. Artificial respiration is often used in conjunction with oxygen therapy; the Sharpey-Schafer method is still the simplest and most efficient for general purposes, and there is also the recent rocking method of Dr. Ewe. The Bragg-Paul pulsator for rhythmic compression of the chest is simple and useful for prolonged periods; it kept a patient with progressive muscular atrophy alive for some years. The Drinker apparatus, although complicated, is perhaps the most physiological, and has been much used in respiratory paralysis. Some recent and fairly full data seem to show that with this Drinker treatment only about 10 per cent of the cases with bulbar respiratory paralysis *eventually* recovered, as did about 30 per cent of cases with spinal respiratory paralysis; nevertheless the *immediate* and dramatic value of the apparatus is obvious.

Permissible Claims for Benzedrine Sulphate

(From the *Pharmaceutical Journal*, Vol. CXL,
8th January, 1938, p. 28)

AFTER consideration of the available evidence, the Council on Pharmacy and Chemistry of the American Medical Association has agreed to accept benzedrine sulphate for inclusion in 'New and Non-Official Remedies' providing that the claims for the usefulness of the drug do not exceed the following stipulations:—

Narcolepsy.—Benzedrine sulphate is useful for the treatment of narcolepsy and for controlling symptoms similar to those of narcolepsy in the treatment of post-encephalitic Parkinsonism. Its use is not recommended in the treatment of sleepiness and fatigue in normal individuals, because of the possible danger of pressor effects from continued use, the dangers of eliminating the warning signal of sleepiness in individuals who are over-working, because of the possibility of habit formation or addiction from such use and because cases of collapse have ensued when the drug has been used for this purpose.

Mental effects: mood and fatigue.—Benzedrine sulphate is useful in the treatment of certain depressive psychopathic conditions. Its use is not recommended for developing a sense of increased energy or capacity for work, or a feeling of exhilaration or as a 'pick-me-up' in individuals other than those under the strict supervision of the physician. The Council believes that its use for these purposes should be confined to institutions, since the dangers involved in the use of the drug for this purpose in those going about their daily tasks are similar to the dangers mentioned in connection with fighting off sleep.

Gastro-intestinal effects.—Benzedrine sulphate is useful in facilitating roentgenographic study of the gastro-intestinal tract, but it is not recommended at present for use in the treatment of spastic colitis and pylorus spasm. Further evidence is necessary before serious consideration can be given to other clinical applications.

Reactions and contra-indications.—The very nature of the therapeutic effects as well as side actions of this drug require that its use be promoted with proper cautionary statements as to pressor effect, hyper-excitability, gastro-intestinal disturbance, restlessness and sleeplessness and in overdosage, chills, collapse and syncope. It should also be carefully noted that the

drug is contra-indicated in those having cardiovascular disease, especially when hypertension is a sequence of that disease.

Dosage.—The use of the drug should be instituted with a dose of 2.5 to 10 mgm., and it is recommended that no single dose exceed 20 mgm. In certain conditions it may be necessary to repeat the use of the drug two or three times daily. It is preferable, if possible, to administer the effective quantity during the morning.

The Significance and Treatment of Indigestion

By ERNEST BULMAR, M.D., F.R.C.P.

(Abstracted from the *Practitioner*, Vol. CXL, February 1938, p. 135)

THE meaning of some words differs according to the user, and indigestion is one of these; even to the medical man the word has no fixed meaning. He would probably intend to convey that abnormal sensations were felt in the abdomen during the course of digestion, that is before, during and after meals—he would expect any pain or discomfort to be above the umbilicus, and he would not include sensations arising during phases other than peptic digestion; he would not admit conditions associated with swallowing or with defaecation, and it is certain that he would not dub as indigestion pain arising from gallstone colic, acute pancreatitis, or even coronary thrombosis. Whether or not he would call the pain of peptic ulcer indigestion I do not know; his attitude would be to evade the issue and call the condition a gastric or duodenal ulcer.

I have not been able to fathom the layman's conception of indigestion, and it is obvious that he has many meanings when he uses the term. How many times have physicians thought they had discovered a history of duodenal ulcer in the applicant for life assurance when he admitted having had indigestion? A little deeper inquiry, however, showed that it was merely an occasional headache, or spots in front of the eyes, or undue fatigue at night, or lack of concentration which he had interpreted as due to some difficulty in digesting his food, although there had been a complete absence of the abdominal symptoms of such a disturbance of function. In hospital work the term is equally indefinite, and seems to mean flatulence in most of the patients.

There is something much more sinister in the implications of the complaint of acute indigestion; it is usually made when the patient suspects that the severity of a pain is much more than can be simply accounted for, one feels that he is using a euphemism to deceive his relatives but probably not himself, and certainly not his doctor. I have learnt to respect the unexpressed fear but to search for some grave explanation in the three cases of severe upper abdominal or substernal pain seen by the physician—gallbladder, cardiac, and pancreatic pain.

It would seem elementary to caution the unwary never to accept the patient's complaint of indigestion, but to press him to explain exactly what he means. Whether the term should be retained in medical parlance is doubtful—gastric discomfort is much better described as dyspepsia, which does at least indicate what phase of the digestive process is disordered; nevertheless it might be profitable to explore what is actually meant by the term. My own vague conception is that indigestion comprises that medley of conditions characterized by abnormal sensations in the upper part of the abdomen, but in which investigation fails to show evidence of such obvious causes as gastric or duodenal ulcer or gastric cancer; I envisage a chronic and not an acute condition, and one which produces long continued discomfort rather than a risk to life.

INCIDENCE OF INDIGESTION

During the period from 1st January, 1930, to 15th October, 1937, I have seen personally 9,580 new

outpatients and 2,262 of these had disturbances of the digestive system, a percentage of nearly 25.

If my definition of indigestion is applied to a series of 2,170 outpatients the following list can be made:—

	Number of patients
Aerophagy	103
Gastric neuroses	20
Dyspepsia of uncertain origin	288
Gastroparesis	24
Chronic gastritis	111
Upper abdominal colic	33
Spastic colon	102
Viscerospasm	75
Chronic cholecystitis	100
TOTAL	856

I am doubtful about the admissibility of chronic cholecystitis, but I have left it in as it is so important a cause of difficult dyspepsias.

I propose to deal briefly with the diagnosis and treatment of each of these groups, and for this purpose I have chosen to go through both my hospital and my private case notes rather than to give merely a 'textbook' description—many of the conditions are so elusive in their clinical features that even the diagnoses I have given are made with some misgivings.

AEROPHAGY

This troublesome condition may seem too trivial to write about, but it accounts for 10 per cent of disorders of the alimentary tract if the mouth, pharynx and gullet are excluded; it has been in my experience a condition which usually goes unsuspected by the patient's medical attendant; it gives rise to symptoms which are as troublesome as those of serious organic diseases of the alimentary tract, and rarely it can cause an acutely painful abdominal distension suggesting a volvulus. Aerophagy is merely a bad habit, but it cannot be too strongly insisted that the habit is sometimes learned in an attempt to relieve by gastric distension the pain of a duodenal ulcer. In every case such a pathological condition must be excluded; this is not difficult as hospital patients must have their desire for an x-ray satisfied, and private patients usually arrive with a sheaf of films. There are two mechanisms by which air is allowed to enter the stomach in uncomfortable quantities; it may be swallowed unconsciously (in some patients there is an audible pharyngeal tic) and when there is a feeling of uncomfortable distension the victim tries to belch, in doing so he swallows more air and this can be proved by laying the hand on the epigastrium and feeling air gurgle into the stomach. Much of the air passes into the bowel and adds colicky pains to gastric discomfort. The second mechanism is rare—the patient closes the glottis and then suddenly depresses the diaphragm so that air rushes into the stomach as the sole channel available.

The symptoms of the condition vary considerably—they can best be illustrated by quoting a case history:—

Female, aged 39 years.—This patient consulted me on 19th August, 1931, and said that for five months she had had severe 'indigestion', although there had been previous attacks of a similar nature. On questioning she told me that her symptoms were those of epigastric distension after food especially, but occurring at other times. Occasionally there was slight pain, but never in relation to meals. She brought a set of skiagraphs of the alimentary tract and a report that the sole abnormality was a low and rather atonic stomach. Her general health had suffered and she felt a considerable loss of energy. Examination was negative except that she was of the ptotic type and her right kidney was palpable; her behaviour on being asked to 'bring up some wind' was typical of aerophagia. My notes end with the two remarks 'sensible woman', 'aerophagia'. I explained the condition to her, and I heard from a relative four

months later that she cured herself in a few days and lost her symptoms.

Diagnosis is simple; aerophagy is suspected if the patient complains of 'flatulence' and questioning reveals that there is considerable and prolonged belching of an odourless gas; before a diagnosis is made, however, it is necessary to see the patient swallow air, and he is asked to bring up some wind; the true aerophagic will at once oblige, and continue until stopped—some indeed have been heard performing before a crowd of envious and sympathetic outpatients, but when the habit has become such an admired accomplishment it is usually incurable.

Treatment is simple but as it depends upon the co-operation of the patient it is necessary to explain to him that so large a quantity of gas cannot be formed within the stomach, and if it were formed there it would only be the result of fermentation and then it would be offensive and inflammable; when the patient has grasped this principle he is asked to lay his hand on his epigastrium during an attempt at belching and to note the gurgle. He is told that he is making matters worse by his active efforts, and forbidden to belch again, except the allowable post-prandial eructation. The next step is to ask him to watch most carefully that he is not unconsciously swallowing air, and after a few days he will realize what he has been doing and stop it. All this requires intelligence, and without intelligent co-operation the treatment of the case is impossible. There are occasionally physical conditions leading to aerography, such as ill-fitting dentures or post-nasal catarrh, and these need appropriate treatment; after the healing of a duodenal ulcer aerophagy may persist but can be put right by explanation; after an operation the condition again is not infrequent, but most good ward sisters are fully alive to its existence and take steps to eradicate the habit before the patient's discharge. I have had no experience of the various carminatives and mechanical devices for the relief of air swallowing, but I adopt the attitude that if the patient has not the intelligence to understand what he is doing he must retain his uncomfortable accomplishment.

GASTRIC NEUROSES

Among 1,576 patients with gastric symptoms, 327 had conditions without an obvious physical basis—gastric neuroses 20, anorexia nervosa 14, dyspepsias of uncertain origin 288, vomiting of uncertain origin 5; this gives a percentage of about 20, and whilst this figure cannot be more than approximately accurate I feel that it errs on the low side—the physician finds a physical explanation if he can do so. The criteria for making a diagnosis of gastric neurosis are arguable—the history may be typical in some cases, there must be a rigorous exclusion of organic disease by a complete physical examination, radiological and biochemical studies, and for the exclusion of gastritis gastroscopy is now becoming a practicable step. Whilst organic disease must not be missed the psychological explanation of symptoms must not be overlooked in order that the correct treatment may be adopted; the neuroses must be diagnosed with trepidation—I have had the painful experience of seeing a cerebral tumour develop in a man in whom I had made a diagnosis of hysterical vomiting. The psychologist is of little help in establishing a diagnosis; all that he is justified in saying after interviewing the patient is that a psychological factor may be producing the symptoms, but he cannot say that such a factor definitely is the cause. A normal individual may be 'sick with excitement', he may lose his appetite through fear, boredom may (popularly at least) give him 'a pain in the stomach'—these things any layman can corroborate. One of a sensitive make-up will react similarly to conditions of long continued excitement, to persistent anxiety, and to overwork, whilst the neuropath is in a state of continual suppressed fear or anxiety about something or nothing and the alimentary tract is a favourite site for the fixation of attention in the hypochondriac, and in the obsessional states.

Treatment must be entirely psychological, and as such it should be given only by the trained psychological expert, the practitioner's duty ending when he has made as definite a diagnosis as thorough investigation will allow. In a certain proportion the results are excellent, but the group includes many of the most hopeless, confirmed and incurable neurotics that are encountered. The following case is given by way of illustration:—

Male, aged 30 years.—This young bank clerk was referred on account of vomiting during and after meals, unassociated with pain; he had lost a considerable amount of weight, felt weak and disheartened, and was anxious about his ability to retain his post. Physical examination and the usual investigations proved negative so I sought the aid of a psychologist. It was found that the patient was the only child of elderly parents who were members of a narrow religious sect which regarded pleasure as sinful; the son had accepted these doctrines until he had become engaged, and had been led into a wider social life entailing a certain number of dinner and supper parties. These he enjoyed, but a conflict at once arose between his enjoyment of the things of the flesh and his religious conviction that such things are sinful. He began to vomit immediately after such parties, then he became nauseated before them and had to go home—at other times he was unable to swallow. Later the same symptoms arose during meals at home. By tactful psychological help his symptoms were recovered completely, and after about three months he recovered completely, and has remained well apart from one mild relapse.

CHRONIC GASTRITIS

In 10 per cent of the 1,121 patients with organic disease of the stomach or duodenum I have made a diagnosis of chronic gastritis; this has been inferential as gastroscopy has not been an available method of investigation in the series studied. I have felt that organic disease of the stomach existed but had difficulty in naming the lesion except by most indirect evidence—furring of the tongue, rarely a diminution of the gastric acidity with excess of mucus (the alcoholic type is now rare), negative radiological examination of stomach and gallbladder. Probably the re-introduction of the term gastritis of recent years has led to its too free use, but nevertheless there are certain interesting clinical types.

(1) *Simulating ulcer*.—Pathological examination of stomachs, either excised at operation or specially fixed immediately after death, has clearly proved the existence of an antral gastritis or of a duodenitis giving rise to symptoms indistinguishable from those of ulcer. Clinically, such a diagnosis may be made if the symptoms of ulcer are overwhelming and the radiological examination is negative (in the duodenum, however, a negative x-ray must be accepted with hesitation). In a recent case the gastritis has been demonstrated gastroscopically and I am now adopting this procedure in these cases. The treatment is the same as that of peptic ulcer.

(2) *Simulating cancer*.—I have had several elderly patients complaining of loss of appetite, epigastric pain, some nausea or vomiting, and marked loss of weight in whom x-ray examination proved negative, and a test-meal inconclusive; I have watched them whilst they continued at home on a strict ulcer-diet, and I have seen in a few months a disappearance of symptoms, and a steady gain in weight. They have all been watched for sufficiently long to exclude any possibility of a growth, but with considerable anxiety—opportunities for pathological or gastroscopic study have been lacking.

The case quoted below is another example of this group:

Male, aged 60 years.—This man was a healthy farmer and had had no illness of note; he had had grossly infected gums and his teeth were all extracted—six weeks later he began to feel sick and fairly rapidly he developed nausea, complete loss of appetite, and vomiting with marked loss of weight. Physical

examination was negative, a test-meal showed a very high acid curve with a trace of blood in the first specimen, and an absence of mucus; x-ray examination showed a deformed pylorus with some stasis. On this evidence surgical intervention was deemed essential with a diagnosis of cancer of the stomach; at operation the stomach was normal externally, and there was no sign of gallbladder disease—a chronically inflamed appendix was removed. He made a slow recovery on the usual regime for ulcer, but the only diagnosis possible was that of chronic antral gastritis. Gastroscopy at that time was not available.

(3) *The classical type.*—It is unnecessary to describe the clinical picture of alcoholic gastritis, and the similar conditions due to faulty diet, bad teeth, and other causes. There seems no sphere which so merits further study as that of gastritis, both from the points of view of aetiology, of pathology and of treatment—the latter being far from satisfactory, especially in gastritis with high acidity in which resort has even been made to the old fashioned silver nitrate treatment. I have not considered the atrophic types of gastritis with achylia—they do not appear to produce gastric symptoms, and are of interest chiefly in their relation to the anemias

SPASTIC COLON

If the broad rule that gastric and duodenal disorders produce pain above the umbilicus were more generally stressed, this group would not be included; spastic colon may produce predominantly colonic symptoms—lower abdominal pain and constipation with attacks of severe colic—but it is not uncommon for a patient to complain of a pain coming on either immediately after food or some hours after and relieved by the next meal—symptoms so far resembling those of gastric or duodenal disease—but when asked to point out the site of the pain he indicates that it is below the umbilicus, extending from the right to the left iliac

fossa. X-rays exclude a peptic ulcer but show a markedly spastic condition of the large bowel. Such cases are usually well controlled by a low-residue diet, the avoidance of irritant purgatives, and sufficient beladonna to relieve the spasm—it will be seen that they form a not inconsiderable group and account for 102 cases.

GASTROPTOSIS AND VISCEROPTOSIS

These terms must remain indefinite. I have applied them to patients in whom there has been no evidence of organic disease, but who were of the hyposthenic type with a narrow costal angle, a wide pelvis, and palpable kidney or kidneys. Radiology has shown a low position of the viscera, and organic disease has not been found. Probably they would best be classified among the neuroses, but they are such a well-marked physical type that there is presumably some connection between this and their sensitive alimentary tracts—they seem to be unusually aware of the working of their abdominal autonomic nervous systems. So far as treatment is concerned, I have no contribution to make to the depressing problem.

UPPER ABDOMINAL COLIC

This term has been applied to a group of patients who are subject to sudden attacks of severe epigastric colic of a few hours' to a few days' duration with long intervals of complete freedom. Peptic ulcer, gallbladder disease and other obvious causes have been excluded and the diagnosis remains conjectural, doubtless some are pancreatic colic, but this is impossible to prove, the rest remain unsolved problems.

CHRONIC CHOLECYSTITIS

I mention this group for the sake of completeness—that it comprises only 5 per cent of the whole suggests either that cases have been overlooked or that they are referred direct to the surgeons.

Reviews

THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE INCLUDING MEDICINE, SURGERY, OBSTETRICS, GYNÆCOLOGY, AND OTHER SPECIAL SUBJECTS.—Edited by Sir Humphry Rolleston, Bart., G.C.V.O., K.C.B., M.D., D.Sc., D.C.L., LL.D. To be completed in eleven volumes. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Cash price—Rs. 25 per volume. Also available on the instalment system at Rs. 10 per month, price—Rs. 26-8 per volume

ONE of the first problems that young medical men and women have to face when they start in practice is the question of their library. They will be appalled by the number of books published each year and above all by the frequency of the appearance of fresh editions of the few books they do possess, so that they never have the satisfaction of feeling that their libraries are in any way up to date.

Whatever special line they decide to follow they will learn that they have first of all to be physicians and though they make a special study of some particular branch of medical practice they will find that they cannot divorce the knowledge they acquire from that of general medicine, and further that it is not sufficient simply to start with a sound knowledge of general medicine, but if they are to be successful they must keep this knowledge up to date. The first requisite therefore for the library of any medical man or woman is a good reference book on general medical practice and the second is some means of supplementing from time to time the information contained therein. Few can afford to discard their old (in the sense that any medical book becomes 'old' in a few years) books and

purchase the latest publication, even if there is a suitable one available.

It is some years since a comprehensive and authoritative 'system of medicine' was published in Great Britain, comparable in any way to Clifford Allbutt's classical work, and it is very appropriate that the task of editing such a work should be undertaken by a physician and writer of the eminence of Sir Humphry Rolleston, who assisted Sir Clifford in the last edition of his 'system'.

The publication of a *British Encyclopædia of Medical Practice* has been undertaken by Messrs. Butterworth's, the well-known legal and medical publishers. We are now in a position to talk not of promise but of actual achievement, as already six volumes of this very important mine of medical knowledge have been published. One of the main drawbacks of a work of this kind is usually that the first volume is out of date long before the last has been published, but a feature of this publication is the very commendable promptitude with which the volumes have appeared, so that at the end of a little over a year six volumes have already been issued: the original estimate that the work would be complete in nine volumes will not however be adhered to, as the sixth volume has only taken us as far as 'J'.

This work we feel will solve the problem to which we referred in the opening paragraph of this review, of finding a really reliable and comprehensive book of reference on general medicine, and the difficulty of keeping up to date is being met by a promise on the part of the editor and publishers that supplementary volumes will be issued from time to time.

We shall review the volumes one by one in this journal but we must first refer to the general arrangement and the format of the work. The subject-matter is arranged alphabetically and each chapter is prefaced with a summary of the subject in the form of a list of section headings, in which excellent use has been made of large type: this not only facilitates rapid reference but gives one a bird's-eye view of the subject if one proposes to read the chapter through. The page itself is an exceedingly pleasing one, the type is large and clear and the marginal captions form excellent guides without breaking up the page, and incidentally one's train of thought, as ordinary captions, when used in excess, are liable to do. The binding is serviceable but very attractive, dignified but not sombre, and it gives one the impression that it will stand up well to the ravages of India's climate and smaller fauna. The volumes are examples of the best type of British medical publication and they have a further recommendation, peculiar to British medical publications, in that they are very reasonably priced.

We very strongly recommend any of our readers who can possibly afford it to invest in this medical encyclopædia.

L. E. N.

A TEXTBOOK OF X-RAY DIAGNOSIS.—By British Authors. (In three volumes.) Edited by S. C. Shanks, M.D., P. Kerley, M.D., M.R.C.P., D.M.R.E., and E. W. Twinning, M.R.C.S., L.R.C.P., D.M.R.E. Volume II. 1938. H. K. Lewis and Company, Limited, London. Pp. xii plus 458, with 307 illustrations. Price, £2 2s.

THE reader's attention is drawn to the review of the first volume of this very important publication in the last number of the *Gazette*.

The major portion of this volume is devoted to the alimentary tract; the subject is divided into 25 chapters which cover over 300 pages. There are four shorter sections on the biliary tract, the abdomen (the solid viscera), gynaecology, and obstetrics, respectively.

We commend particularly to clinicians the sections on normal variations in the various structures: it is tempting for the radiologist to justify his existence, and also for the clinician to justify his advice in recommending an expensive examination by finding some irregularity somewhere. A thorough knowledge of the normal picture and the possible normal variations will help him to follow the dictates of his conscience and say 'nothing abnormal found'.

The opinion expressed on the x-ray diagnosis of appendicitis is cautious: attention is focussed on the appendix region and the writer does not suggest, as some radiologists and surgeons do, that certain appearances in other parts of the intestinal tract point definitely to chronic appendicitis; in fact his advice to those about to have their appendices removed on x-ray evidence alone, can be summed up in the word 'Don't'.

When gastric carcinoma becomes clinically obvious it is too late to do anything about it. The writer suggests that an x-ray diagnosis can be made earlier than a clinical one. This may be true of certain types of carcinoma, but we do not think that he has established his case here, and we cannot agree that when gastric carcinoma is clinically apparent there are always unequivocal x-ray signs.

The same very high standard is maintained in this second volume.

MODERN TREATMENT IN GENERAL PRACTICE: A YEAR-BOOK OF DIAGNOSIS AND TREATMENT FOR THE GENERAL PRACTITIONER.—Edited by C. P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E., F.A.C.S. Volume IV, 1938. Butterworth and Company (India), Limited, Calcutta. Pp. xii plus 440. Illustrated. Price, Rs. 7

THE reprinted special articles from our very practical contemporary the *Medical Press and Circular* have proved so popular amongst general practitioners, especially amongst those in the colonies and in foreign

countries, that already three series have been published. The title used for these has been *Modern Treatment in General Practice*. The publishers have now broken away from the practice of numbering these as volume I, volume II, etc., and are using the year instead to distinguish between the different series. If this change means that they are proposing to publish such a book each year, it is good news, as these books have done much to facilitate the work, and improve the scientific outlook, of the general practitioner.

The scope of the present volume is slightly wider than that of its predecessors and nearly half the articles are from the series 'Pitfalls in Diagnosis'. These articles are as practical and useful as the ones on treatment, as in most instances when an accurate diagnosis is made the treatment is automatic.

The articles range from such obviously important subjects as artificial pneumothorax in the treatment of phthisis to ones of such very great practical importance to the family physician as the treatment of chronic discharging ear in children. The *Ebers papyrus* recommends the incense of goose grease and cream from the milk of a cow, or as an alternative a concoction of asses' ears, red lead, caraway and olive oil. Mr. Charles Beney does not, but he considers that the common factor in all good treatment for the last three and a half millennia—he does not go further back than that—was cleanliness, and he might add dryness.

The quality of all the articles in this book is of the high standard that we can always count on in the *Medical Press and Circular*. There is a change in the colour of the binding to mark a slight change in policy, but otherwise the format is the same and the book is distinguished for its lightness, an important point in a book of this kind.

L. E. N.

FORENSIC MEDICINE: A TEXTBOOK FOR STUDENTS AND PRACTITIONERS.—By Sydney Smith, M.D. (Edin.), F.R.C.P. (Edin.), D.P.H. Sixth Edition. 1938. J. and A. Churchill Limited, London. Pp. xvi plus 654, with 169 illustrations. Price, 24s.

THE book is by an author with large practical knowledge, and like another excellent book on the subject was originally inspired by the wealth of medico-legal work at Cairo.

The field covered is complete. All practical details are given. Non-essential descriptions do not exist. 'The human spermatozoon', for instance, 'consists of a head, neck and tail' only. When stained as described 'details of the neck will probably not be made out'. Again, 'to avoid mushroom-poisoning the only safe rule is to leave mushrooms alone. . . There are no simple rules for excluding poisonous varieties'.

Comments may be made on three points in chapter XI, which deals with the examination of blood-stains:—

(i) The second absorption band in the spectrum of hæmochromogen, in the green, does not really look broader than the first band in the yellow, in spite of the fact that the statement supported by a diagram is found in books.

(ii) No mention has been made of Sutherland's method of performing the precipitin test. It is undoubtedly the best. In it there is no possibility of obtaining a false reaction with monkey's serum. This point needs special comment inasmuch as legal opinion in India may be affected by the book.

(iii) The hypothesis of von Dungern and Hirsfeld should now be thrown overboard. Bernstein's triple allelomorphism has come to stay. Combinations, AB parent with O child and O parent with AB child, are not possible.

The size, the paper, the printing and the binding are good. No printer's errors arrest attention.

The book should be on the desk of medico-legal workers anywhere.

S. D. S. G.

A TEXTBOOK OF MEDICINE.—By Charles Phillips Emerson, M.D. 1937. J. B. Lippincott Company, Philadelphia and London. Pp. xxv plus 1296. Price, 36s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 27

THE range of medicine has increased so much of late that it is almost beyond the powers of a single individual to cover the whole ground himself. Sir William Osler and Sir Frederic Taylor will perhaps be the last to have made the attempt. At the same time there is a definite advantage in having only one author, so that the book does not lose its uniformity and continuity. Dr. Emerson should be congratulated for bringing out this textbook of medicine which has several unique features. Internal medicine has been presented in terms of the clinical features of the disease, which have been explained by pathological, biochemical and other findings. A disease syndrome has been regarded as the defensive process and not a mere expression of the activity of the invading organisms so that the aim of treatment should be not to suppress but to render the symptoms unnecessary. Short biographies of a few of the men to whom we are indebted for advances in medicine have been given, for better understanding of a disease in the light of historic developments. Special scientific explanatory paragraphs and footnotes have been given, which are useful.

The book is very comprehensive; omissions are remarkably few. The relative space designed to each subject is fairly proportionate, except that on anæmias, which require more attention. There are selected references at the end of each subject. Reference to Napier's work in connection with kala-azar should have been included for more accurate information regarding its diagnosis, otherwise anyone reading this section will be guided to search for Leishman-Donovan bodies also in the spinal fluid, urine and stool.

On the whole, the book is good and can be recommended to physicians and medical students.

R. C.

TEXTBOOK OF GASTROSCOPY.—By N. Henning. Translated by H. W. Rodgers, F.R.C.S. 1937. Oxford University Press, London, Humphrey Milford. Pp. 86. Illustrated. Price, 7s. 6d.

THE study of gastric disease has long been handicapped by the lack of a method of examining the mucosa in its normal state. Post-mortem and even operation specimens are unsatisfactory, in the first because of the great change which occurs rapidly after death, and in both because of the limited nature of the material available for study. Gastroscopy has shed new light on many of our old conceptions of gastric disease, showing that some were wrong and others right. It has solved many problems for us, and raised others.

Gastroscopy cannot be practised without a gastroscope and there are not many in India. This book, however, is important in showing us the scope of this new and important diagnostic method; small though the book is, it does this very well, with the aid of many diagrams and some very well-reproduced coloured plates.

The reviewer has seen the gastroscope in use, and, though it must take a little time to perfect the technique, it is not a difficult one and the picture of the mucosa is very clear.

We strongly recommend this book, which was originally written by a pioneer and translated by an expert in gastroscopy, to both physicians and surgeons: it will, we hope, stimulate them to introduce this method more widely in India.

THE PHYSIOLOGY OF THE KIDNEY.—By H. W. Smlth, A.B., Sc.D., M.S. (Hon.). 1937. Oxford University Press, London and New York. Pp. 310. Illustrated. Price, 15s. Obtainable from Oxford University Press, Bombay and Calcutta

THIS book deals with the physiological aspects of the renal function in an able and comprehensive

manner. The function of the kidney in man and other vertebrates suggests that this organ has an extraordinarily complex structure. On close anatomical analysis, however, it is found to consist of a very large number of structurally similar and relatively simple functional units.

The subject of renal physiology has been a matter of controversy for a very long time. For example, the answer to the question as to what extent each of the three processes, filtration, tubular re-absorption, and tubular excretion, entered into the conservation or excretion of any particular substance by the kidney, remained unsatisfactory during all these years.

Starting from the theory of Ludwig in 1844 that the urine formation began only with a 'passive' process of filtration in the glomeruli and coming up to the theory of a 'specific vital activity' of the kidneys (by which process apparently they excrete everything through the glomeruli, only to salvage the valuable materials in the tubules, while permitting the waste products to escape), as advocated by Cushman within more recent years, we find long chapters of rival theories put in, all based on inconclusive evidence. Recently, however, Richards and his collaborators demonstrated beyond question the simultaneous existence of glomerular filtration and tubular re-absorption and Marshall and his collaborators demonstrated the existence of tubular excretion.

The author in a painstaking manner has gone into all the different theories of renal function and has given an excellent summary in chapter III which will amply repay perusal.

The book has been well written and the various functional tests of the kidneys simply and ably described; its perusal will be of use to students of medicine in arriving at an understanding of the mechanism underlying the physiology of the kidneys.

J. P. B.

TEXTBOOK OF OPHTHALMOLOGY.—By Sir W. S. Duke-Elder, M.A., D.Sc. (St. And.), Ph.D. (Lond.), M.D., Ch.B., F.R.C.S. Volume II. Clinical Methods of Examination, Congenital and Developmental Anomalies, General Pathological and Therapeutic Considerations and Diseases of the Outer Eye. 1938. Henry Kimpton, London. Pp. xxv plus 2094, with 742 illustrations, including 24 coloured plates. Price, 63s.

THE second volume of this classical book containing over one thousand pages is divided into four sections. The first section of the volume is devoted to the clinical methods of examination of the eye and contains chapters on the objective and subjective examinations. Section two is devoted to the aetiology of deformities, the gross developmental anomalies affecting the eye as a whole and the developmental and congenital anomalies affecting individual structures of the eye, with their pathology and treatment. Section three contains chapters on the diseases of the corneal epithelium, diseases of the cornea and finally one on diseases of the sclera. The methods of examination, deformities and diseases of the eyes are discussed in great detail. The volume has 742 illustrations and 24 coloured plates which are all excellent. These are mostly borrowed, but in each case the source has been generously indicated.

An interesting part of the book is the introduction of photographs of eminent ophthalmologists and in this volume we find those of von Graefe, Treacher Collins, Fuchs, Axenfeld, Morax and Johnathan Hutchinson. There is also an extensive list of references in each chapter.

The book is beyond praise and one marvels at the enormous amount of work involved in producing so great an achievement. The author is certainly deserving of the highest praise and congratulations, and the whole of the English-speaking world owe him a debt of gratitude, as in our opinion it is the best book on ophthalmology written in the English language. As a book of reference all other textbooks on ophthalmology fade into insignificance. We strongly recommend it to

every medical man who is interested in eye work in India.

E. O'G. K.

TREATMENT BY DIET.—By Clifford J. Barborka, B.S., M.D., D.Sc., F.A.C.P. Third Edition. 1937. J. B. Lippincott Company, Philadelphia and London. Pp. xiv plus 642. Illustrated. Price, 21s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 15-12

WITHIN the last few years our scientific knowledge of vitamin content, mineral elements and other constituents of food has increased considerably. The application of this knowledge to the treatment of disease is becoming more comprehensive each year, and diet therapy at present forms an important factor in the treatment of many diseases. The appearance of the third edition of Dr. Barborka's book shows its demand.

The book presents a practical and systematic method of prescribing diets and contains an abundance of English menus. It is divided into a preliminary part dealing with the dietetic principles in health, followed by sections on diet therapy in various diseases which have been divided into two groups, viz, the diseases such as diabetes mellitus, gout, etc., in which diet is of paramount importance and the ones, such as tuberculosis, hypertension, etc., in which diet is of varying importance. There are introductory notes in each section explaining the nature of each disease and the rationale of the diet to be prescribed.

A few new additions have been incorporated in this edition; for instance, a discussion of the present status of the clinical aspects of the vitamins has been added, the present conception of protamine zinc insulin is given; and the discussion on obesity has been broadened.

There are a few comments to be made. Treatment of sprue is inadequate; only one diet with carbohydrate content of 150 grammes has been given. There is no reference to alcohol intake in connection with the reducing diet for obesity. Infant diets have not been dealt with.

There is a useful appendix and a bibliography at the end of the book. The get-up of the volume is good.

R. C.

SISHU-KHADYA (DIETETICS FOR THE CHILDREN).—Written in Bengali. By Dr. B. B. Pal, L.M.S. First Edition. (Pravasi Press, Calcutta.) 1938. Published by Bijoy Bhushan Pal, 39-5A, Gopalnagar Road, Alipur, Calcutta. Pp. 102. Price, Re. 1

IN view of the scarcity of Bengali books on infant feeding, based on scientific knowledge, this booklet is welcome. It deals, in brief, with proximate principles of food, breast feeding, artificial feeding, ante-natal care, teething, etc. Various proprietary foods have been recommended, but without practical instructions as to the method of their use and dosage. More emphasis should have been laid on the necessity for the regular use of vitamins in the diet.

R. C.

LIPPINCOTT'S QUICK REFERENCE BOOK FOR NURSES. COMPILED AND ARRANGED FROM VARIOUS SOURCES.—By H. Young, R.N. With the assistance of G. A. Morrison, R.N., and M. Eliot, R.N. Third Edition. 1937. J. B. Lippincott Company, Philadelphia and London. Price, 9s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 6-12

THIS is a most valuable book for trained and student nurses.

It contains general information which the nurse in training will find most helpful, especially the student nurse studying for the final examination.

The description of various methods of administering treatment is of value and interest, especially that on

oxygen therapy and the description of and most useful information on sulfanilamides.

The charts at the back and front, one on the symptoms and treatment of poisons and the other on the common contagious diseases, are extremely helpful.

This book well deserves the title of 'Quick Reference', and we strongly advise all nurses to procure a copy as soon as possible.

E. M. C.

MEDICAL RESEARCH COUNCIL: SPECIAL REPORT SERIES, NO. 229. 'A CLINICAL AND GENETIC STUDY OF 1,280 CASES OF MENTAL DEFECT'.—By L. S. Penrose. 1938. Published by His Majesty's Stationery Office, London. Pp. 159. Price, 2s. 6d.

'No less than the administrative authorities, the Medical Research Council have been aware of the importance of mental defect as a social problem, and they have constantly desired to promote investigations which would throw light on its causes. They have recognized that lack of knowledge may be the main limiting factor in combating this evil, and that such knowledge can come only by means of skilfully-directed research.'

The Council agreed to co-operate with the Darwin Trust in supporting work on this subject by Dr. L. S. Penrose who has now studied, clinically and genetically, a representative group of 1,280 patients of all grades and types of mental deficiency. The present report contains the results of this extensive and prolonged investigation.

'It is of interest to note that the incidence of defect amongst parents and "sibs" of patients was estimated to be as high as from 7 to 9 per cent (the incidence amongst the patients' own children being much higher), and that this exceeds by some 6 to 8 per cent the figures for the population in general.'

'As regards the general deductions of this extensive inquiry, Dr. Penrose found no unequivocal evidence of sex-linked genes (inheritance factors) in the causation of mental defect. On the other hand, there was definite evidence in favour of Mendelian recessivity and dominance respectively in some of the rarer conditions he found among these patients, such as phenylketonuria, cretinism, microcephaly and cerebral diplegia.'

'His data and results will also be of exceptional interest to students in other fields of pure and applied science. It can be claimed that these researches constitute a new and refreshing approach to the old and much discussed problem of the relative rôles of heredity and environment in the development of the human race.'

THE DIRECTORY OF BRITISH HEALTH RESORTS, 1938: OFFICIAL HANDBOOK OF THE HEALTH RESORTS ASSOCIATION.—Edited for the Association by R. F. Fox, M.D. (Lond.), F.R.C.P., F.R.Met.S. Published by J. and A. Churchill, Limited, London. Pp. 288. Illustrated. Price, 2s. 6d.

THIS is not a commercial publication sold for profit but is issued by the British Health Resorts Association, Limited, a voluntary body which exists not to make money but to perform a national service in instructing the public in the health resorts that are available in the British Isles. This is a distinct service, for it is a popular idea amongst the public, and to some extent, among members of the medical profession, that one must go abroad to obtain efficient spa treatment. Perusal of this book will speedily disabuse a mind so misinformed.

It is a book that will be of use to all practitioners in the British Isles because they can find in it an appropriate place to recommend to their patients who are convalescing or suffering from any chronic complaints that are likely to be benefited by any special form of treatment or environment that is indicated.

It will also be of use to doctors overseas who may have patients proposing to visit Great Britain, as it will enable them to advise them where is the best place

to go if they are proceeding home on grounds of ill health. There are also notes on the main climatic features of the dominions and the principal colonies of the Empire and an indication of what special mineral springs, etc., may be found there.

The last 100 pages are devoted to advertisements of hotels in the various resorts which, according to a note on page 11 of the handbook, are vouched for by the association as well run establishments.

MALARIA IN EUROPE: AN ECOLOGICAL STUDY.—

By L. W. Hackett, M.D., Dr.P.H. 1937. Oxford University Press, London, Humphrey Milford. Pp. xvi plus 336. Illustrated. Price, 10s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

This book is so pregnant with thought, nearly every line being a concentrate of wisdom, that it does not lend itself to review.

One must simply say that to read it must humble anyone whose tendency is to be dogmatic. Like Zinsser's book *Rats, Lice and History* it is a model of an epidemiological study and to read it must elevate the merely mechanical executive medical officer to a higher plane, in fact to quite another plane.

C. S.

MEDICAL RESEARCH COUNCIL: SPECIAL REPORT SERIES, NO. 230. 'THE CHEMISTRY OF ANTIGENS AND ANTIBODIES'.—By J. R. Marrack.

1938. Published by His Majesty's Stationery Office, London. Pp. 194. Illustrated. Price, 3s.

MEDICAL bacteriologists are of necessity closely concerned with chemical studies which may lead to fuller knowledge of the conditions of life of pathogenic micro-organisms, or to better understanding of the responses—often highly specific—which these organisms

evoke when they invade the human body. Work on these lines, if progress is to be made, must obviously take account of fundamental advances in the science of chemistry, and it is therefore important that knowledge of these advances and of their bearing on the special problem should be made readily available to the investigators. Dr. Marrack has accordingly collected the more important results of recent experimental work upon the chemistry of antigens and anti-bodies, and has reviewed that subject in the light of present-day knowledge of molecular structure.

KEESING'S MEDICAL DIGEST. Published by Messrs. Keesing's Medical Digest Limited, 1, Regent Street, London, S.W.1. The Subscription is very low, being one guinea for Great Britain (two years £1-18-6) and £1-5-0 (two years £2-5-0) abroad, postages and a new binder for every year, included. (Publishers are willing to send a specimen volume for perusal to everyone who asks for it, without any cost or obligation)

THE 'digest' habit is growing in all forms of literature. In this connection the name of Keesing is well known. They have now issued a medical digest which is combined with a diary, the whole forming a very handy book that can easily be slipped into the pocket. Each month they issue about 32 pages of 'digest' of recent work likely to be of value to the practitioner. It is printed on very thin but opaque paper in a small-page form. A three-monthly index is issued. There is also a diary with a full page for each day and special forms for confinements and cash accounts. All these are held together by a very neat and serviceable spring-hinged cover.

The idea is a good one and well executed. The extracts given in the first three months of the 'digest' that have so far been received are practical and are taken from a representative collection of journals of several countries.

Abstracts from Reports

THE SEVENTH ANNUAL REPORT OF THE ASSOCIATION FOR THE PREVENTION OF BLINDNESS, BENGAL, 1936-37

THE Committee of the Association for the Prevention of Blindness, Bengal, have great pleasure in presenting the Annual Report of the Association which has recently completed the seventh year of its existence. It started in the year 1930 under the patronage of the Hon'ble Lady Jackson and has had to surmount great difficulties in the way of finance and provision of propaganda material. It has now grown into one of the public utility services in Bengal and has amply justified its existence by the amount and quality of the service rendered and it is gratifying to know that the lay public are becoming more awake to the importance of prevention of blindness and the cure of eye disease. From all districts in Bengal appeals for assistance are being received but owing to limited finances many have to be turned down.

It is a matter of congratulation for everyone connected with the movement that Her Excellency the Marchioness of Linlithgow has graciously consented to become the patroness of the association. Her Excellency's patronage should give a big stimulus to greater efforts in this worthy cause.

One of the principal aims of the association was achieved during the year, namely, the organization of a first travelling eye dispensary, which is the first of its kind in India. The dispensary, called the 'Jubilee Travelling Eye Dispensary', started on the 28th March, 1936, with the object of preaching the gospel of prevention of blindness and bringing the benefits of modern ophthalmology to the very doors of the people in remote villages. This travelling eye dispensary has

proved to be a tremendous success and from every sub-division in which it has worked glowing reports were received of its popularity and usefulness. The committee were inundated with letters and telegrams begging that the dispensary might be kept longer in the area in which it was working. As much ground had to be covered, only three months could be allotted to each district. May the day be not long distant when the aim of the committee is accomplished, to establish in Bengal one travelling eye dispensary for each division, namely, five in all.

The committee hope in the coming year to start a travelling boat eye dispensary in East Bengal to work on the same lines as 'The Jubilee Travelling Motor Eye Dispensary' using the rivers instead of the roads to bring the benefits of modern ophthalmology to the remote villages and to teach methods of prevention of blindness.

In the campaign for the prevention of blindness it is perhaps not yet realized that the problem is largely one of the prosperity of the people and the great bulk of preventable blindness will gradually diminish as the standard of living improves. If the standards of living throughout India were the same as in Europe then the problem of blindness would be the same as in Europe. Speaking broadly, the prevention of blindness in India is not a medical problem but a social, economic and financial one.

It is gratifying to know that His Excellency the Viceroy has made it his ambition to make the Indian countryside a better and happier place to live in and large sums of money have already been set aside for financing schemes in rural areas which aim particularly at providing a good water supply, improved sanitation, and improved methods in the breeding of cattle.

Other noticeable improvements are the establishment of union board dispensaries, better roads, village schools, libraries and playing grounds for rural schools. From every quarter one sees evidence that Government are concentrating their activities on rural development, which has been so neglected in the past. The fulfilment of these schemes must lead to a general improvement in the health of the people and as a necessary corollary a diminution in the amount of preventable blindness.

Take, for example, the disease keratomalacia, one of the great causes of preventable blindness in children. It is due to lack of fat in food and, with improvement in the standard of living and public health, will gradually disappear. At present all that the medical department can do is to provide cod liver oil to the few who come to the hospitals for treatment.

At present the Government is not prepared to spend money directly on prevention of blindness but by the development of rural areas it has commenced to spend it indirectly.

The problem of prevention of blindness in general is so immense, it is important to face facts and realize that the remedy cannot be successful for many years and that the most important work of an association for the prevention of blindness is to bring home to the members of the administration and the people in general the importance of prevention of blindness and the cure of eye diseases and suggest remedies for prevention and cure.

PROPAGANDA

Propaganda activities have considerably increased during the year under review. These have been rendered possible on a wider scale in the *mofussil* by the travelling eye dispensary which did splendid work in the three districts it toured during the year.

Posters form one of the most important vehicles of propagating instruction in methods of prevention. They are simple, attractively colourful and have succeeded in attracting the attention of the public. They were freely distributed through the Bengal Branch of the Indian Red Cross Society and the Jubilee Eye Dispensary and to Health Exhibitions, various hospitals, *mofussil* dispensaries, to medical men and others interested in the movement of prevention of blindness.

Magic lantern slides form another very important part of propaganda work. The association possesses two magic lantern slide lectures entitled:—

- (1) 'Care of the Eyes', with 32 slides.
- (2) 'Prevention of Blindness', with 54 slides.

These slides have been made locally and copies together with copies of the lectures can be obtained by applying to the Honorary Secretary at the office of the Association for the Prevention of Blindness, Bengal, at the Eye Infirmary, Medical College Hospitals, Calcutta.

Popular lectures are regularly given by trained eye doctors in schools, colleges, and other places under the supervision of the honorary secretary of the association. These lectures are essentially practical and consist of simple methods of prevention and treatment together with magic lantern slide demonstrations and they are delivered according to the special syllabus prepared and printed for the guidance of the lecturers. They have been greatly appreciated and have been found most useful for educating teachers and their pupils in methods of prevention of blindness. The cost of those lectures has been met by a grant from the Indian Red Cross Society. Each lecturer is paid Rs. 20 for a course of two lectures. Many lectures were also delivered in the districts of Burdwan, Birbhum and Bankura by the Medical Officer-in-Charge of the Jubilee Travelling Eye Dispensary whilst working in those places.

The cinema film in two reels entitled 'Lamps of Life' has been shown freely in different places in Calcutta and in the *mofussil*. Copies have been lent for exhibitions and health exhibitions and a copy can always be obtained on loan from the registered office of the association.

The association is well equipped with booklets on subjects which are important in the prevention of blindness and the care of eye diseases. They are written by ophthalmologists in a very simple language and are well illustrated. These booklets are being gradually translated into Bengali and Urdu. Requests for copies of these booklets and posters keep coming from different parts in and outside Bengal.

The association as usual took a prominent part in the Annual Health Week Exhibition held at the Museum in Calcutta and in many other health exhibitions held in and outside Calcutta. It provided models, posters, booklets, magic lantern slides and films, etc. A trained ophthalmologist was put in charge who gave demonstrations and delivered lantern lectures.

It is unfortunate that India is so backward in the development of broadcasting, as in other countries it has proved a tremendous weapon for propaganda purposes and its uses in prevention of blindness would be enormous.

Occasional lectures have been delivered from the Calcutta Broadcasting Station but the people whom broadcasting at present reaches are few.

During the year epidemic dropsy was prevalent in many parts of Bengal, outbreaks also occurred in parts of Bihar, the United Provinces and Burma. The disease is almost exclusively confined to Bengalees. It is more commonly called *beri-beri* by the public although it is an entirely different disease. *Beri-beri* is due to food deficient in Vitamin 'B', whilst epidemic dropsy is a bowel disease associated with the ingestion of diseased, stored, parboiled rice or according to some authorities of impure mustard oil.

As pointed out in last year's report, glaucoma is a frequent complication of epidemic dropsy and is one of the worst diseases that can affect the eyes and unless the correct treatment is given it leads to partial and often complete blindness. It is a disease that can to a large extent be prevented and information for its prevention and cure has been disseminated on many occasions through the lay papers and the radio.

Large numbers of patients suffering from epidemic dropsy and glaucoma in all its stages present themselves at the various hospitals in Calcutta for treatment.

If one visits the various out-patients' departments at the eye hospitals in Calcutta, one sees piteous sights of children, adults, middle-aged and old people blinded by this disease. Surely it is a Bengal tragedy. A booklet on epidemic dropsy and glaucoma has been brought out by the association and copies can be obtained on request.

FINANCE

In the General Fund, the total receipts including the opening balance for the year were Rs. 12,619-3-4 against Rs. 7,750-15-3 of the previous year and the expenditure was Rs. 5,253-3-3 against Rs. 4,352-7-3 of the previous year, and increase in income was mainly due to more members enlisted and donations received.

Subscriptions and donations in 1936-37 amounted to Rs. 3,367-4-3.

The association has safely passed through the difficult stage of infancy owing to the magnificent efforts of honorary workers who have spared no pains to see the association grow to its present position and usefulness. The activities have greatly extended and spread to different spheres in the year under report. One travelling eye dispensary has been established and plans are far advanced to start a boat travelling eye dispensary in East Bengal which it is hoped will come into existence in the middle of 1937. Much, however, requires to be done and the committee are fully alive to the fact. Funds are required and it is hoped that the committee will not be hampered by lack of these. The cause is a noble and worthy one. An extract from an article by the Editor, *Indian Medical Gazette*, of February 1937, is here not out of place:—

'The above extract shows what a live and progressive body this association is and that in the six years of its existence it has maintained its progress in spite of the fact that this period included the worst years of

trade depression when even firmly established charitable organizations suffered severely. The executive of this association is to be congratulated on the manner in which it is steadily expanding its activities and we know of no more worthy object to which the charitably minded might subscribe, for it is clear from this report that any funds available are carefully spent so that the subscriber can feel assured his money is being expended in full for the object for which it was given.

[We feel we cannot do better than endorse the remarks quoted above as they are equally applicable to the seventh year's work of this important association.]

THE REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES IN THE PUNJAB FOR THE YEAR 1936

Due to financial stringency the year 1936, like its predecessor, has been an uneventful one so far as new developments and expansion of medical relief are concerned. No hospital was provincialized during the year. Normal activities of the department, however, show encouraging results. Five new dispensaries were opened and three of those already existing were closed during 1936, thus raising the total number to 961, of which 687 are in rural areas. Available accommodation for in-patients in hospitals open to the public was increased by 342 beds, of which Jullundur district alone claimed 148, and Lahore 48, as a result of the opening of the Rai Bahadur Amar Nath Tuberculosis Institute attached to the Mayo Hospital, Lahore. The scheme of subsidized dispensaries is on its trial. The annual cost of such a dispensary is estimated at Rs. 1,100 as against Rs. 2,500 of a rural dispensary. At present the entire cost of maintenance of rural dispensaries is borne by Government and it is highly desirable for local bodies to exert themselves to provide funds for the opening of new dispensaries in areas where medical relief is not adequate.

The total number of in-patients and out-patients treated shows an increase of 7.85 lacs as compared with the previous year. Due to heavier rains malaria was more prevalent during the year under report and accounts for an increase of 1.48 lacs out of the total number given above. Next to malaria, diseases of the ear and skin showed the largest increase and the least and only an insignificant increase was recorded in the number of tuberculous patients. The Inspector-General of Civil Hospitals rightly remarks that the figure recorded is not a true indication of the extent to which unfortunately tuberculosis is prevalent. The total number of surgical operations performed showed an increase of 14,278 over the previous year's figure of 592,442, the percentage of deaths remaining constant at 0.20.

The expenditure of the department increased by Rs. 1,39,844 to Rs. 51,32,145, the increase being mainly accounted for by repairs and renewals of apparatus (Rs. 40,227) and the annual increments of the staff (Rs. 47,326). As usual, little income was received from fees. The standard rules for charging fees from well-to-do patients introduced in August 1935 have not proved a success so far, partly because the public have long been pampered by free medical treatment and partly because the local bodies have not followed the lead. Excluding a sum of Rs. 40,000 received from Their Majesties' Silver Jubilee Fund and Rs. 7,500 from the Killa Gift Fund, Lyallpur, instances of public charity were fewer than last year.

The addition of Rai Bahadur Amar Nath Tuberculosis Institute as a self-contained unit for the treatment of tuberculous patients, both in-door and out-door, is a valuable addition to the usefulness of the Mayo Hospital, Lahore, which maintained its popularity for treatment on the most up-to-date and modern lines. The hospital has an x-ray and electrical department of its own. The existing apparatus is shortly to be replaced by a new one at a cost of Rs. 93,000. The surgical work done in the civil hospital, Amritsar, covers a wide field and of the total operations, which

numbered 5,955, cataract accounted for as many as 2,143. Difficulties are reported in accommodating in-patients during the 'eye-season'. This indicates the necessity of building an ophthalmic hospital and relieving the congestion in the main hospital. The proposal for extension of accommodation will be considered when the financial position of the province permits. The Ripon Hospital at Simla also continues to be handicapped by lack of accommodation. Proposals for its expansion are under consideration. The Lady Willingdon Hospital, Lahore, is now popular with all classes of the public, the daily average attendance being 92.61. Six hundred and fifty-four labour cases were treated during the year under report. This number provides clinical material for 48 students only, while the total number of students to be trained every year is 77. It was, therefore, necessary to make arrangements for the training of the rest of the students at Madras. This is only a makeshift arrangement, the permanent solution being to increase accommodation of in-patients in the hospital in order to train all the students of the King Edward Medical College, Lahore. Proposals are under the consideration of the Inspector-General of Civil Hospitals for providing additional accommodation for 116 in-patients on the present site or for building a new hospital for 200 patients on another site. The Teka Devi Health Centre has been completed and is now ready for the reception of patients. The provision of radium at a cost of Rs. 40,000, sanctioned from His Late Majesty's Silver Jubilee Fund, has proved very useful in the treatment of carcinoma cervix uteri. Forty-five such cases were treated in 1936 against 26 in the previous year. The popularity of the Lady Aitchison Hospital, Lahore, can be judged from the fact that the average daily attendance of new patients in the out-patient department went up from 86.01 in 1932 to 140.40 in 1936. The existing staff of the Punjab Dental Hospital is reported to be insufficient to cope with the work, and it may be necessary to appoint additional dental surgeons if the work goes on increasing at this pace. The Lady Hailey Women's Hospital, Bhiwani, and Memorial Mission Hospital, Ludhiana, are doing splendid work in the cause of medical aid for women. The arrangements made at the latter hospital for the treatment of pulmonary tuberculosis are reported to be excellent. All these hospitals maintained a creditable standard of efficiency in spite of the handicaps under which some of them had to work for financial reasons.

A sum of Rs. 60,826 was paid by Government during 1936-37 towards the maintenance of the inmates of the five leper homes in the Punjab, as compared with Rs. 59,400 during 1935-36. The scheme for the establishment of a settlement for 'burnt out' cases in the Lower Bari Doab Colony, mentioned in the last year's review, had to be dropped as unworkable.

New hospitals at Ludhiana, Jagraon and Alipur will be built in the near future, as the existing buildings are in a bad condition. Government have read with regret that local bodies are not doing their duty so far as improvements to hospital buildings in their charge are concerned. They are said to be content to look forward to the day when the provincialization scheme will shift the responsibility of their reconstruction on to Government. There are 66 hospitals and dispensaries maintained by local bodies that still remain to be provincialized, as and when provincial finances permit. The process of taking over by Government will of necessity have to be spread over a number of years and meanwhile it is highly desirable that local bodies should keep these public buildings in a proper state of repair.

The year shows a remarkable increase in the number of women patients, both indoor and outdoor. Thanks to the combined efforts of the Medical, Public Health, Education and Rural Reconstruction Departments and Indian Red Cross Society, there are signs of a general awakening in the public, who have begun to realize the necessity of the proper medical aid for their womenfolk. This has brought to the fore the problem

of making adequate provision for female medical aid to meet the growing demand. Separate women's hospitals exist in a few district headquarters, while the rest have women sub-assistant surgeons in charge of women's sections attached to main hospitals. Jhelum has neither, but it has the Mission Hospital where the arrangements for female medical aid by lady doctors exist. About two-thirds of the *Tehsil* headquarters hospitals and dispensaries have no arrangements for the treatment of women patients by doctors of their own sex. The inadequacy of the provision for proper female medical aid is clear, and it should receive due consideration in any future scheme of expansion.

Medical education is becoming increasingly popular among girl students and a fairly large number of them have to be refused admission every year for want of accommodation. During the year 5 women students qualified for the M.B., B.S. degree and 26 passed the L.S.M.F. diploma. Two hundred and thirty-three women qualified for I.D.S. (Indigenous Dais Certifi-

cate), 66 for N.D.S. (Nurse Dais Certificate) and 45 for D.M. (Diploma in Midwifery).

PROCEEDINGS OF THE ALL-INDIA OPHTHALMOLOGICAL SOCIETY, VOLUME V, SESSION 1936, MADRAS

THE report of the fifth conference of the All-India Ophthalmological Society held at Lahore in December 1936 has just reached us. The report of the meeting and the presidential address occupy only about 15 pages at the end of the volume, the other 256 pages being devoted to the 43 papers read at the conference. This is always a well-bound and well-printed publication and the illustrations in the papers are well executed. The papers cover a wide field of ophthalmology so that this annual volume gives a valuable epitome of the work and progress in ophthalmology in India where it is a subject of such great importance.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL N. M. WILSON, O.B.E., K.H.S., Surgeon-General with the Government of Madras, is appointed to officiate as Director-General, Indian Medical Service, with effect from the 27th May, 1938, *vice* Major-General E. W. C. Bradfield granted leave.

Colonel D. H. Rai, M.C., Inspector-General of Civil Hospitals, C. P. and Berar, has been appointed to act as Director of Public Health, C. P. and Berar, in addition to his own duties, with effect from 19th April, 1938, *vice* Lieutenant-Colonel S. N. Makand granted leave.

Colonel A. C. Munro to be officiating D. D. M. S., A. H. Q. Dated 13th May, 1938.

Colonel S. G. S. Haughton, C.I.E., O.B.E., K.H.S., to be Officiating D. D. M. S., Eastern Command. Dated 1st April, 1938.

Lieutenant-Colonel H. E. Shortt, Director of King Institute, Guindy, to act as Surgeon-General with the Government of Madras, with effect from the date of taking charge, *vice* Major-General N. M. Wilson, O.B.E., K.H.S., on other duty.

Lieutenant-Colonel H. E. Shortt, Acting Surgeon-General, Madras, to officiate temporarily as the Director of Public Health, Madras, in addition to his own duties, with effect from the date of taking charge, until further orders.

Lieutenant-Colonel V. Mahadevan, Surgeon, First District Superintendent and Lecturer in Surgery, Stanley Medical School, Madras, First Surgeon, Government Rayapuram Hospital, Superintendent, Raja Sir Ramaswami Mudaliyar Lying-in-Hospital, and President, Board of Examiners, Madras, to act as Professor of Operative Surgery, Medical College, and Surgeon, Government General Hospital, Madras, with effect from the date of taking charge, *vice* Captain Sangham Lal.

Lieutenant-Colonel S. C. Alagappan, Acting District Medical Officer, Superintendent, District Headquarters Hospital, Salem, to act as Surgeon, First District Superintendent and Lecturer in Surgery, Stanley Medical School, First Surgeon, Rayapuram Hospital, Superintendent, Raja Sir Ramaswami Mudaliyar Lying-in-Hospital, and President, Board of Examiners, Madras, with effect from the date of taking charge, *vice* Lieutenant-Colonel V. Mahadevan.

Lieutenant-Colonel R. C. Clifford, M.C., D.S.O., is appointed to the post of Civil Surgeon, Simla West, with effect from the forenoon of the 20th April, 1938.

On his return from leave, Lieutenant-Colonel E. C. A. Smith has been reappointed as Superintendent, Central Mental Hospital, Yeravda, with effect from the forenoon of 3rd June, 1938.

Lieutenant-Colonel B. Z. Shah took over charge of the office of Director of Health and Prison Services, Sind, Karachi, from Lieutenant-Colonel B. F. Eminson, on the afternoon of the 30th April, 1938.

Lieutenant-Colonel H. H. Brown to be D. D. M. O. W., Army Headquarters. Dated 28th April, 1938.

Lieutenant-Colonel F. Phelan to be Officiating A. D. M. S., Lucknow Dist. Dated 2nd April, 1938.

Lieutenant-Colonel P. Banerjee made over charge of the Burdwan Jail to Lieutenant-Colonel N. C. Kapur, on the forenoon of the 23rd April, 1938.

Lieutenant-Colonel N. C. Kapur made over charge of the Chittagong Jail to Captain John Brebner, on the afternoon of the 19th April, 1938.

Major W. Aitchison, Civil Surgeon, Cawnpore, returned from leave on 4th April, 1938.

Major B. J. Griffiths, Civil Surgeon, from Jhansi to Agra, from 8th April, 1938.

Major L. F. Burns to be Officiating D. A. D. M. S. (Mob.), Western Command. Dated 2nd May, 1938.

Major K. H. A. Gross, an Officiating Agency Surgeon, is posted as Agency Surgeon in Bundelkhand, with effect from the afternoon of the 4th May, 1938.

Major D. P. Lambert, on return from leave, is posted as Civil Surgeon, Fyzabad, from 5th May, 1938.

On return from leave Major G. Joyce assumed charge of the office of Civil Surgeon, Lyallpur, on the 26th May, 1938.

Captain R. De Soldenhoff has been appointed to officiate as Professor of Midwifery and Gynaecology, Grant Medical College, and Senior Specialist in Obstetrics with Gynaecology, Bai Motlibai and Sir D. M. Petit Hospitals, Bombay, pending further orders, with effect from the afternoon of 4th June, 1938, *vice* Lieutenant-Colonel W. C. Spackman granted leave.

Captain C. B. Miller has been appointed to officiate as Resident Medical Officer and Junior Specialist in Obstetrics with Gynaecology, St. George's Hospital, Bombay, pending further orders, with effect from the forenoon of 3rd June, 1938, *vice* Captain R. De Soldenhoff.

Captain Sangham Lal, Acting Professor of Operative Surgery, Medical College, and Surgeon, Government General Hospital, Madras, to act as District Medical Officer, Salem, and Superintendent, District Headquarters Hospital, Salem, and Medical Officer, Central Jail, Salem, with effect from the date of taking charge, *vice* Lieutenant-Colonel S. C. Alagappan.

Transferred to Civil Employment

Captain F. R. Cawthorn, on 8th April, 1938, as Agency Surgeon, Kurram.

Captain P. I. Franks, on 11th April, 1938, as Surgeon to H. E. the Governor of Bengal.

Captain G. P. Charlewood, on 17th April, 1938, as Civil Surgeon, Coorg.

Captain S. W. Allinson, on 17th April, 1938, to Civil Burma.

Captain J. G. Stonham, on 18th April, 1938, to Civil Burma.

Captain A. M. Sheridan, Civil Surgeon, from Cawnpore to Moradabad, from 11th April, 1938.

Captain V. Srinivasan, Civil Surgeon, Bilaspur, has been transferred to Jubbulpore where he assumed charge on the afternoon of 12th May, 1938.

LEAVE

Major-General E. W. C. Bradfield, C.I.E., O.B.E., K.H.S., Director-General, Indian Medical Service, is granted provisionally combined leave for 3 months and 21 days, with effect from the 27th May, 1938.

Major-General I. M. Maerac, C.I.E., O.B.E., K.H.S., D. D. M. S., Eastern Command, proceeded on 5 months and 14 days' combined leave *ex-India*, with effect from the 1st April, 1938.

Colonel A. A. C. McNeill, K.H.S., D. D. M. S., Army Headquarters, proceeded on 4 months and 5 days' combined leave *ex-India*, with effect from the 13th May, 1938.

Colonel W. E. R. Williams, O.B.E., V.H.S., proceeded on 6 months' combined leave *ex-India*, with effect from the 2nd April, 1938.

Colonel J. Scott, D.S.O., O.B.E., D. D. M. O. W., Army Headquarters, proceeded on 6 months' leave on medical certificate *ex-India*, with effect from the 16th April, 1938.

Lieutenant-Colonel A. H. Shaikh proceeded on 9 months' leave *ex-India*, from 14th January, 1938.

Lieutenant-Colonel P. N. Basu, Civil Surgeon, Rae Bareilly, has been granted leave on average pay for 8 months partly in and partly out of India, from 6th April, 1938.

Lieutenant-Colonel R. E. Flowerdew, C.I.E., O. C., C. I. M. H., Bannu, proceeded on 12 months' combined leave *ex-India*, with effect from the 16th April, 1938, pending retirement.

Lieutenant-Colonel B. S. Dhondy, O. C., I. M. S., Ferozepore, proceeded on 8 months' combined leave in India, on 2nd May, 1938.

Lieutenant-Colonel S. M. A. Faruki, Specialist in Ophthalmology, Rawalpindi, proceeded on 4 months' combined leave *ex-India*, with effect from the 11th May, 1938.

Lieutenant-Colonel J. M. R. Hennessy, Civil Surgeon, Jubbulpore, has been granted leave on average pay for 4 months *ex-India*, from 13th May, 1938.

Lieutenant-Colonel W. C. Spackman, Professor of Midwifery and Gynaecology, Grant Medical College, and Senior Specialist in Obstetrics with Gynaecology, Bai Motilbai and Sir D. M. Petit Hospitals, Bombay, has been granted leave on average pay for 4 months and 4 days followed by leave on half-average pay for 3 months and 27 days, with effect from the afternoon of the 4th June, 1938.

Lieutenant-Colonel H. Chand, Civil Surgeon, Jullundur, proceeded on leave on average pay for 2 months, with effect from the 13th May, 1938.

Lieutenant-Colonel F. J. Anderson, Professor of Surgery, Medical College, Calcutta, is granted leave *ex-India* for the period 23rd May to the 22nd July, 1938.

Major S. C. H. Worseldine, Civil Surgeon, Fyzabad, has been granted 1 year's leave from 24th March, 1938.

Captain H. S. Smithwick, Civil Surgeon, Sholapur, has been granted leave on average pay for 8 months, with effect from the afternoon of 3rd May, 1938.

PROMOTIONS

Captains to be Majors

G. R. M. Apsey. Dated 22nd May, 1938.

J. H. Boulton, Civil Surgeon, Gorakhpur. Dated 29th April, 1938.

Lieutenants to be Captains

W. A. Hopkins. Dated 8th January, 1938, with seniority from 31st August, 1937.

J. L. Mewton. Dated 9th January, 1938, with seniority from 1st March, 1937.

J. W. R. Sarkies. Dated 9th January, 1938, with seniority from 31st August, 1937.

L. U. Kamm. Dated 9th January, 1938, with seniority from 31st August, 1937.

T. Denness. Dated 10th January, 1938, with seniority from 31st August, 1937.

RETIREMENTS

Lieutenant-Colonel Som Dutt, M.C. Dated 28th March, 1938.

Lieutenant-Colonel J. B. de W. Molony, O.B.E. Dated 3rd April, 1938.

Lieutenant-Colonel A. J. Symes. Dated 12th April, 1938.

Notes

PHOTOGRAPHING SECTIONS OF THE HUMAN BODY

By A. LION

TOMOGRAPHY—AN IMPORTANT ADVANCEMENT IN THE FIELD OF X-RAY PHOTOGRAPHY

WHEN taking a photograph with long exposure, such as, for instance, when photographing a quiet street in the dusk, it does not matter if some one should pass before the camera while the picture is being taken, as he will not show on the plate. Compared to the long exposure, the brief moment while this person passes in front of the camera is too short; the person will be considerably underexposed and even in the most unfavourable condition he will appear in the picture only as hardly more than a shadow. This fact is known to every amateur photographer, and there would be no reason in mentioning it, if it had not recently been put to a novel use in the field of x-ray photography.

In taking x-ray pictures, the whole depth of the body is photographed instead of the surface of an object, as is the case in ordinary camera work. All layers of the object which lie behind each other in the path of the x-ray are shown summarily in a single plane, that of the x-ray film regardless of whether the object is a human body or a piece of metal casting to be analysed for its metallurgical properties. In the x-ray film appear darker and lighter shaded areas and it is only by experience that the expert can tell where these darker or lighter shaded areas are located, that is, whether on top, on the bottom or in the centre of the x-rayed object. Another factor is important: if a shaded area lies above a lighter area, the two may cancel each other in their effect on the picture so that possibly nothing will be seen in the x-ray picture. Neither is it possible to eliminate from the picture any sections of the object which are of no interest at the moment. For instance, when taking an x-ray picture of the lung, almost 60 per cent of the picture area is taken up by the ribs and only the parts between the ribs can be recognized with any clarity. If the focus is unfortunately situated in the lung, however, pathologically densified tissues may cover up the cavities (parts of the lung in which the tissue is destroyed) so that neither darker nor lighter shaded areas may be recognizable in the picture.

These shortcomings of the ordinary x-ray technique make it very difficult at times to interpret an x-ray picture. Several means of overcoming these shortcomings have been attempted in the course of the years.

Thus, obliquely taken pictures were tried, although it was found that in this way the x-ray picture was distorted too much. Later stereoptical pictures were made by taking two pictures at a short distance from

on the previously mentioned fact that in the photographic plate only the fully exposed objects are clearly shown, while all underexposed objects are only vaguely sketched in. When using 'tomography', which is the

Swinging movement of the tomograph during one exposure.

X-ray picture of a normal lung.

each other and thereby producing a three-dimensional illusion as in the stereoptical photographs. These solutions never proved really satisfactory, however, until recently a method was developed which is based

name given to this type of x-ray photography, a certain section of the object to be examined, such as the lungs or the skull, is fully exposed while all that is above or below that section must be underexposed. This

sounds theoretically simple, but has proved practically very difficult and it has taken years before a satisfactorily working 'tomograph' was created.

Professor Dr. Chaoul of the Charite of Berlin and Dr. Grossmann have developed an apparatus for x-raying sections or thin layers—for instance, in the lung—without making the parts above or below that section, and especially the ribs which interfere so much with the picture, visible in the x-ray. Similarly the experiment recounted before where a person passes in front of a camera and therefore does not become visible in the picture, in tomography, too, the parts of the body which are above or below the section of the body to be examined are moved past the lens; they are only moved theoretically, however, as practically the body, in this case the patient, remains lying quietly on the examination table and only the x-ray apparatus is moved.

In the tomograph manufactured by the Electricitäts-gesellschaft 'Sanitas' of Berlin, the x-ray tube and the film container are built into a unit in such a fashion that they can be turned round a turning point which

sufficient. The tomograph makes it possible to, so to speak, cut out body sections from a few millimetres to two centimetres thickness from the body for photographic purposes.

The equipment consists of a double armed pendulum revolving around a horizontal axle, with the tube attached to the longer arm on top, and the film carrier to the short arm on the bottom. As the pendulum with the x-ray tube swings into motion, the film carrier also moves under the table on which the patient lies, in a plane parallel to the plane of the section. As the pendulum swings from one extreme amplitude through the vertical centre position to the other extreme amplitude, the x-ray focus on one side and the film carrier on the other side move along the arc of a circle segment representing approximately one half of a right angle. The whole apparatus is rather simply designed, works absolutely noiselessly and is easy to operate. The swing of the pendulum is released by pushing a button which at the same time turns on the x-ray apparatus which is automatically disconnected as soon as the pendulum has reached its other extreme amplitude, that is, after approximately one second. The

Tomogram (section photograph) of the same lung.
The disturbing shadows of the ribs are eliminated.

lies at the height of the desired body section. While the picture is taken, the x-ray focus moves along the arc of a circle from left to right, while the film moves simultaneously from right to left, but remaining always parallel to the table on which the patient is lying, and therefore also parallel to the desired plane of the section through the body of the patient. Through this arrangement it is achieved that every point in the plane of the section always falls on the same point of the film, notwithstanding the constant movement of tube and film during the x-ray exposure. All other points in the body, whether they are above or below the plane of the section, are reproduced in the picture at constantly changing points of the film, and are therefore underexposed and do not show clearly in the picture in which only the plane of the section is clearly shown. By adjusting the turning point of the apparatus to any desired height, certain sections of the body can be x-rayed in the heights at which the turning points of the apparatus are set. Generally, three such sectional pictures are sufficient for an examination of the lung. In order to achieve this effect, a certain length of exposure is required, although one second is usually

turning point, representing the height of the plane of the section, can be easily adjusted as the apparatus has a scale showing the height above the table in centimetres.

Even the layman can imagine the value of such an equipment for medical examination and for the accurate diagnosis of disease. It is always amazing to see an ordinary x-ray picture of the thorax with the ribs interfering with the picture, beside a tomographic picture which really shows a section through the lung tissue without a shadow of the ribs or the spine. It is now possible to determine the exact position of disease foci in the lungs, the skull or any other part of the body, without having to speculate on the depth in which such disease foci or foreign bodies such as bullets, etc., are located; the tomograph makes it possible to picture sections through the body in any height in which the disease is suspected to lie. Tomography is an immense advancement over conventional x-ray photography which in itself is one of the most important medical implements of the last decades, because tomography gives an entirely new aspect to x-ray photography.

NATURE'S RICH ENDOWMENT OF HEALING WATERS TO CZECHOSLOVAKIA

No other country has been blessed with such a wealth of natural means of healing as the Czechoslovak Republic, whose curative springs were used in ancient times. The group of springs at Karlovy Vary (Carlsbad), Mariánské Lázně (Marienbad), and Frantiskovy Lázně (Franzensbad) is unique. Some of them gush forth at nearly the temperature of boiling water.

Czechoslovakia has a remarkable variety of curative springs. There are not only simple cold springs with chemical or physical substances which cannot be definitely ascertained, but also simple hot springs, e.g., those of Teplice-Sanov, which, although they show no exceptional contents of minerals, have been of service for centuries as an excellent curative means for rheumatism, gout, and nerve diseases. They attain temperatures up to 115°F. It is assumed that the thermal springs are closely connected with the glaciers of the ice period which came as far as the neighbouring Ore Mountains.

The acidulous group is one of the most numerous of the natural mineral waters. It is interesting to note that in the neighbourhood of Carlsbad there are at least 500 acidulous springs, and in the neighbourhood of Marienbad no fewer than 800, of which of course only an insignificant number is used for curative purposes. These springs contain greater quantities of carbon dioxide, and are used either as table water, or for curative purposes. Those at Bilina are most popular for drinking cures, because, as the strongest alkaline springs, they are specially efficacious for maintaining ordered metabolism. There is another group, of which those in Luhacovice are specially known, a spa specializing in diseases of the respiratory organs and blood circulation.

Most interesting of all are the alkaline sulphur or Glauber salt springs, found exclusively on the western spurs of the Ore Mountains. Whereas the Carlsbad springs gush forth at a temperature of 162°F., the Marienbad and Franzensbad springs are cold. You would imagine that, as these groups of springs have the same composition, they would have the same healing effects, but the spas have recently specialized in the curing of certain diseases. Thus Franzensbad, lying in level country, has become a spa for women's diseases and heart troubles, Marienbad for obesity, and Carlsbad, in a beautiful rocky valley, with mostly hot springs, specializes in curing not only diseases of the digestive and intestinal organs, liver, and spleen, but also a number of diseases of metabolism, such as diabetes and gout.

The Teplice basin is very rich in bitter waters, also found in other places. Mention should be made of the well-known Salská bitter water, which, like many others of this type, is not drunk on the spot, but is exported in the same way as Saratoga and others. It is only in sodium-chloride springs that our Republic is poor. The most important representative of this group is Darkov Spa, which is effective in curing nervous diseases and scrofula. Sulphur springs are found in great numbers in the country, and the most beautiful and most effective for ailments of the joints and rheumatism are at Trencianské Teplice and Piestany.

It is no wonder that a country so richly endowed also has quite a number of moor deposits. These are in the surroundings of the world-famous spas of West Bohemia, and in the frontier district of North Moravia and Silesia. The freshly-dug mud cannot be used immediately for curative purposes, but must undergo a lengthy disintegrating process, to enable the substances contained in the mud to become effective.

In mountain districts, protected by a girdle of frontier mountains such as the Ore Mountains, Krkonose Mountains, and the Carpathians, which are a natural protection against cold winds from the north, a number of climatic health resorts have developed on the south side of the mountains. These are admirably suited for healing diseases of the organs of respiration

and the lungs, and also for the nerves. The most beautiful and highest health resorts are in the High Tatra, where the pure air and mountain sun are highly efficacious. The best known of these resorts are: Strbské Pleso, Stary Smokovec, Novy Smokovec, Tatranská Lomnica, Tatranská Polianka, etc. Frontier nooks, where the mountains protect them from wind and changes in weather, boast of a number of well-managed sanatoria, such as the spas of Grafenberk and Dolni Lipová; they were the first to introduce water cures.

BRAND'S ESSENCE OF CHICKEN

THE value of this preparation as an invalid food is indicated by the following extracts from letters sent to the makers by medical practitioners of experience. 'I use it frequently for influenza, pneumonia, malaria, typhoid, cholera, etc., and also in cases of gastric illness where an easily digested food is required'. 'As a general tonic and convalescent food which can always be relied upon, there is nothing better, to my knowledge, than Brand's Essence of Chicken. It has the advantage of being very palatable and easily digested'.

'I have always found the quality and purity of Brand's Essence of Chicken to be above reproach. I constantly prescribe it in cases where a natural stimulant and general invigorating influence is required and always with satisfactory results'. 'It is invaluable for pneumonia, malaria, typhoid, cholera, etc., where a protein concentrate with a high degree of digestibility is required'.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

LEPTOSPIROSIS IN INDIA

By B. M. DAS GUPTA

From the Department of Protozoology, School of Tropical Medicine, Calcutta

IN a previous communication, Das Gupta and Chopra (1937) reported the occurrence of a case of leptospirosis in Calcutta with recovery of the causal organism (*Leptospira icterohæmorrhagiae*). Five more cases have since come under our observation. It has been possible to isolate the leptospira from one of these five cases and the diagnosis of the remaining four has been established by agglutination reaction and other tests.

Epidemiology

With regard to the epidemiology of the disease, as it occurs in Calcutta, there is no evidence of contracting the infection by river-bathing or by contact with polluted water. The theory of water-borne infection, especially in sporadic cases, generally accepted in Europe is not, therefore, established in our cases. As all these cases were living in rat-infested houses (there is hardly any rat-free house in Calcutta), the infection might have been acquired by contact with the urine of infected rats. It is a curious fact that the presence of natural leptospiral infection in the rat population of Calcutta has been found to be of rare occurrence. Knowles and Das Gupta (Knowles, 1932) found only two rats infected out of 193. Last year, at the suggestion of Colonel Taylor, a systematic examination of rats was undertaken. The kidneys and liver of each rat were examined by the microscopical and cultural methods. Guinea-pigs were inoculated with the kidney emulsions, one animal being used for inoculation of materials from three or four rats.

The total number of rats (chiefly *Nesokia bengalensis*) examined was 162. No leptospira was found in any of them. Twenty specimens of rats' sera were tested for agglutination reaction with the local human strains, but the results were invariably negative, there being not the slightest evidence of agglutination or lysis, even in a low dilution of 1:10.

The disease in Calcutta is not confined to the individuals engaged in any particular occupation. The first case was a carpenter, the second a water-carrier, the third a cook, the fourth a grocer, the fifth a private servant, and the sixth was a porter.

It has occurred sporadically in different parts of the city. No two cases were seen in the same house nor in the vicinity.

The six cases which have, so far, come under our observation had the following seasonal incidence:—Two cases occurred in August 1937, 2 in December 1937, 1 in January 1938 and 1 in April 1938.

Clinical features

Three cases had a fatal termination and all became delirious before death. Acute onset, severe headache, agonizing pain all over the body, specially in the lumbar region, cramps in the calf muscles, conjunctival congestion, and marked jaundice were constant features. Four cases had bleeding from the gums and one of these also had epistaxis, melæna and patchy hæmorrhages under the skin. There was suppression of urine in two cases. The urine of three patients was examined, this showed evidence of marked renal irritation, albumen, urinary deposits, casts (chiefly hyaline and granular), leucocytes and red blood cells. All the specimens were very highly coloured on account of the presence of bile. One of the patients developed lobar pneumonia but in no other case was there any evidence of respiratory complication. As none of our patients were seen before the sixth day of illness, the degree of pyrexia at the early stage could not be determined. Low-grade fever persisted for two weeks or more in all the three cases that recovered. There was no relapse of the pyrexia in any case. Two fatal cases had a sub-normal temperature before death.

LABORATORY NOTES ON INDIVIDUAL CASES

Case 1

S. K. B. The patient was seen on the 9th day of illness. Blood examinations by microscopical and cultural methods and by inoculation into guinea-pigs were immediately undertaken.

Direct examination of blood.—Several smears were carefully searched under the darkground illumination, and some films were stained by Tribondeau's modification of Fontana's method and examined, but no leptospira could be found in any specimen.

Culture.—(a) On glucose broth—sterile.

(b) On Fletcher's medium—of the six tubes inoculated with varying amounts of blood from 0.2 c.cm. to 1.5 c.cm. two were found contaminated and the remaining ones gave scanty growth of leptospira from the 13th to the 15th day.

Animal inoculation.—As young guinea-pigs were not available at the time, two fairly large animals, weighing 400 and 442 grammes respectively, were inoculated with 3.5 c.cm. of blood intraperitoneally. The blood of these animals was examined daily from the 3rd to the 28th day of inoculation, far beyond the usual fatal period, with negative results. On the 29th day the peritoneal fluid of the bigger animal showed scanty leptospiræ. Four days later, this guinea-pig was sacrificed. On opening the abdomen no signs of leptospiral infection were apparent. The section of the liver and kidneys, however, showed the presence of leptospiræ. Apparently this animal passed into a 'carrier' condition. Unfortunately, the tissues were prepared only for the detection of leptospiræ by the silver-impregnation method, so that histological changes could not be studied in them.

Urine.—Direct examination of the centrifuged deposits showed a fair number of leptospiræ from the 19th to the 24th day. Two young guinea-pigs, weighing 150 and 162 grammes respectively, were each inoculated intraperitoneally with 2.5 c.cm. of urine collected aseptically on the 19th day. Both the animals died of leptospiral infection.

Protection experiments.—Two guinea-pigs each weighing 150 grammes (approximately) were taken. One was inoculated intraperitoneally with 0.25 c.cm. of the patient's serum taken on the 25th day of the disease

and the other with the same amount of normal rabbit serum. Next day both the guinea-pigs were given intraperitoneal injections of 0.2 c.cm. of the liver emulsion of a guinea-pig infected with the leptospira recovered from the patient himself. The one receiving the patient's serum previous to inoculation with the infecting organism remained alive and well, and developed immunity against further inoculation with the same strain. But the other animal which had normal rabbit serum succumbed to leptospiral infection on the 6th day of inoculation. As in the preceding experiment two guinea-pigs were inoculated with the patient's serum and normal rabbit's serum, respectively. They were then given injections of 0.2 c.cm. of the liver emulsion of a guinea-pig infected with the strain isolated from case 4. The patient's serum afforded protection against this strain as well, but the control animal (which received normal rabbit's serum) died of leptospiral infection. The above tests were repeated using the patient's serum obtained on the 209th day of illness and the results were exactly the same as before.

Agglutination tests.—

Strains	Patient's serum (collected on the 25th day of illness)	Patient's serum (209th day of illness)
* <i>L. icterohæmorrhagiae</i> (Wijnberg).	1/10,000	1/3,000
* Hond Utrecht IV (canicola)	1/1,000	1/100
* Rachmat ('Indian' strain)	1/1,000	..
* Salinem ('Indian' strain)	0	..
* Swart V. Tienen ('Indian' strain).	0	..
* Andaman strain CH31 <i>L. icterohæmorrh.</i> (London)	1/3,000	..

* The tests were carried out against these strains by Professor Schöffner and Dr. Sorgdrager.

Case 2

K. B. (fatal). He was seen on the 13th day of illness in a semi-conscious state. Microscopical examination of blood.—Microscopical examination of blood by the darkground illumination and by means of stained films was carried out. The results were consistently negative.

Culture.—(a) On Fletcher's medium—two tubes remained sterile for a considerable period and the remaining two showed scanty coccoid organisms.

(b) On glucose broth (blood was taken half an hour before death)—there was a rich growth of a virulent streptococcus which killed white mice in less than 48 hours, the streptococcus being recovered from the heart blood of the mice.

Animal inoculation.—Two guinea-pigs were inoculated with 3 c.cm. of blood each. None showed any evidence of leptospiral infection, but both these animals became absolutely refractory to the strain of leptospira recovered from case 1, and also the sera of these animals protected guinea-pigs against the above strain but not against the strain isolated from case 4. The guinea-pig used as control was extremely susceptible to the infection.

Examination of post-mortem material.—Fragments of the liver and kidney were available within half an hour of death. No leptospiræ could be demonstrated in the liver or kidney emulsions or in sections stained by Levaditi's method.

Case 3

T. This patient came under our observation on the 10th day of illness. Direct examination of blood (on the same day)—negative.

Blood culture (10th day).—Two young guinea-pigs, weighing 150 and 155 grammes respectively, were inoculated with the patient's blood. The peritoneal fluid of these animals was systematically examined for a period of three weeks, but no leptospira could ever be detected, nor did the serum of these animals develop any protective antibody, as in the case of the guinea-pigs inoculated with the blood of case 2.

Urine.—During the 3rd week of the disease eight specimens of urine were centrifuged as soon as they were voided and examined both by darkground illumination and by means of films stained by Fontana's method. Five of these samples were also inoculated into guinea-pigs. The results were negative in every case.

Protection experiments.—Patient's serum afforded protection against the strain isolated from case 1, but the guinea-pigs succumbed to the infection following an inoculation with the strain recovered from case 4, although they had been treated with the patient's serum previously. To avoid any experimental flaw these tests were repeated, and the results were identical.

Agglutination tests.—

Strains	Patient's serum (10th day)	Patient's serum (45th day)
* Andaman CH11	1/1,000	1/30
* Moseou V (<i>L. grippotyph.</i>)	1/1,000	0
* Wijnberg (<i>L. ictero.</i>)	1/300	1/3,000
* H. Utrecht IV (<i>L. canicola</i>)	1/100	1/10
* Andaman CH31	1/100	0

* Swart V. Tienen	0	..
* Hond HC	0	..
* Ballico	0	..
* Pomona	0	..

* Carried out by Dr. Sorgdrager.

Case 4

H. C. B. As the patient was seen during the first week of illness (6th day), particular attention was paid to the discovery of the parasite by direct examination of the blood. Accordingly several smears were prepared and very carefully examined under the dark-ground illumination. Besides, half a dozen films were stained by Tribondeau's modification of Fontana's method and thoroughly searched for leptospiræ; none could be found.

Blood culture (6th day).—(a) On glucose broth—sterile.

(b) On Fletcher's medium—the culture was examined every other day from the 7th to the 30th day, when it showed a scanty growth of leptospiræ. As it was not examined on the 29th day, leptospiræ might have been detected on that day also. It is important to note that the organism took an unusually long time to grow.

Animal inoculation (6th day).—Two young guinea-pigs were given intraperitoneal injections of the patient's blood. Both the animals developed typical signs of leptospiral infection and died on the 7th and 8th day respectively, although the liver and kidney emulsion of these animals failed to show leptospira in them.

Urine.—Centrifuged deposits of five specimens of freshly-voided urine obtained between the 15th and 25th day were examined under the darkground illumination with negative results.

Protection experiments.—The patient's serum protected guinea-pigs against the strain isolated from the patient himself, but failed to do so in the case

of the guinea-pig inoculated with the strain recovered from case 1. As in the previous cases, the tests, repeated a number of times to ensure accuracy, always yielded the same results.

Agglutination tests.—

Strains	Patient's serum (11th day)	Patient's serum (26th day)

Case 5

J. K. R. (fatal). Seen on the 8th day of the disease, died within 4 hours of admission.

Direct examination of the blood—negative.

Blood culture.—(a) On glucose broth—sterile.

(b) On Fletcher's medium—no growth for five weeks; the tubes were then discarded.

Animal inoculation.—A four-day old guinea-pig was inoculated with 1 c.cm. of the patient's blood. The peritoneal fluid of this animal showed a few leptospiræ 48 hours after inoculation and the guinea-pig died two days later of leptospiral infection.

Post-mortem examination.—As autopsy was not permitted a small fragment of the liver was removed through a small incision in the abdominal wall within three hours of death. Direct examination of the liver emulsion and section of this organ stained by the silver-impregnation method showed no leptospiræ, although marked degeneration of the parenchymal cells and cellular infiltration in the portal areas were seen in sections stained by the iron-hæmatoxylin method.

Case 6

C. J. (fatal). Came under our observation on the 8th day of illness and died on the same day.

Blood smears—negative.

Blood culture—no growth.

Animal inoculation.—Three young guinea-pigs were each inoculated with 1 c.cm. of blood. None of them showed any evidence of leptospiral infection for three weeks, peritoneal fluid being negative throughout.

The serum of these guinea-pigs failed to afford protection against the two local strains.

Post-mortem examination.—Portions of the liver and kidneys were available about 48 hours after death. The sections were found crammed with long filamentous

bacilli evidently of post-mortem origin; and no leptospira were found.

Agglutination test.—

	Patient's serum (8th day)	REMARKS
* <i>L. icterohæmorrhagiæ</i> ..	0	As the serum was available only on the 8th day of illness, it was not likely to obtain more definite serological evidence of leptospiral infection.

De (Calcutta) ..	1/20	

* Carried out by Dr. Sorgdrager.

Discussion

Very recently Gaines and Johnson (1937) have made an extraordinary observation regarding the detection of leptospira by microscopical examination of blood. They observed :—'In our experience examination of the blood by darkfield examination was the most satisfactory method of diagnosis and gave positive results for all patients. Some had as high as 25 organisms per high power field and in none the search was time-consuming'. These workers also pointed out that '*leptospira persisted in the blood stream months after the onset of illness*' (italics ours).

We carried out direct examination of the blood both under the darkground illumination and by means of stained films using the silver impregnation method. On no occasion did we succeed in detecting the organism, although inoculation of blood into Fletcher's medium at the same time gave positive cultures in two cases.

Fletcher (1927) reported the detection of scanty leptospiræ in the blood films stained by Fontana's method in only 3 out of 32.

Taylor and Goyle (1931) examined the blood of several cases under the darkground illumination, but no spirochætes were ever found. It is difficult to reconcile these observations with the findings of Gaines and Johnson (1937), and one cannot help suspecting that they may have been dealing not with the true organism but with artifacts which arise from the disintegration of red cells and platelets, and may bear a striking resemblance to spirochætes. These peculiar structures were described by Balfour (1911) and also by Knowles and Das Gupta (1924). In spite of the emphasis placed on the nature of these pseudo-organisms, several observers have mistaken them for true spirochætes. Other workers who have studied this disease are inclined to the view that leptospiræ disappear from the blood stream by the end of the first week of illness and on no occasion could they be demonstrated after the 9th day.

As regards the susceptibility of guinea-pigs to leptospiral infection, Taylor and Goyle (1931) reported that in the Andamans out of 22 guinea-pigs inoculated with the blood of the infectious jaundice cases only one died of leptospiral infection, although positive cultures were obtained from many of the bloods used. Even in this case they were unable to demonstrate the organism in the kidneys and liver, though the animal showed typical signs of leptospiral infection. Later work of these observers, however, shows that they succeeded in infecting young guinea-pigs with the Andaman strains. In our experience guinea-pig inoculation was invariably successful when suitable materials were used. One animal, rather large, weighing 442 grammes, inoculated with a patient's blood obtained on the 9th day of illness, passed into a 'carrier' state. It is not unlikely that some of the guinea-pigs used by Taylor and Goyle for diagnostic inoculations behaved in the same way and that the infection remained undetected, as the peritoneal fluid of the inoculated animals was not examined.

In our series of animal inoculations, one very young guinea-pig just weaned, showed leptospiræ in the peritoneal fluid as early as the 2nd day of inoculation, although the blood of this animal was not positive till two days later. This is an interesting observation in that such an early detection of the causal organism in the guinea-pig (inoculated with the blood of a human case) is, as far as we are aware, recorded for the first time. It has been noted, however, that during a serial passage of the virus through guinea-pigs, the leptospiræ frequently appear in the peritoneal fluid of the 'subpassage' animal inoculated with the infected blood or liver emulsion as early as the 2nd day of inoculation, by whichever route the injection is given.

It will be seen, from the results of the agglutination tests recorded above, that the two strains isolated in Calcutta belong to the same serological type as the classical *L. icterohæmorrhagiae* strain of Europe and differ from many Eastern strains, including a number of the so-called Indian strains. Strains Rachmat, Salinem, Swart V. Tienen and probably others have been referred to as Indian strains in literature, but to my knowledge this is the first time that a real Indian strain has been isolated and typed. The so-called Indian strains listed above were isolated in the Netherlands Indies and the Dutch workers call them Indian strains. Therefore, in the interest of clarity and in honour of Colonel R. N. Chopra, C.I.E., K.H.P., I.M.S., we should prefer to call the strain first isolated in Calcutta 'Strain Chopra, Calcutta'.

Sera of cases 3 and 4, taken on the 10th and 11th day of the disease respectively, gave an agglutination reaction markedly different from that obtained later during the convalescence. Dr. Walch-Sorgdrager of the Institute of Tropical Hygiene at Amsterdam, who very

kindly carried out most of the agglutination tests referred to in this paper, informed me that he had also sometimes noticed paradoxical reaction in his cases, but could not quite explain this anomaly.

If we analyse the results of the protection experiments performed with the sera of 4 convalescents against the two strains isolated from cases 1 and 4, we notice that there are at least three different strains of the causative organism in our series of six cases. For purposes of convenience the results of these tests are shown in the following table:—

Serum collected during convalescence from			Strains recovered from	Results.
Case 1	Case 1	Protection.
" 1	" 4	"
" 3	" 1	"
" 3	" 4	Death.
" 4	" 1	"
" 4	" 4	Protection.
Serum of the guinea-pig which acquired immunity following inoculation of blood of case 2.			" 1	"
			" 4	Death.

It will be seen from the above table that the infecting organism responsible in case 3 is identical with that of case 2. But the strains recovered from cases 1 and 4 are distinct from one another and from case 2 or 3. We may mention here that to ensure accuracy the immunization experiments were carried out many times.

About seven months after recovery the serum of case 1 gave complete protection against the two local strains, but there has been a fall in the agglutination titre.

Erber (1932) reported that wild rats invariably gave positive agglutination reactions in dilutions from 1:50 to 1:2,000. But in Calcutta the sera of 20 rats, including one caught in a patient's house, reacted completely negatively with the two local human strains. The incidence of natural infection with leptospira in wild rats in Calcutta is exceedingly low, as will be seen from the work of Knowles (1928) who found none infected out of 180 rats examined and from that of Knowles and Das Gupta (Knowles, 1932) who recorded the presence of leptospira in 2 out of 193 animals. Besides, in connection with the present investigation 162 rats were very carefully examined, with negative results, although the most recent methods advocated for the detection of leptospira were employed.

The guinea-pigs inoculated with the blood of a patient on the 13th day of illness developed immunity against a local strain (case 2), while those which received inoculations on the 8th and 10th day of illness did not (cases 6 and 3).

The urine of three cases was systematically examined for the presence of leptospira, both by

direct microscopical examination and animal inoculation, but in one case only could it be demonstrated (case 1). This is in accord with the findings of Taylor and Goyle (1931) who record the presence of leptospiræ in 15 out of 48 cases examined. Kouwenaar (1926), however, was able to detect leptospiræ in the urine of about 77 per cent of his cases.

In none of our fatal cases did we succeed in demonstrating leptospiræ in kidney and liver sections. Our experience of the failure to find post-mortem evidence of the presence of leptospira in the fatal case corresponds with the results obtained by Taylor and Goyle (1931) in the Andamans. It has been noted by some observers that the organism disappears from the liver by the 7th day in human cases and this is probably the reason for our negative findings.

Sanarelli (1928) noticed that experimentally-infected animals frequently showed secondary invasion with other organisms, especially the streptococcus and the paratyphoid bacillus. Moreover, in cases of infectious jaundice in human beings, the latter organism is frequently present in the blood. In order to determine the rôle played by these secondary organisms, he carried out some experiments in collaboration with Dr. Pergher. The results seem to indicate that these secondary organisms in themselves are able to produce the characteristic symptoms, but rarely so severe as to cause death.

We cultured the blood of all our cases, both on Fletcher's medium and on glucose broth; on no occasion was any organism of the paratyphoid group recovered, although the blood culture taken from case 2 half an hour before death gave a rich growth of virulent streptococci.

As noted by Taylor and Goyle (1931) the blood cultures usually take seven to ten days to develop, but in some cases did not show till the 21st day. In one of our positive cultures the growth first appeared as late as the 30th day (case 4).

All our cases showed the characteristic symptoms of the severe type of the disease. It is quite likely that, as in other countries where the disease is prevalent, milder forms with or without jaundice also occur in Calcutta, which are yet to be recognized.

Summary

(1) The occurrence of six cases of leptospiral jaundice in Calcutta during the last eight months is recorded. The identity of the disease was established in every case by laboratory examination.

(2) The causal organism has been isolated from two cases. It belongs to the same serological group as the classical *L. icterohæmorrhagiae* strain of Europe and differs from many Eastern

strains, including two from the Andamans (CH31 and CH11).

(3) Although the infecting organisms recovered from the two cases gave almost identical agglutination reactions, yet they could be differentiated from one another by protection tests.

(4) The disease occurred sporadically in different quarters of the city and is not associated with river-bathing or contact with polluted water, nor has it a predilection for any particular occupation.

(5) The incidence of natural infection with leptospira in the rat population of Calcutta is exceedingly low.

I wish to express my indebtedness to Colonel R. N. Chopra, C.I.E., K.H.P., I.M.S., Director of the Calcutta School of Tropical Medicine, for providing every facility for carrying out this investigation and to Colonel J. Taylor, D.S.O., C.I.E., I.M.S., for many helpful suggestions. To Prof. W. Schüffner and to Dr. Walch-Sorgdrager of the Institute for Tropical Hygiene, Amsterdam, I should like to express my grateful thanks for so generously supplying me with cultures and anti-sera and for carrying out the serological tests, as recorded in this paper. My sincere acknowledgments are also to Major H. C. Brown, C.I.E., I.M.S. (retired), of the Wellcome Bureau of Scientific Research, London, for testing the serum of case 1 for agglutination reaction. I also thank Prof. M. N. De and Dr. D. R. Dhar of the Medical College, Calcutta, for drawing my attention to two cases under their care.

PEPTIC ULCER IN NORTHERN CIRCARS

A NOTE ON THE INCIDENCE

By M. NARASIMHA RAO, M.B., B.S.
Research Fellow, Andhra University

THERE was a time when it was thought that gastric ulcers were never encountered in Indians. As late as 1927, quoting Rogers, Rehfuß (1927), an authority on gastric disorders, writes 'Natives of India are almost free from this condition'. But subsequent reports from all over India prove that the above statement is not based on correct information. Hingston (1927) collecting statistics from a few discrete centres in India, such as Madras, Calcutta, Rangoon and Patna, concludes that people from all these areas do suffer from peptic ulcer, though the disease is not very common in certain areas. In fact, he believes, from his experience, that the low figures in certain areas, Bengal for example, are not due so much to the rarity of the disease as to the outlook of the medical practitioners who treat the disease.

Even in India, the disease is reported to be commoner in South India than in the other

During the years 1930-35, there were 3,932 admissions to the first surgeon's wards and 3,929 (corrected figure) to the second surgeon's wards. Of these 7,861 admissions 537 were true cases of peptic ulcer (only cases corroborated on the operation table with or without the positive test meal and barium meal findings); 282 from the first surgeon's wards and 255 from the second surgeon's, i.e., 6.83 per cent of the total admissions were *bona fide* cases of peptic ulcer.

Of these 537 cases of peptic ulcer it is interesting to note that duodenal ulcers are far in excess of gastric ulcers; 466 (86.8 per cent) are duodenal, 35 cases (6.5 per cent) pyloric, and 36 (6.7 per cent) are gastric. In fourteen cases the duodenal and gastric ulcers were associated.

Sex.—The relative sex incidence cannot be taken as representing the true figures, in that admissions to the hospital in the female wards are very few owing to the unwillingness on the part of the women to enter the hospital even in the late stages of the disease. Of the total 537 cases only 33 (6.2 per cent) were females.

The following table represents the relative sex incidence in the peptic ulcers :—

TABLE II

	TOTAL PEPTIC ULCERS		GASTRIC		DUODENAL		PYLORIC	
	Number	Percentage	Number	Percentage	Number	Percentage	Number	Percentage
Males ..	504	93.8	32	88.9	437	93.8	35	100
Females ..	33	6.2	4	11.1	29	6.2

In South India, a group of four districts, the Northern Circars are taken into consideration and the following figures represent the incidence of the disease in the Circars as judged from the records of the Vizagapatam Medical College Hospital, the largest of its kind in the Circars. As the surgical treatment of peptic ulcer is the routine of the hospital, figures are mentioned only in reference to the surgical admissions to the hospital.

Expressed in terms of sex, the relative incidence of gastric ulcer in women is slightly higher than in men, for the proportion of duodenal to gastric ulcers in men is 13.6 : 1, and in women 7.25 : 1.

Age.—The disease is seen to occur at all ages. The age incidence is taken as the age of the patient at admission minus the duration of the disease. A common fallacy in such a calculation is that though the patient is able to say with certainty the duration of the disease, he is not able to give his age correctly; as the agriculturist or the labourer, who is the common victim of the disease, is so ignorant as not to know his age correctly.

The following table represents the average age incidence in males and females respectively :—

TABLE III

	Males (years)	Females (years)
Gastric ulcer ..	30.7	33.5
Duodenal ulcer ..	30.17	32.52
Pyloric ulcer ..	29.78	..

Occupation.—The vast majority of admissions are in the labouring class of people, whose occupation chiefly is agriculture or manual labour for daily wages. There are very few instances of the disease in the higher class Hindus. Very few are from people other than Hindus, i.e., Christian or Mohammedan.

The classification of all the cases into various occupations is found to be impracticable. Hence to facilitate classification they have been arbitrarily divided into sedentary, active and very active. Under the first have been included occupations such as clerks, landlords, school teachers; under the last have been included all manual labourers working for daily wages and agriculturists. All the others have been included in the second category. The following table represents the incidence when viewed in the light of the above classification:—

TABLE IV

	Duodenal	Gastric	Duodenal and gastric
Sedentary ..	11.93	17.65	12.34
Active ..	19.27	26.46	19.79
Very active ..	68.80	55.89	67.87

Residence.—Of the total 488 cases, where the address has been noted correctly, 56.97 per cent were from Vizagapatam district proper. Of the two neighbouring districts, 14.75 per cent are from Ganjam and 20.08 per cent from East Godavery. Of the remaining, 6.4 per cent of the cases were from the more distant West Godavery; the remaining being stray cases from other districts.

Seasonal variation.—Hutter (1928) pointed out that gastric ulcers occurred during the cold months of the year from December to February, as did recurrences.

The peak of the incidence curve of duodenal ulcer, on the other hand, was reached in May. The incidence was lowest in November.

Autopsy records

Of the 699 post-mortem examinations conducted in this hospital till the end of the year 1935, 90 cases showed gastric or duodenal ulcers in either the acute or chronic stage (12.8 per cent). Of these 54 or 7.7 per cent were chronic peptic ulcers. Of these 2.3 per cent were gastric and 5.4 per cent duodenal.

Some of the individual cases in the series deserve notice. In 17 cases where the cause of death was due to the severe systemic disease such as septicæmia there were found, either in the duodenum or stomach, single or multiple erosions or ulcers. These are termed by some 'agonal'. These agonal erosions may probably be explained by the fact that the stomach has the power of excretion of certain bodies in

blood stream (neutral red), and these erosions are caused as a result of the injury to the capillary walls and the mucous membrane during the excretion of the toxin.

In eight cases (15 per cent) death was due to post-operative broncho-pneumonia. This was probably due to the low condition of the patients, who were such bad risks for the major operation of gastrojejunostomy. This brings home the fact that during the routine operative treatment of peptic ulcer the general condition of the patient has to be given prior consideration rather than the enthusiasm of the surgeon for doing such a major operation.

The complication of hæmorrhage in these cases seems to be very rare, as only two cases were encountered during the present series. Two rare instances of duodenal diverticula (Narasimha Rao, 1938) and two cases of granulomatous ulcers of the stomach have been encountered in the present series. A curious instance of an acute pyloric erosion in a newborn babe among 46 post-mortem examinations held by me on fetuses during the two years was also encountered.

A separate entity—pyloric ulcer—other than gastric or duodenal ulcer has been included in Tables II and III, but due to the difference in nomenclature and definition, understood by some as an ulcer just at the pylorus corresponding to the pyloric vein (which is considered by Moynihan to be very rare) and considered by others as an ulcer in the pyloric antrum, and by a few as duodenal ulcers extending up to the pylorus, the cases typed as pyloric ulcers have been excluded and only frank cases of gastric and duodenal ulcers are considered.

The relative preponderance of duodenal over gastric ulcers is a well-established fact, but the relative proportion of the two seems to be slightly higher in the present series when compared with others.

In 5,733 operations at Mayo Clinic up to 1920 the proportion of duodenal to gastric ulcer was 4:1 (Stewart). Curiously enough the London Hospital surgical statistics as well as those of two London Hospital surgeons, Walton and Souther, show an approximately equal frequency for gastric and duodenal ulcers, but the statistics of most British surgeons agree fairly closely with those of Moynihan (2½:1) whilst some give an even higher ratio, Wilkie of Edinburgh 6:1 and Young of Glasgow 8:1.

It is interesting to note that though the figures in the present series are far higher than those of foreign clinics, they are even lower than figures from other clinics in South India. Madras statistics (Chaudhuri, 1926) show the high figures of 17.1:1 and 25.1:1 (Skinner, 1932) and Somervell (Bradfield, 1928) from Travancore from a series of 540 cases gives even a higher figure still: 26 cases of duodenal ulcer for every gastric ulcer.

The following is a summary of the above in a tabulated form :—

TABLE V

	Duodenal ulcers	For every gastric ulcer
Walton and Souther ..	1	1
Meynihan and others ..	2½	1
Mayo Clinic ..	4	1
Wilkie ..	6	1
Young ..	8	1
Vizagapatam Hospital ..	12.0	1
Madras (1925) ..	17.1	1
" (1931) ..	25	1
Travancore ..	26	1

The relatively greater preponderance of duodenal to gastric ulcers is found in both sexes as evidenced by the following table :—

TABLE VI

Author's name	Males (duodenal to gastric)	Females (duodenal to gastric)
Wilkie ..	11 to 1	2½ to 1
Young ..	11 to 1	2 to 1
Present series ..	13.6 to 1	7.25 to 1

The incidence of the disease in females seems to be higher in other centres in South India than in the present series.

TABLE VII

	Males	Females
Vizagapatam ..	11.9	1
Madras (Bradfield) ..	24	1
Travancore (Somervell) ..	32.8	1

Occupation

Earlier writers in England were of the opinion that ulcers occurred with special reference to boot-makers and cooks. New Lodge Clinic statistics seem to point out to a special liability amongst the members of the fighting services. Peculiar to this part of the country the disease is found to be common (67.9 per cent) in the poor hard-working labourers and agriculturists. A consideration of one year's consecutive cases shows that out of 40 cases, one was a Brahmin, one Mohammedan, two Kshatriyas, two Vaisyas, and all the others were from other caste Hindus, chiefly the lower labouring classes. Such seems to be the case in Travancore also; as Somervell, comparing the incidence in various castes, comes to the conclusion that 'duodenal ulcer is far rarer in Brahmins and far commoner in Hindu outcastes, relative to the total number of cases'.

But these two findings are not quite in accordance with those of Bradfield (Madras) for,

according to him, 'the beggar, the coolie, the rich man, the scholar, and the agriculturists are all numbered amongst its victims', and he proves his case by showing that the proportion of the cases of peptic ulcer in the various communities is proportional of the population communities to the total population in Madras.

Age.—The average age of onset of gastric ulcer in Britain is considerably lower in women than in men, 26 compared with 45 (Stewart). On the other hand, the average age of onset of duodenal ulcer is almost identical in men and women, 38 and 39 respectively. But our figures show that the average age of onset of both the diseases in women is more than in men by about two years. It is also peculiar that the average age of onset in each is roughly the same in both the diseases.

The greater number of cases come from Vizagapatam district, this is to be expected from the hospital being situated at the district centre. Considering the greater distance of the neighbouring districts and the fewer admissions, it cannot be concluded that there is any great disparity in the incidence of the disease in these districts.

Autopsy records

Statistics from various countries show that the disease is relatively more frequent in certain parts of the world; for instance, it is rare in Russia (0.8 per cent) and common in Denmark (16.7 per cent), Germany and England (5 per cent) and North America 6.3 per cent (Rehfuss). Compared with the above the present figure of 12.8 per cent may be considered to be a fairly high figure.

Out of 4,000 consecutive autopsies at the Leeds General Infirmary a chronic ulcer healed or unhealed was found in 9.55 per cent of post mortems. Brinton, Toslin and others say that peptic ulcer is common in as many as 5 per cent of all autopsies, but C. H. Mayo met with only a fraction of 1 per cent, and 7.7 per cent in the present series go to show that the disease is more common than in many other countries.

Comment.—It is curious to note that the disease is so common in the Northern Circars, from the biggest hospital of which the above data have been recorded. It is also peculiar that the disease should be more prevalent in the lower labouring classes than in others. The main features in which the labourer differs from others are (a) the unhygienic and insanitary surroundings, (b) the poor inadequate diet he is accustomed to, (c) the hard manual labour he does for many hours in the day, and (d) want of personal hygiene.

The insanitary surroundings and the want of personal hygiene make him more susceptible to disease in general. But his daily diet probably plays a rôle in the chronicity of the ulcer; for, on analysis, the diet is found to be rich in carbohydrate, poor in fats and proteins, and deficient

particularly in vitamins A and B. The probable factors responsible for the common incidence of the disease in the Circars may be outlined thus:

(i) Bad pyorrhœa alveolaris and constipation are so common in these patients that probably the teeth and gastro-intestinal tract act as septic foci from where elective localization of organisms may occur in the stomach or duodenum.

(ii) The labourers, the commonest victim of the disease, cannot afford to have regular meals and the irregularity in the intervals and the variety of food may predispose to dyspepsia and frequent pylorospasm. The patient frequently gives a history of such a frequent dyspepsia before the onset of the typical symptoms of peptic ulcer.

(iii) The diet of these lower classes is deficient in vitamins A and B, and as McCarrison and others believe such partial avitaminosis probably may give rise to changes in the gastro-intestinal tract which predispose to ulcer formation.

(iv) As Tirumurti and Ramachandra Rao (1936) pointed out, 'there is the possibility of malarial infection (Circars abound in agency tracts where malarial infection is very common) favouring the formation of gastric or duodenal ulcers' in at least some of these cases.

Summary

Statistics from the hospital and post-mortem records of the Vizagapatam Medical College Hospital show that peptic ulcer is a fairly common disease in the Northern Circars.

The probable causes for such common incidence are outlined.

Acknowledgment

I take this opportunity to express my thanks to the Superintendent, King George Hospital, and Professor of Pathology Medical College, Vizagapatam, for access to the records, and to Dr. Kini for the helpful guidance.

VITAMIN B AND PEPTIC ULCER

By M. NARASIMHA RAO, M.B., B.S.

Research Fellow, Andhra University

(From the Department of Biochemistry, Medical College, Vizagapatam)

DIET, as a contributory factor in the ætiology of peptic ulcer, was known to the early pathologists. In recent years the subject has been elaborated and various aspects of diet brought to light, and held to be responsible causative agents. Some of them were: 'carried' foods, coarse foods, 'hot' foods, foods at high temperatures, marked difference in the temperature of various dishes; irregular meals, meals at long intervals, etc. That diet probably is partly responsible for the frequency of peptic ulcer in India has been pointed out by McCarrison, Bradfield and Somervell. And the various ways in which the diet was accused were: increased carbohydrate content of the food; markedly low fat diet; gross deficiency of vitamins A, B and C.

Now that laboratory methods have been developed for assaying the various constituents of the food, an investigation into the diet as to its quality and deficiency can be conducted more rationally.

It has been observed by the writer that the diet of the labourer, the common victim of peptic ulcer in South India, is lacking in the essential vitamins A and B, in addition to variations in the proximate principles. The present investigation has been attempted for the purpose of studying the amount of vitamin-B deficiency by microchemical techniques, in patients with peptic ulcer.

Towards the biochemistry of avitaminosis B, contributions have been largely made by the Oxford school of workers. The following may be noted as their essential conclusions. In the brains of experimental polynuritic pigeons it has been found that there was increased quantity of lactic acid and diminished tissue respiration in glucose or lactate solutions, when compared with healthy controls. It has also been shown beyond doubt that diminished oxygen intake was entirely due to lack of vitamin B in the tissue (Peters, 1936). Hence they concluded that vitamin B was needed for the oxidative removal of lactic acid. Thus the fact was scientifically established that vitamin B was specially concerned with carbohydrate metabolism. Peters and Thompson (1934) have studied the metabolism of pyruvate *in vitro* and came to the conclusion that pyruvic acid, as an intermediary metabolite, was inversely proportional to the vitamin content of the brain. This observation on the brain was applied to other tissues of the body, especially the blood; and it was found that blood has increased intermediate carbohydrate metabolites, especially pyruvic acid which is formed in brain (Thompson and Johnson 1935). Other intermediate carbohydrate metabolites also have been found

in the blood of avitaminous birds—especially methyl glyoxal—as shown by Geiger and Rosenberg (1933), but this could not be corroborated by Gavrilseu and Peters (1931) and Johnson (1936). Johnson and others (1935) attempted to correlate the above facts for the purpose of assessing the vitamin deficiency of an individual by estimating the pyruvic acid in blood. They established the level in normal patients but could find no person with B deficiency in England for investigation. But in China, Platt and Lu (1935) published their observations of the presence of pyruvic acid in the blood of beriberi patients. Subsequently they (1936) confirmed beyond doubt that the same can be applied as a fairly accurate laboratory test for the avitaminosis B.

Many methods have been advocated for estimating the pyruvate in blood. A qualitative one can be used—a modified Rothera's test with nitroprusside and strong ammonia—a blue-green colour indicates the presence of pyruvic acid. Other tests are those of Simon and Piaux's, and Posternak's quoted by Case. Quantitatively various methods of estimation are available.

1. MacLean's method. Precipitation of pyruvic acid with phenyl hydrazine and subsequent estimation of unchanged hydrazine.

2. Clift and Cook's method (1932) is based on the capacity of binding bisulphite.

Each method has its own advantages and disadvantages according to the medium in which the pyruvic acid is contained; namely, muscle filtrate, blood or cerebrospinal fluid.

The two methods used in the present investigation are modified MacLean's and Cook's. The disadvantage of the first method is in the proper extraction of the hydrazone of the pyruvic acid from the blood, the advantage being that pyruvic acid can be estimated as such. Whereas, in the second method the advantage is the amount of accuracy obtained, with the disadvantage that the pyruvic acid is estimated as an unknown quantity of the bisulphite-binding substances in the blood; the proportions of the remaining variable moieties being also unknown. But with the idea of having a clearer reading of the results by a harmonious combination of both the methods it was attempted to use both the methods together and the attempt was only partly successful.

Pyruvic acid.—The estimations were done by Case's method (1932). Peter's and Thompson's modification (1934) was also tried but was found to be less efficient, due to the following reasons :—

1. Large quantities of ethyl acetate have to be used.

2. The extractions are greater in number and not quite satisfactory and demarcative.

3. Greater time is required.

Case's method involves the following principle :—

Excess of 2 : 4 dinitrophenyl hydrazine is added to the deproteinized extract of the blood

(the blood being taken under basal conditions). Pyruvic acid hydrazone along with other hydrazones is formed in the solution and with the uncombined hydrazine are extracted with ethyl acetate. Neutralization of the acids used for deproteinization is done to prevent the subsequent extraction of hydrazones other than that of pyruvic acid. Neutralization of the ethyl acetate extract instead of the preliminary trichloroacetic acid extract is done to facilitate rapid instead of repeated extractions with ethyl acetate. The combined hydrazones are evaporated and extracted with toluene, which gives them up more readily than ethyl acetate. The pyruvic acid moiety is extracted from the others in toluene with cold sodium carbonate, which dissolves only the pyruvic acid hydrazone in the cold. The 2 : 4 dinitrophenyl hydrazone of pyruvic acid is extracted from the carbonate after acidification with ethyl acetate and crystallized. The estimate is done by the colorimetric method against a standard 2 : 4 dinitrophenyl hydrazone of pyruvic acid, the solvent being alcoholic potash which gives a deep red colour.

Experimental details.—The patient is not permitted to take any solid or liquid food subsequent to the previous night's dinner. The morning coffee was allowed in some cases. Rest in bed is essential in the morning till the time of taking blood, the idea being to eliminate errors due to intermediate products of carbohydrate metabolism, resulting from exercise; 2.8 to 3 c.cm. of blood are taken and immediately transferred to a weighed centrifuge tube containing 7 c.cm. of 5 per cent trichloroacetic acid solution, mixed thoroughly, and the exact amount of blood added then obtained by reweighing. After standing for half an hour the precipitate is separated by centrifuging and extracted twice in the same fashion with 5 c.cm. of 5 per cent trichloroacetic acid. The combined extracts are then made up to 25 c.cm. and 5 c.cm. are taken and titrated to pH 2.0 with N.NaOH (N/100 HCl with thymol blue acid range is used as control). The amount of N.NaOH required to adjust to pH 2.0 the remaining 20 c.cm. is added and the volume made up to 25 c.cm. with distilled water. One hundred c.cm. are taken out for estimating the bisulphite-binding substances and 15 c.cm. are allowed to stand 24 hours with 0.1 milligramme 2 : 4 dinitrophenyl hydrazine made up in 1 c.cm. of 2 N.HCl. The whole is now shaken with 20 c.cm. of ethyl acetate in a glass-stoppered 50 c.cm. separating funnel. After separation the aqueous layer, which is nearly colourless, is extracted with a further 10 c.cm. of ethyl acetate. As soon as the aqueous layer is colourless, which is usual after three extractions, it is discarded. The united ethyl acetate extracts now contain all the unchanged 2 : 4 dinitrophenyl hydrazine together with the hydrazones which have been formed. The liquid is also acid owing to the extraction of a certain amount of hydrochloric and trichloroacetic acids. These are neutralized by shaking with solid calcium carbonate. The solution is decanted into a glass evaporating basin, washing the calcium carbonate with further ethyl acetate until it is colourless. The washings are added to the main bulk of the fluid. The contents of the dish are evaporated on a water bath to 1 c.cm. and then after removal from the bath 20 c.cm. of toluene are added. The slightly cloudy yellow solution is again transferred to the separating funnel and is thoroughly shaken with 5 c.cm. of cold 25 per cent Na₂CO₃ solution. If pyruvic acid is originally present its hydrazone dissolves in the aqueous layer, colouring it brown. This extraction is repeated with fresh Na₂CO₃ solution until the latter remains

colourless. Three repetitions usually suffice. The united sodium carbonate layers are now acidified by adding concentrated hydrochloric acid drop by drop. Great care has to be taken in neutralizing, especially in the last stages, for fear of splashing. If the temperature of the flask rises by rapid addition of acid it is advisable to cool the mixture during the process. The 2 : 4 dinitrophenyl hydrazone of pyruvic acid is precipitated and a lemon-yellow suspension results. This is extracted in a separating funnel with successive portions of ethyl acetate until the aqueous layer is colourless. Usually four 10 c.cm. extractions suffice. The ethyl acetate solution now contains all the pyruvic acid hydrazone which is present and it is evaporated to dryness in a glass basin on a water bath. The yellow residue is dissolved when cool in 5 per cent alcoholic potassium hydroxide, giving a deep red solution which is made up with a further known quantity of alcoholic potash to a colour matchable with the standard.

For the purpose of the standard a pure preparation of pyruvic acid 2 : 4 dinitrophenyl hydrazone is made and a stock solution of this is kept in ethyl acetate of such a strength that 1 c.cm. is equivalent

to 0.1 mgm. pyruvic acid. A known volume is taken, evaporated to dryness, and dissolved in alcoholic potash just before actual colorimetry. The standard synthetic 2 : 4 dinitrophenyl hydrazone of pyruvic acid prepared in this laboratory gave a melting point of 216°C. (uncorrected value) at 29°C. temperature and 759.6 mm. pressure, the values given by other authors being 216.5° (Platt and Lu, 1936) and 214° (Allen, 1930).

Bisulphite-binding substance values

Principle.—The deproteinized blood extract at pH 2 is taken and excess of bisulphite added. The excess bisulphite is removed with N/10 and N/100 iodine. Then the combined bisulphite is liberated by the addition of Na₂PO₄ and immediately the amount estimated by N/100 iodine. This is the modification of Clift and Cook's method by Elliott *et al.* (1935).

Experimental details.—The remaining 10 c.cm. of the deproteinized blood extract at pH 2 are taken and allowed to stand for 15 minutes with 2 c.cm. saturated NaHSO₃ solution. One c.cm. starch solution is then added and then the uncombined bisulphite oxidized with N/10 iodine solution till the last drop gives a definite

* Done after meals.

† Not done under ideal conditions.

blue colour. The colour of the solution is adjusted to a faint purple, using N/100 Na_2SO_3 solution followed by N/200 iodine solution. Then 2 grammes of $\text{Na}_2\text{H}_2\text{PO}_4 \cdot 12 \text{H}_2\text{O}$ are added and the iodine titration is carried out at once with N/200 iodine made with oxygen-free water. The end point is taken when the standard faint violet persists for 30 seconds. The original method of Clift and Cook required 10 c.cm. of oxygen-free 8 per cent NaHCO_3 solution instead of the phosphate and carrying on the final titration at low temperatures. The bisulphite binding substances are expressed as mgm. Pyruvic acid per 100 grammes fluid (1 c.cm. N/100 iodine—0.44 mgm. pyruvic acid).

Results.—Table I summarizes the findings of bisulphite-binding substances in the blood of patients suffering from gastric or duodenal ulcers the diagnosis being made by history, test meal and barium meal findings. Some of them that were operated upon were verified.

The pyruvic acid as hydrazone is estimated in nearly all the cases but unfortunately values of many of the cases had to be discarded because of the slight difference in the tint for calorimetric estimation which usually crept in on account of two reasons, *viz*, the least delay in calorimetry after the development of the colours and impurities in the ethyl acetate with which the pyruvic acid is extracted.

Table II shows the pyruvic acid values when estimated as pyruvic acid dinitrophenyl hydrazones.

TABLE II

Comment

It is difficult to assess the amount of pyruvic acid present in man during health. The only record that could be found is that of Platt and Lu (1936). They have recorded the readings of 23 healthy Chinese college students whose values varied from 2.22 to 4.82 mgm. bisulphite-binding substances per 100 gm. of blood with an average of 3.27 mgm. An attempt has been made to find the bisulphite-binding substances

values in healthy labour classes, as the majority of the 30 cases studied is from the same classes.

TABLE III

Serial number	Values of bisulphite-binding substances
1	4.7
2	3.1
3	2.7*
4	5.2*
5	3.3
6	3.1
7	6.353
8	4.580
9	3.228
10	3.906
11	1.704
12	3.354
13	1.457

* These cases could not be studied under basal conditions.

Thus it is seen that considering the 11 cases done under ideal conditions the bisulphite-binding substances values vary from 1.457 to a maximum of 6.353, the average being 3.457 mgm. Platt and Lu report the content of the blood in established beriberi cases to be markedly increased. But in none of the cases have they reported values higher than 10 mgm. per cent. But in this connection it must be mentioned that some of the 'gastric' cases showed values higher than 10. An attempt has been made to find the corresponding values of beriberi cases admitted to the hospital. Seven cases showing marked avitaminosis B were studied and the values are noted hereunder (table IV).

TABLE IV

Serial number	Values
1	9.4
2	7.7
3	7.7
4	4.3
5	6.7
6	15.08
7	4.91

It is interesting to note that one of the cases (6) has shown a value of above 15, and others, except case 4, show uniformly high values.

Of the bisulphite-binding substances content of 'peptic ulcer' patients excluding cases 7 and 12, where there was much unavoidable experimental error, the variation is from 2.1 to a maximum of 23.73.

Fixing the maximum in a normal individual as 4.8, as judged from the healthy students, nine of the values are within the normal range and the remaining ones beyond it; so much so that it appears that higher bisulphite-binding substances values are fairly frequent in

these patients. But this observation is not without possibilities of error, the chief of which is the presumption that the pyruvic acid moiety of the bisulphite-binding substances always bears the same high percentage to the total. But from the readings in Table II it appears it is not quite true. The observations on this aspect are so meagre that the discussion on the subject cannot be complete, but from the proof advanced so far by Platt and Lu (1936) that bisulphite-binding substances values run parallel to the vitamin-B deficiency it may be concluded with a fair amount of certainty that these patients are suffering from partial avitaminosis B. The truth of the statement may be substantiated by the fact that it is in these lower classes that beriberi is fairly common.

The discussion of the subject on the basis of these findings and findings of animal experiments will be given in another paper.

Summary

Bisulphite-binding substances in blood of peptic ulcer patients are found to be increased in a good percentage of cases, showing a definite deficiency of vitamin B in these patients.

Acknowledgments

I take this opportunity of thanking Major J. A. W. Ebdon for approving and encouraging me in the work; and of expressing my indebtedness to Dr. V. K. Narayana Menon for his guidance and valuable suggestions; to Dr. D. Narayana Rao for his constant help and interest during the course of the work. My thanks are also due to Dr. P. Kutumbiah and Dr. D. V. Subba Reddi for permitting me to investigate their cases of peripheral neuritis; to Mr. T. S. Ramabhadran for preparing a liberal supply of ethyl acetate; and to Mr. T. V. C. Apparao for assisting in the preparation of standard 2:4 dinitrophenyl hydrazone of pyruvic acid.

TREATMENT OF PHRYNODERMA BY VITAMIN-A CONCENTRATE

By M. V. RADHAKRISHNA RAO, M.B., B.S., Ph.D.
Nutrition Research Laboratories, Indian Research Fund Association, Coonoor, S. India

PHRYNODERMA (toad-skin) is the name given to a papulo-follicular dermatosis commonly seen in malnourished individuals (Nicholls, 1933). During recent years considerable attention has been paid by nutrition workers to the study of the condition. A brief review of the literature on the subject and an account of its clinical and anatomical features have been given in a previous communication (Radhakrishna Rao, 1937a).

While it is generally agreed that phrynoderma is a separate clinical entity associated with malnutritional states, the exact cause of the condition is still not quite clear. Several workers have described the condition as occurring in association with xerophthalmia and keratomalacia. This finding, together with the results of the histological examination of the papular eruption in phrynoderma, suggested that the condition was probably attributable to a deficiency of vitamin A in the diet. The beneficial results, reported by several workers, of the therapeutic administration of cod-liver oil and, in a few cases, of vitamin-A concentrate on the papular eruption support the above view. Frazier and Hu (1931, 1935 and 1936) have observed that as a result of providing a well-balanced diet and administering 30 c.cm. of cod-liver oil daily, and without any local medication, the papular lesions gradually disappeared, leaving delicate, atrophic, pigmented scars. Loewenthal (1933) also reports the beneficial effects of the administration of cod-liver oil and, in two cases, of 'avoleum'—an extract containing only vitamin A. Reiss (1936) and Youmans (1937) obtained similar results after the administration of cod-liver oil. Goodwin (1934) reported a case in London in which the papular eruption disappeared when the patient was given a good mixed diet with the addition of cod-liver oil. Frazier and Hu (1936) also tried the effect of treatment with carotene (subcutaneously) in one case and halibut-liver oil in another with equally satisfactory results. Nicholls (1935) mentioned that milk or eggs quickly cured phrynoderma and 'sore-mouth'.

This paper reports the results of a clinical investigation of the effect of vitamin-A concentrate on the papular eruption in phrynoderma.

Description of cases and results of treatment

The investigation, of which the present paper forms a part, was commenced in a children's boarding school in the Nilgiris, and later on extended to a day school in the same district. The majority of children attending these schools belong to poorer classes. Children who showed marked evidence of phrynoderma were

selected for treatment, while mild cases were kept as controls. Treatment consisted in giving vitamin-A concentrate ('preparation A') of the Glaxo Laboratories. Each cubic centimetre of this concentrate, which contains no added vitamin D, contains 72,000 I. U. of vitamin A, or each minim (containing 4,000 I. U. of vitamin A) is equivalent in vitamin A to 2 drachms of standard cod-liver oil. No alteration was made in the diet and no local medication was applied. The control cases received no treatment. The results of treatment over a period ranging from 50 to 140 days were very satisfactory, but they were not definitely conclusive, as the controls also showed slight improvement during the period of observation. It is hoped to undertake further therapeutic tests with vitamin-A concentrate on cases of phrynoderma with a view to confirming the above observations.

In two cases, reported below, marked improvement was noticed in the papular eruption after the administration of vitamin-A concentrate:—

Case 1.—R., a boy, aged about 9 years, was noticed during an examination of the children in a day school for evidence of malnutrition. He was undernourished and under-developed for his age; his general condition was poor and angular stomatitis was present. The skin was dry, and there was a generalized hyperkeratosis of the hair follicles; the papules were very marked, especially on the extensor aspects of the limbs, shoulders and gluteal regions (plate X, figures 1 and 2); scratching of the skin produced a white powdery desquamation. Slight earthy discoloration of the bulbar conjunctiva was present.

The boy was given 2½ minims (10,000 I. U. of vitamin A) of Glaxo Laboratories 'preparation A' every day for 112 days (the boy has had in all 16.2 c.cm. of the vitamin-A concentrate). During the first month of treatment no striking improvement was apparent in the skin condition, but there was rapid improvement after this period, the papules gradually disappearing. When the boy was examined at the end of 112 days, the papules had completely disappeared (plate X, figures 3 and 4), leaving faint scars, the skin was smooth and glossy, and his general condition showed improvement.

Case 2.—The patient, a girl, aged 6 years, showed a well-marked and profuse papular eruption, similar to that seen in case 1 (plate XI, figures 1 and 2). The child had slight angular stomatitis, but no Bitot's spots or xerophthalmia. Treatment consisted in giving 4½ minims a day of Glaxo Laboratories 'preparation A' for 63 days. During this period the patient has had in all 16 c.cm. of the vitamin-A concentrate. The papular eruption had completely disappeared from the face and body at the end of this period of treatment. With the exception of a few papules, the eruption on the arms had also disappeared. The marked improvement which resulted may be seen from the photographs taken before and after treatment (plate XI).

Discussion

The marked improvement in the papular eruption after the administration of vitamin-A concentrate in both the cases reported above confirms the previous observation that 'the condition is probably a manifestation of a nutritional deficiency in which lack of vitamin A is an important factor' (Radhakrishna Rao, 1937a). The results reported here are similar

to those of Loewenthal (*loc. cit.*) after the administration of 'avoleum'.

It is generally agreed that the nutrition of the skin suffers in vitamin-A deficiency. The histopathological features of the skin in human keratomalacia were described in a previous paper (Radhakrishna Rao, 1937b), and it was pointed out that there is a striking similarity between the microscopic lesions in the skin in keratomalacia and those found in phrynoderma. Moreover, the pathological changes occurring in phrynoderma are similar to the morphological appearances met with in other epithelial structures in avitaminosis A.

The absence of definite clinical signs of xerophthalmia, which is accepted as the visible manifestation of vitamin-A deficiency, in some of the marked cases of phrynoderma is difficult to explain if the latter is ascribed solely to vitamin-A deficiency. It would be interesting to study whether these cases exhibit sub-clinical ocular lesions when the dark-adaptation tests are applied.

While the morphological appearances of the follicular lesions and the results of the therapeutic tests strongly suggest that phrynoderma is due to a nutritional deficiency in which lack of vitamin A is an important factor, further therapeutic tests with vitamin-A concentrates are rendered necessary before the problem of aetiology is finally solved. The beneficial effect of the administration of vitamin-A concentrate on the papular eruption may presumably be also due to the better absorption and utilization of the food consumed. Smith (1932, 1938) and Smith and Sprunt (1935) have presented evidence to show that an atrophy of the sebaceous glands and thinning of the epithelium occur in the tails of albino rats fed on diet deficient in vitamin-B₂ complex. Further study is required to determine the rôle of this factor (vitamin-B₂ complex) in human phrynoderma.

Summary and conclusion

The effect of vitamin-A concentrate (Glaxo Laboratories 'preparation A') on the papular eruption in phrynoderma was studied in two advanced cases. In both instances, the follicular lesions had disappeared after the administration of about 16.0 c.cm. of the concentrate.

The result of the therapeutic tests confirms the previous observation that phrynoderma is probably a manifestation of a nutritional deficiency in which lack of vitamin A is an important factor.

STUDIES ON THE POTENCY OF PROPHYLACTIC VACCINES

1. CHOLERA VACCINE

By C. L. PASRICHA

MAJOR, I.M.S.

D. N. CHATTERJEE

and

B. M. PAUL

(From the Cholera Bacteriological Enquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)

CHOLERA vaccine is extensively used for prophylaxis, particularly during epidemics of cholera and in endemic areas of the disease. There are three main sources of cholera vaccine, the vaccines prepared by certain recognized laboratories, the vaccines prepared by local commercial firms and a certain amount of vaccines imported from abroad. The recorded observations on cholera vaccines such as those of Taylor, Ahuja and Singh (1936) deal with the keeping properties of vaccine and the relative value of strains of vibrios in the preparation of cholera vaccines. The present paper records the results

of the examination of fourteen samples of vaccines representing cholera vaccines from the three sources mentioned above.

The methods employed in the examination of the vaccines are summarized below:—

(1) *The test for the sterility of the vaccine.*—Each vaccine was examined for the presence of viable aerobic and anaerobic bacteria. The test was carried out in fluid medium, and in order to ensure that the phenolic content of the final dilution shall be less than 0.01 per cent, 0.4 c.cm. of the vaccine was added to 30 c.cm. of nutrient broth of pH 7.6. In the case of the test for anaerobic bacteria, cooked meat was added to the nutrient broth to occupy a depth of about one inch at the bottom of the tube and before inoculation the medium was heated to 100°C. for half an hour to expel dissolved oxygen, and then cooled to 37°C. The tubes after the addition of vaccine were placed in McIntosh and Fildes's anaerobic jar in an atmosphere of hydrogen. Both the aerobic and anaerobic tubes were kept under observation for 14 days. In addition, smears were examined from each vaccine. Gram-positive contaminating organisms were not seen in any of the samples.

(2) *The test for the freedom from abnormal toxicity in the vaccine.*—For this two tests were employed:

(a) For excess of phenol, 0.5 c.cm. of the vaccine was injected subcutaneously into an adult white mouse and the animal kept under observation for seven days. Freedom from any serious symptoms was taken to signify absence from excess of phenol or other preservative in the vaccine.

(b) For the presence of any abnormal toxins, 5 c.cm. of the vaccine was injected intraperitoneally into guinea-pigs of about 300 grammes in weight and the animals kept under observation for seven days. Freedom from any serious symptoms was taken to signify absence of any abnormal toxins in the vaccine.

(3) *The examination of antigenic response in rabbits.*—Two rabbits were injected intravenously with each vaccine. The amount of vaccine injected into each rabbit was one half of the total human dose recommended by the manufacturer and was injected in a series of three graded doses at intervals of five days. The serum of each animal was examined for the presence of cholera agglutinins before the inoculation of vaccine and again 10 days after the last dose. The results recorded are the average of the findings in the two animals.

(4) *The antigenic response in man.*—One full prophylactic dose as recommended by the manufacturer of each vaccine was given to human volunteers in two subcutaneous injections. A sample of blood was collected before the injection of vaccine and again 14 days after the second injection. Only those individuals in whom there were no cholera agglutinins in 1 in 10 dilution of the serum were selected for the inoculation of the cholera vaccine.

(5) *The protective value of vaccine.*—This was tested by immunizing five guinea-pigs with the test vaccine, followed 10 days later by the injection of 2 M. L. D. of a toxic strain of recently isolated *V. cholerae* of the Inaba type. The immunizing dose used for each guinea-pig was half the adult human dose and this amount was injected intraperitoneally. Control series of animals showed a 100 per cent mortality after the injection of the test dose of cholera vibrio.

A second series of guinea-pigs were immunized with the cholera vaccines and 10 days later injected intracutaneously with 0.1 c.cm. of a live culture of *V. cholerae* known to give rise to a marked skin reaction. The skin reactions which consisted of a well-marked induration and flush were read after 12 hours. In the control uninoculated guinea-pigs, the skin reaction was apparent after 12 hours and consisted of an indurated flushed area about 3–5 cm. in diameter which gradually faded and disappeared in 48 hours.

Fourteen cholera vaccines from different sources were examined. Six of these were prepared in recognized laboratories and eight were commercial products. The results are given below in tabular form.

TABLE I

The vaccines tested, the number of vibrios per c.cm. as stated on the label, the adult dose and the number of months before date of expiry at time of test

Serial number.	Number of vibrios in millions per c.cm. as stated on the label	Adult human dose recommended by the manufacturer in c.cm.	Number of months before date of expiry at time of test
1	8,000	1.5	12
2	8,000	1.5	7
3	8,000	1.5	5
4	8,000	1.5	No information.
5	8,000	1.5	12
6	8,000	1.5	12
7	2,000	1.5	24
8	5,000	1.5	20
9	No information	1.5	No information.
10	No information	1.5	No information.
11	5,000	1.0	10
12	5,000	1.0	18
13	5,000	1.5	12
14	2,000	3.5	18

It will be seen that there is considerable variation (from 2,000 to 8,000 million vibrios per c.cm.) in the strength of the different vaccines, and further that there is no general agreement as to the length of time a vaccine is to be considered to have retained its activity. The preparations of certain recognized laboratories are allowed six months to one year, whereas many of the commercial firms allow a year or more. As the majority of the commercial preparations only give the expiration date it is not possible to know the length of time allowed for each

product. At the time of the test, vaccines nos. 12 and 14 were claimed to be potent for 18 months. In the majority of the preparations no instructions were given as regards the method of storage.

All the vaccines passed the sterility test and were free from any abnormal toxicity. The results of the tests for the antigenic response, the protection experiments and the skin reactions are summarized in table II.

It will be seen that with the first six preparations, which are the products of certain recognized laboratories, the agglutinin response in rabbits and in man and the protection test gave satisfactory results. Of the eight samples of commercial vaccines tested, four (nos. 7, 8, 9 and 14) showed the development of agglutinins and possessed protective properties and four vaccines gave uniformly negative results. So striking was the difference with the two groups of vaccines that the tests were repeated with the samples of commercial vaccines, using fresh series of animals. The results obtained were similar. It may be noted that the various preparations were given serial numbers and it was not possible to identify the products of any company whilst the various tests were in progress. The analysis was made after all the tests were completed.

The skin reactions were absent or only a trace of reaction occurred in guinea-pigs immunized with the vaccines possessing satisfactory agglutininogenic and protective properties. There was a well-marked skin reaction in animals immunized with vaccines, which did not produce cholera agglutinins in rabbits and possessed no protective value for guinea-pigs. The results of this test corroborate the other findings.

Six vaccines were tested for direct agglutination with standard cholera 'O' and cholera 'H' and 'O' sera and cross agglutination with sera prepared with each vaccine. Three of these vaccines (nos. 3, 5 and 6) were the products of recognized laboratories and three were commercial preparations. Of the latter, one was known to give rise to cholera agglutinins and two (nos. 9 and 10) gave no cholera agglutinins. The results, summarized in table III, show that the comparatively simple test of direct agglutination gives valuable information as to the antigenic structure of the organism used in the preparation of the vaccine.

Summary

1. The results of the examination of fourteen cholera vaccines are recorded. The vaccines were tested for sterility, freedom from abnormal toxicity, antigenic response in rabbits and man and protective value in guinea-pigs.

2. All the vaccines passed the test for sterility and were free from abnormal toxicity.

3. All the six cholera vaccines prepared by recognized laboratories gave satisfactory antigenic response and protected guinea-pigs against 2 M. L. D. of *V. cholerae*.

Vaccine no. 6	3,000	1,000	3,000	1,500	4,000	1,500	Nil	Nil
Vaccine no. 9	1,000	125	1,500	1,500	1,500	500	Nil	Nil
Vaccine no. 10	Nil	Nil	Nil	Nil	Nil	Nil	5,000	Nil
Vaccine no. 11	Nil	Nil	Nil	Nil	Nil	Nil	Nil	6,000
Inaba 'O'	2,000	2,500	1,500	2,000	1,500	125	Nil	Nil
Inaba 'H' and 'O'	3,000	2,000	2,500	3,000	3,000	1,500	200	Nil

4. Four of the eight commercial preparations of cholera vaccines produced cholera agglutinins and possessed protective properties and four vaccines gave uniformly negative results. It is suggested that the cultures used in the preparation of these vaccines were not tested for identity

by the generally accepted tests applicable to *V. cholerae*.

SPONTANEOUS SUBARACHNOID HÆMORRHAGE

By R. N. CHAUDHURI, M.B. (Cal.)

*Assistant Professor of Tropical Medicine, School of
Tropical Medicine, Calcutta*

THE spontaneous form of subarachnoid hæmorrhage has come much into prominence lately and is now recognized as a definite clinical entity. The most important cause is rupture or slow leakage of an aneurism on one of the arteries at the base of the brain, especially in the circle of Willis; a favourite position being the junction of the anterior communicating artery with the anterior cerebral. Such an aneurism is believed to be congenital, due to inherent weakness of the walls of the arteries. It has been shown that at the angle of bifurcation or junction of two vessels on the circle, the inner muscular coat is frequently absent and an aneurism develops at the weak point. It is usually found in young people in whom there is no evidence of syphilis or atheroma. There may be several aneurisms at different points in the basal arterial system. They are of small size, and at times they are so small as to escape superficial inspection. From their resemblance to a sprig of mistletoe, they are described as 'berry aneurisms'.

Less commonly and in older people, subarachnoid hæmorrhage may be caused by the rupture of a degenerate artery with or without the preliminary formation of a small aneurism. Aneurism of the cerebral artery may also result from embolism in infective endocarditis and cause hæmorrhage.

It is well to bear this pathological condition in mind in all puzzling cases of lesions in the central nervous system, especially those which do not seem to fit in with any other pathological state.

Clinical features

Cerebral aneurisms of the type described above may cause no disability until they rupture, although in a few cases recurring headaches, pressure signs due to implication of some cranial nerves, have been noted. It is the rupture or a small leakage that causes the symptoms and the signs, and their severity depends on the situation of the rupture and on the degree of leakage. The victim usually a young adult complains of sudden and severe pain in the back of the head and the neck, a sensation as if something had burst in the head. There may be history of overwork or fatigue preceding the onset. The headache increases in severity and this is followed by lethargy, stiffness and tenderness of the neck, head retraction, nausea and vomiting. Gradually consciousness becomes impaired though not necessarily lost. The patient becomes irritable, and complains of his head. At other times there may be delirium, convulsions and periods of coma. Kernig's sign is generally present. The clinical picture is

therefore one of meningeal irritation of acute onset and the diagnosis is made by lumbar puncture, which yields a uniformly and often heavily blood-stained cerebrospinal fluid under pressure. If the corpuscles are allowed to settle, the supernatant fluid is seen to be yellow. The effusion of blood may extend forward through the optic foramen along the sheath of the optic nerves and cause subhyaloid hæmorrhages. There may also be transient albuminuria and glycosuria.

In favourable cases the bleeding stops, the headache and the irritability gradually abate, the patient may pass into sleep and later wakes up with consciousness restored. The leakage from the small aneurisms may induce thrombosis within and around the sac, and it has been observed at necropsy that such an aneurism can clot and fibrose. This explains survival from the initial hæmorrhage, but if there is repetition within a few days or weeks, as is not uncommon, then the prognosis becomes definitely graver. A patient may have recurring attacks of unconsciousness at long intervals, due to small leaks. The only abnormality that may be found in such chronic cases is the yellow coloration of the cerebrospinal fluid (xanthochromia) due to long antecedent hæmorrhage.

In unfavourable cases the symptoms which are due to frank rupture of the aneurism are like those of severe cerebral hæmorrhage. The patient passes into deep coma and succumbs. Lumbar puncture yields copious, almost pure, blood.

Case report.—A. H., a Bengali Mohammedan, aged 18 years, a book-binder by occupation, was admitted into the Carmichael Hospital for Tropical Diseases on the 9th August, 1937, with a history of irregular fever, breathlessness on exertion, swelling of the legs and diarrhoea of one year's duration. He also complained of recurrent attacks of headache.

There was nothing of importance in the previous history except that he had kala-azar in 1928 and hookworm infection in 1935 for both of which he was treated in this hospital.

He was pale and anæmic with œdema of both legs. The liver was slightly enlarged. The spleen was not palpable. There was a hæmic murmur in the heart. He had slight daily rise of temperature and the pulse was rather rapid. After a few days' stay in the hospital he complained that he had been passing an excessive amount of urine for some time. The urine was therefore measured regularly from 15th August to 13th September; the daily output varied from 40 to 108 ounces. The urine examination showed specific gravity 1015, reaction acid, albumin a trace, urobilin a trace, no sugar, a few pus cells, no tube casts. The blood pressure was 105/70 mm. of mercury. The eyes were normal.

Blood counts (done by Dr. Sen Gupta) showed hæmoglobin 2.6 gm., red cells 1,370,000 per c.mm., MCV 78.03 cu. μ , MCH 19.05 $\gamma\gamma$, MCHC 24.9 per cent. Total nucleated cells were 4,600 per c.mm., polymorphonuclears 3,013 (65.5 per cent), lymphocytes 782 (17 per cent), large mononuclears 161 (3.5 per cent), eosinophils 506 (11 per cent), basophils 92 (2 per cent), and normoblasts 46 (1 per cent). The reticulocyte count was 1.4 per cent.

The van den Bergh test was negative. The Wassermann reaction, aldehyde and antimony tests were negative. The gastric analysis showed hypochlorhydria. The Mantoux test was negative (1 in 100,000 dilution).

In view of the microcytic hypochromic anæmia the patient was given a course of ferrous sulphate, 18 grains a day, from the 14th August to 3rd September. There was steady improvement of the blood as well as in his general condition. The hæmoglobin improved from 2.61 to 12.1 gm. and the red cells from 1.37 to 4.92 millions. On the 14th he had epistaxis due to an acute local inflammatory condition, which was checked by argyrol spray.

On 1st October, the patient complained of severe headache. He was given a dose of saline purgative and a few doses of aspirin but to no effect. The urine was examined again, it showed marked reaction for albumin, but no casts were found. The fundus oculi was healthy. The headache persisted for the next two days in spite of sedatives and large doses of alkalis. On the 4th the pulse was slow (62 per minute) and the blood pressure 152/80 mm. of mercury. The temperature was normal. The patient was obviously suffering from a great deal of pain in the head. The neck was stiff and the head was retracted to a certain extent. The patient resented interference. The cranial nerves were normal. Pupils were equal and reacted to light and accommodation. There was no papilloedema nor intraocular hæmorrhage. Consciousness was clear, and he talked normally. There was no sign of paralysis of the limbs nor loss of sensation. The knee and ankle jerks were slightly exaggerated on both sides. Kernig's sign was positive. Babinski's sign was positive on both sides. The superficial abdominal reflexes were present but rather sluggish. There was no vomiting. The urine was diminished in quantity. Other organs of the body appeared healthy.

On lumbar puncture the cerebrospinal fluid flowed with increased pressure. It was intimately mixed with blood and appeared to be of similar density in the two successive specimens. Ten cubic centimetres of the fluid were withdrawn. The patient was immediately relieved of pain to a considerable extent. The cerebrospinal fluid was allowed to settle in the refrigerator and it was found that the blood cells had fallen to the bottom of the test tube, while the supernatant fluid was yellow. This finding along with the clinical picture led to the diagnosis of spontaneous subarachnoid hæmorrhage of meningeal type. The Wassermann reaction of the fluid was negative and the culture was sterile. The urea and non-protein nitrogen content of blood was normal.

Next day headache increased and the neck was stiff, as before. The pupils were dilated, but were equal and reacted normally. The temperature went up to 101.8°F., pulse 64 and respiration 24 per minute. Lumbar puncture was done again with considerable relief of pain. The same had to be repeated on the following day also. The character of the fluid was about the same each time. The patient was given daily injections of intravenous glucose and hexamine. Ice bags were constantly applied over the head and neck and sedatives given as required.

The symptoms gradually subsided. On the 10th the patient was practically free from pain and rigidity of the neck. The urine was free from albumin. The blood pressure came down (110/70 mm. of mercury). On the 14th he had no headache or fever, but he was found to have homonymous hemianopia of the right half of the visual field. This finding was subsequently corroborated by Dr. Refatullah of the Eye Hospital. The fundus oculi was healthy. A skiagram of the skull was taken; this did not show any abnormality in the region of the pituitary fossa. One remarkable feature observed was the disappearance of polyuria previously complained of, after the attack.

The patient was kept in the hospital for a further period of about three months. Except the hemianopia and occasional slight headache he had no complaints. He was given a second course of ferrous sulphate for three weeks which raised the hæmoglobin to 14.2 gm. and red cells to 5.11 millions. General health improved further, and there was a gain of 13.5 lb. in weight altogether.

Discussion

Diagnosis of cerebrospinal fever was obviously excluded in this case. Albuminuria and the raised blood pressure with a previous history of polyuria led to the suspicion of uræmia, but they were only of short duration, and the urea and non-protein nitrogen content of the blood were normal. Encephalopathy, due to the massive doses of iron given to this patient, was also considered, but the character of the cerebrospinal fluid was against it, and the second course of ferrous sulphate was uneventful. Pituitary tumour was another possibility, and the polyuria was very suggestive. There was, however, no sign of dyspituitarism and there was no radiological evidence of any change in the sella turcica.

In a young person with healthy arteries and negative Wassermann reaction the cause of hæmorrhage giving rise to a meningeal syndrome was presumably rupture of a congenital aneurism. The bloody cerebrospinal fluid was not due to the accidental puncture of a vessel for three reasons:—

(1) It was intimately mixed with the fluid and all the specimens after each lumbar puncture presented the same appearance.

(2) The blood did not clot.

(3) When the fluid was kept in a refrigerator and the red cells allowed to settle the supernatant fluid was xanthochromic.

The aneurism was apparently pressing on the pituitary body giving rise to polyuria previous to its rupture. The homonymous hemianopia was an interesting sequel in this case, which was evidently caused by an organized blood clot pressing on the left optic tract.

Temporary marked albuminuria was perhaps of the same significance as glycosuria in brain injury.

Repeated lumbar puncture, though not advocated by some authorities, owing to the apprehension of provoking fresh leakage from a healing rent, was definitely beneficial in this case. Drainage did not have any tendency to increase the bleeding.

Acknowledgment

My thanks are due to Dr. L. E. Napier, under whom the patient was treated, for his permission to publish this record and to Dr. P. C. Sen Gupta who did repeated blood counts.

THE EFFECT ON RATS OF SUPPLEMENTING A NORTH INDIAN DIET WITH VEGETABLE PROTEINS (SPROUTING PULSES) AND CALCIUM

By R. K. PAL

Liaison Officer between Human Nutrition and Agricultural Research

and

N. SINGH

Field Worker, Indian Research Fund Association

WILSON and his associates (1936) in discussing the results of a diet survey in Calcutta remark that the protein element in nutrition in India may ultimately prove to be the most important, and it will certainly be the most difficult to remedy. Aykroyd and Krishnan (1937), on the other hand, showed that inclusion of skimmed milk powder, calcium lactate and yeast greatly enhanced growth and improved the general condition of rats fed on a poor south Indian diet and addition of proteins such as casein or an amino acid such as cystine had but only slight effect in improving the nutrition of the rats on the same basal diet, and they are of opinion that the above idea of Wilson *et al.* may

be erroneous. We (Pal and Singh, 1938) corroborated the latter workers' results, namely, that addition of calcium enhances the nutritive value of Indian diets based on rice, as assessed by the growth of groups of young rats, and this effect is slightly increased if phosphorus is also added at the same time.

Up till now very few practical suggestions have been made for improving the nutritive value of the poor north Indian diet by addition of cheap supplements. The inclusion of animal proteins, fish or meat, is not always possible as in many cases it is avoided on religious grounds and even though there may not be any religious prejudice, the poor cannot afford to take it, just as they cannot afford the luxury of a liberal supply of milk or milk products in their diet. Under these circumstances it is a difficult problem how to improve the poor north Indian diet without much increase in the cost. So with a view to investigating the effects on rats, of the addition of an extra quantity of pulses (in a sprouting condition) as a source of vegetable protein and calcium lactate, both individually and together, to the poor north Indian diet, and to find out whether the protein element (Wilson *et al.*, *loc. cit.*) or the calcium (Aykroyd and Krishnan, *loc. cit.*) acts as a better supplement to the typical poor north Indian diet, this present work was taken up.

Experimental

Four groups of half a dozen young rats of an average weight of 54.5 gm. were given the following diet, corresponding roughly to the daily diet of an adult of the poorer classes in north India, mixed and fed in the proportions indicated below.

Whole wheat flour (<i>Triticum vulgare</i>)	8 oz.
Raw polished rice (<i>Oryza sativa</i>)	.. 8 "
Black gram (<i>Phaseolus mungo</i>)	.. 2 "
Dhal Arhar (<i>Cajanus indicus</i>)	.. 2 "
Amaranth leaves (<i>Amaranthus gan-jeticus</i>)	.. 2 "
Brinjal (<i>Solanum melongena</i>)	.. 2 "
Onions (<i>Allium sepa</i>)	.. 1 "
Chillies (<i>Capsicum annum</i>)	.. 2 gms.
Coriander (<i>Coriandrum sativum</i>)	.. 2 "
Mustard oil	.. 1 oz.

Group I was given the basal diet alone. Group II had the basal diet with the addition of a quarter ounce of sprouted gram. Group III was given the basal diet supplemented by 0.88 gm. calcium lactate, or 0.15 gm. for each rat. Group IV received the basal diet together with both the supplements in similar quantities.

The experiment lasted for eight weeks during which the weight of the animals was recorded once every week. The following table and the chart show the average rate of increase in the four groups of animals under experiment for eight weeks.

TABLE I
Average increase in weight in grammes in eight weeks

Group	Initial weight	1st week	2nd week	3rd week	4th week	5th week	6th week	7th week	8th week
I	54.5	59.7	66.7	74.5	79.3	87.8	93.8	97.8	102.1
II	54.5	63.5	70.5	83.2	90.0	99.7	107.7	112.7	119.5
III	54.5	62.8	73.3	83.5	86.7	97.0	106.0	112.0	115.3
IV	54.5	61.7	74.0	89.0	94.7	107.7	117.0	120.7	126.1

At the end of the experimental period the length of the animals was measured (from the mouth to the end of the tail), and after the

II	30.1 "	2.56 "
III	31.1 "	2.65 "
IV	32.0 "	2.76 "

length of the animals and that of the femur for comparison.

Discussion

In another paper, we (Pal and Prasad, 1938) have suggested that increase in weight may not always be a completely satisfactory criterion of better growth and nutrition so we took the length of the skeleton and that of individual bones as well, to study developmental differences in the different groups of animals. In this experiment too, we took into consideration, the increase in weight, and also the difference in the length of the animals as well as their individual bones (*e.g.*, femur) of all the animals, for the comparative study of the growth and nutrition. A perusal of table I shows that the first group of animals on basal diet had on the average an increase of 57.6 gms. in eight weeks, the second group that was given a quarter ounce of sprouted Bengal gram in addition to the basal diet, had a gain of 65 gms., the third group having 0.88 gms. of calcium lactate as supplement to the basal diet, showed an increase of 60.8 gms., and the fourth group having a combination of both as supplements to the diet, had on the average a gain of 72.6 gms. in eight weeks. This shows that 0.15 gm. of calcium lactate was almost equally good, as a supplement to the ordinary north Indian diet, as addition of 1/24 oz. of sprouted Bengal gram daily, for each rat; whereas a combination of both acts slightly better than each individually, as a supplement.

A comparison of table I, showing the final weight of the four groups of experimental animals, with table II, giving the average length of the skeleton and of the femur of the four groups of animals, shows some interesting facts. The first group of animals, on the basal diet alone, weighing 102.1 gms. on the average, had an average length of the skeleton 29.25 cm. with average length of the femur as 2.46 cm., the second group, with sprouted Bengal gram as a supplementary diet, weighing 119.5 gms., were 30.1 cm. long with femur 2.56 cm., the third group whose diet was supplemented by calcium lactate weighing 115.3 gms. were 31.1 cm. long with the femur 2.65 cm. long, on the average, whereas the fourth group, that was given both sprouted Bengal gram and calcium lactate in similar quantities in addition to the basal diet, weighed 126.1 gms., having an average body length of 32.0 cm. with 2.76 cm. as the average length of the femur. All these data make it easy to say that the ordinary diet of the poor people of

northern India, is deficient in proteins as well as in calcium, which when added to the diet act as good supplements in promoting better growth and nutrition. When sprouted gram is added alone, the development of the muscles is more, while when only calcium is added, the skeletal development is more, but when both are added to the diet there is a more or less harmonious development of both the skeleton and the muscles, promoting better growth and development, as shown by the maximum increase in weight and also in length of the skeleton, amongst the four groups of experimental animals. Freudenberg and György (Stewart and Percival, 1928) think that when both proteins and calcium are present in food in sufficient quantities proteins form a compound with calcium by virtue of its acidic groups, that the resulting compound having a preponderance of basic groups combines with phosphate ions, and that the calcium-protein-phosphate complex so formed breaks down with deposition of calcium phosphate and liberation of original protein which then probably becomes available for other tissues such as muscles. That is probably the reason why a combination of proteins and calcium acts as a better supplement to the ordinary north Indian diet, than each added separately. Such a diet comes very near in composition to the diet no. 11 consisting of atta chapatties smeared with butter, fresh raw cabbage, raw carrots, sprouted Bengal gram and fresh cow's milk, with small quantities of meat twice a week, advocated as the best of all different types of cheap well-balanced diets for Indian people, by Aykroyd and Krishnan (1936).

Summary

Addition of sprouted Bengal gram and calcium, separately or together, enhances the nutritive value of a poor north Indian diet. The increase in weight on a supplement of sprouted Bengal gram is mostly due to development and growth of muscles, whereas calcium as a supplement, promotes better growth and development of the bones and the skeleton, which are mostly responsible for the increase in weight. A combination of both as a supplement, produces an algebraic sum of the effects due to each and as such acts better than either of them individually.

VOLVULUS AS A CAUSE OF INTESTINAL OBSTRUCTION

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S.J.
Surgeon, King George Hospital, Vizagapatam
 and

D. VENKOBA RAO, M.B., B.S.
House Surgeon, King George Hospital, Vizagapatam

VOLVULUS of the small and large intestine is one of the many causes of intestinal obstruction in India. Reports of this condition in English journals are rare. In the literature on this subject it is said, however, that volvulus as a cause of intestinal obstruction is more common in some parts of Russia, and eastern Europe, as it is in India.

There were eight cases of volvulus admitted and treated from 1932-1936, six of them were in the pelvic colon and two in the small intestine. Three of the six cases of volvulus of the pelvic colon were admitted for acute intestinal obstruction, two were admitted for pyloric obstruction and had remarkably long mesosigmoids (one of the anatomical types conducive to the formation of volvulus as described by Leichtenstern, Keinboe, Lardennois and Aubourg) and the remaining one was admitted for chronic colic, worse at night with occasional signs of intestinal obstruction for a short period, relieved by subsequent passage of a large amount of flatus. The two cases of volvulus in the small intestine were associated with the congenital abnormality of imperfect fixation of the mesentery. The volvulus in these cases was found along the mesenteric axis formed by the superior mesenteric vessels.

The following are the notes of the cases admitted :—

Acute cases of intestinal obstruction due to volvulus of the pelvic colon

(1) A male aged 40 years was admitted for acute intestinal obstruction with absolute constipation and vomiting lasting eight days. A 'ladder pattern' was seen extending from the left iliac fossa right up to the epigastrium. His general condition and pulse at the time of admission were very poor and he was moribund. Post mortem showed a volvulus of the pelvic colon which had become gangrenous.

(2) A male aged 40 years was admitted with a history of constipation and inability to pass faeces and flatus of three days' duration. Vomiting had started 24 hours before admission. On admission the general condition and pulse rate were found to be good. Under spinal anaesthesia the abdomen was opened by a left paramedian incision. On opening the abdomen a volvulus of the pelvic colon with enormous distension of the loop, which had undergone one complete clockwise turn, was found. Excision of the pelvic colon, with end to end anastomosis, was done after undoing the twist. The patient was discharged cured.

(3) A male aged 50 years was admitted with a history of constipation of three days' duration and distension of abdomen but no vomiting. Ladder pattern was distinctly visible, more on the left side, extending from the left iliac fossa to the epigastrium. General condition and pulse were satisfactory. Under spinal anaesthesia, the abdomen was opened by a left paramedian para-umbilical incision. A volvulus of the enormously distended pelvic colon, twisted one and a

half turns clockwise, was found. Excision of the pelvic colon with end to end anastomosis was done. Patient was discharged cured.

Chronic case of intestinal obstruction due to volvulus of the pelvic colon

(4) A male aged 60 years was admitted for recurring attacks of pain and constipation lasting for a short period, usually relieved later by passage of large quantities of flatus. Pain generally started at the left of the umbilicus and was accompanied by a lot of discomfort and difficulty in breathing. After admission definite symptoms of obstruction were noticed in the early hours one morning with a tumour-like mass extending from the left iliac fossa to the umbilical region. The abdomen was opened under spinal anaesthesia by a left paramedian para-umbilical incision. A markedly omega-shaped pelvic colon was found, with adhesions at the convexity at its antimesenteric border to the posterior abdominal wall, below the duodeno-jejunal flexure, with one complete turn of the lower

Fig. 1.—Case 2.

part of the pelvic colon behind the upper one. The pelvic colon was also markedly distended. Excision and end to end anastomosis of the pelvic colon was done with very good result.

Chronic cases of pyloric obstruction with chronic appendicitis and remarkably long meso-sigmoid with a tendency to volvulus formation

(5) A male aged 40 years was admitted for pain in the umbilical region of eight years' duration. The pain was periodical, coming at intervals of a month. It usually started in the morning and was relieved after taking food. Treatment was without benefit. For the past year before admission the pain had become more severe and constant, being relieved only slightly after taking food but more after induced vomiting. On inspection, marks of branding and visible peristalsis were noticed at the level of the umbilical region. Liver and spleen were not palpable. No masses were felt. All other systems were normal. Barium meal examination showed deformity of the duodenal cap with slight

pyloric obstruction and the pelvic colon looked very prominent in the 24-hour picture. The biochemical curve showed the total initial acidity of 65 per cent and free hydrochloric acid 40 per cent rising to a fair concentration like a plateau in one and a half hours' time. On opening the abdomen with a right paramedian incision a cicatrized duodenal ulcer as well as chronic appendicitis were found. The pelvic colon presented itself in the region of the epigastrium. It was long and distended but with no signs of obstruction. It was of the anatomical type conducive to the formation of a volvulus. A posterior no-loop gastro-jejunostomy with appendicectomy was done, as well as excision of the pelvic colon with end to end anastomosis. Local anaesthesia with field block and splanchnic block was used, as the condition of the patient was poor. The patient had an uneventful recovery and was discharged cured.

(6) A very markedly emaciated female aged 30 years was admitted for pain in the abdomen of 16 years' duration, coming on after taking food. The pain had become more severe seven months before admission. Pain came after food and was relieved by vomiting. It started on the right side of the umbilicus and shot up to the epigastrium. Barium meal

Fig. 2.—The specimen removed from case 2.

examination showed a markedly dilated stomach with very poor emptying. Barium was found in the stomach even in the 24-hour picture, showing a marked pyloric obstruction. The biochemical test was typical of a duodenal obstruction with 52 c.cm. of fluid in the stomach before starting the test and 200 c.cm. at the conclusion of the test. Under local anaesthesia, field and splanchnic blocks, the abdomen was opened by a right paramedian incision. A markedly cicatrized pyloro-duodenal ulcer was found with a dilated stomach. The appendix, which looked normal to the naked eye, was removed. On histopathological examination it was found to be chronically inflamed. A posterior no-loop gastro-jejunostomy was done. While suturing the stoma two ankylostomes were found. The pelvic colon was very long and distended with a tendency to volvulus formation. It was excised and end to end anastomosis was done. The histopathological examination of pelvic colon was as follows:—

'Mucous membrane shows adenomatous hyperplasia and is polypoid in places. Hyperplastic lymph follicles

are found in the sub-mucous area. The muscular wall shows neuro-muscular hypertrophy'.
The patient was discharged cured.

Volvulus in small intestine causing acute intestinal obstruction

(7) A child two days old was admitted for constipation since birth. All external orifices including the anal orifice were found normal. The child had been given castor oil and calomel immediately after birth, a custom among the illiterate people. On admission the child was in a collapsed condition with abdomen distended and vomiting bile-stained fluid. Pulse was rapid and uncountable. Rectal examination showed nothing abnormal. Barium enema showed barium held up at the splenic flexure. Operation was performed under local anaesthesia, with a little open ether and oxygen, after preliminary treatment for improving the general condition of the patient. Right paramedian incision was used. On opening the abdomen, plum-coloured distended coils of small intestine were found hanging by a narrow pedicle, the axis of the pedicle being formed by the superior mesenteric vessels. There were three turns of the pedicle, anti-clockwise. The mesentery of the small bowel was not fixed and it looked as if the whole of the small bowel was hanging loose from the superior mesenteric vessels. An ileostomy was done, purely as a palliative measure.

Fig. 3.—The specimen removed from case 3.

The abdomen was closed and the child died two hours after operation. A post mortem confirmed the findings observed on the table.

(8) A female child aged nine years with a history of colic since birth, coming on at irregular intervals, relieved by vomiting, was admitted for intestinal obstruction of eight days' duration. The child had absolute constipation with marked distension of the abdomen, ladder pattern was distinctly seen at the umbilical region. The general condition of the patient was poor, pulse feeble, vomiting was frequent and of a faeculent type. With preliminary administration of saline, the abdomen was opened under local anaesthesia combined with nitrous oxide and oxygen. On opening the abdomen gangrene of the small bowel was found and on exploration it was found to be due to a volvulus of the small bowel. The whole of the small bowel was found hanging like a pendulum the stalk being formed by the superior mesenteric vessels. The turn was from left to right about three times. The child's condition was grave on the table and it died subsequently one hour after the operation. Post mortem

showed gangrene of the small bowel with thrombosis of the superior mesenteric vessels. In this case the caecum was sub-hepatic and not fixed.

It is clear from the description of the cases given above that volvulus is a frequent cause of intestinal obstruction in India. The following statement shows the analysis of cases of 'acute abdomen' admitted and treated from the year 1932 to 1935 :—

	Number	Percentage
Strangulated herniae ..	38	30
Appendix with complications ..	18	14
Intestinal obstruction ..	18	14
Distended bladder with retention of urine ..	12	9.5
Intestinal colic ..	12	9.5
Duodenal or gastric perforation	9	7
Liver and gallbladder ..	10	8
Other causes ..	8	6.3
Pancreas ..	1	8
TOTAL ..	126	106.3

Fig. 4.—Case 3.

Out of 126 cases of 'acute abdomen', 18 were due to intestinal obstruction. Out of these, five were due to volvulus, three of the pelvic colon and two of the small intestine. Subsequent to the analysis one case of volvulus, causing acute intestinal obstruction, was admitted and treated, and two more cases were found with potential tendency to the formation of a volvulus in cases admitted for pyloric obstruction due to cicatrized duodenal ulcer.

Three forms of volvulus were described by Rokitsky :—

- (1) Rotation of bowel on its longitudinal axis.
- (2) Rotation of bowel on its mesenteric axis.
- (3) Intertwining of two coils of intestine.

In the cases reported above, there were two cases of volvulus, which occurred as the result

of rotation of the bowel on its mesenteric axis, and these were found in children with congenital abnormalities in the small intestine. The other cases occurred in the pelvic colon and were probably due to rotation of the bowel on its longitudinal and mesenteric axis. There were no cases illustrating the third type of Rokitansky.

It becomes apparent from an analysis of these cases that volvulus, when it occurs in the large bowel, usually involves the pelvic colon. The age incidence is after the third decade of life. Is this the result of changes in the large bowel due to chronic bowel infection which is so common in India? In one specimen removed, because of the potential danger of formation of volvulus, during an operation for pyloric obstruction, the pathological report showed changes which occur in chronic inflammatory conditions. The various anatomical types of pelvic colon which are conducive to the formation of volvulus

Fig. 5.—Barium enema picture of case 7.

must exist in other countries where, however, incidence of volvulus is rare. It is noteworthy that the countries where the incidence of volvulus is not infrequent are those in which chronic large bowel infection such as dysenteries are also common. It may be suggested that the changes observed in the pelvic colon in case 6 may have probably more than a fortuitous relation to the tendency to formation of a volvulus observed in it. Chronic inflammatory hyperplasia of the mucosa and the neuro-muscular hypertrophy of the wall may be the anatomical substrata of a functional inco-ordination in the motor mechanism of the bowel resulting in the formation of a volvulus.

A survey of the literature on treatment of this condition shows no definite line of treatment

(Continued at foot of next column)

SPINAL ANÆSTHESIA

By C. H. BLISS

CAPTAIN, I.M.S.

MANY techniques for the induction of spinal anæsthesia have been described in the past so it is with some diffidence that a new one is suggested. Most methods seem to be somewhat unwieldy, notably that of Jones (1930). In India a simple method is almost a necessity. A technique which makes use of the dorsal curvature to control the level of anæsthesia has not, according to the writer's knowledge, been described previously.

In the description which follows doses are given for a normal adult of about 140 lb. in weight; these doses must of course be flexible and will be varied according to the condition and physique of the patient and the type of operation to be performed.

Anæsthetic agent

There are a great number of anæsthetic agents on the market; the one selected should be non-irritant to the tissues and of lower specific gravity than the cerebro-spinal fluid. Spino-caine is preferred, but many agents are advocated by various authorities, such as tropacaine (Kirschner, 1931), percaine (light), and

(Continued from previous column)

advocated. High enemas, complete excision and end to end anastomosis are mentioned. Books on surgery generally advocate untwisting the volvulus, and as a simple measure the performance of a cæcostomy in addition, as a safety valve. In some cases fixation of the pelvic colon is advocated. Plication and shortening of the meso-colon is also mentioned. Primary excision as a treatment is just mentioned in passing. My colleague, Major Ebdon, advocated and excised the pelvic colon as a curative measure in conditions of volvulus causing intestinal obstruction. Encouraged by his results all the cases of volvulus of pelvic colon reported above were treated with primary excision of the pelvic colon with end to end anastomosis with very good results. In my opinion this is the best line of treatment to be adopted for volvulus of the pelvic colon, provided the condition of the patient warrants such a procedure. It is noteworthy that gangrene of the bowel is a very late manifestation in volvulus. It was seen on post-mortem examination in one case admitted moribund with obstruction of 8 days' duration.

neocaine (Bailey, 1936). Novocaine is another agent which may be used. It should be in 10 per cent solution because it must be strong enough to have the same effect as one of the proprietary preparations. This solution has no fixative and should therefore only be used when absolutely necessary, and with due precautions.

The heavy anæsthetic agents such as percaine (heavy) or stovaine are mentioned merely to condemn. They necessitate the patient being kept with the head up; a posture which precludes the best treatment for the fall in blood pressure which inevitably occurs in this position.

The choice of spinocaine depends on the following factors :—

1. It is light, S. G. 1,000.5 (C. S. F. 1,006-1,008).
2. It is almost non-irritant.
3. It is fixed quickly.
4. The anæsthesia lasts a long time with small quantities.
5. It keeps well and is conveniently dispensed.

A considerable amount of duracaine has been used but has been given up as it was found that the length of anæsthesia was often inadequate and that it was slightly irritant, as evidenced by occasional cases of retention of urine.

Spinocaine, S. G. 1,000.5.

Composition—	Novocaine	..	mg. 200
	Amylo-prolamine (gliadin)	mg. 130	
	Ethyl hydrate	..	mg. 300
	Strychnine	..	mg. 2
	Normal saline	q.s. c.cm.	2

The gliadin allows the spinocaine to mix but not to diffuse with the cerebro-spinal fluid, or, in other words, the anæsthetic agent is rapidly fixed and the anæsthesia lasts longer.

Anatomy and physiology

The space between the third and fourth lumbar vertebra lies on a level with the highest point of the iliac crests. It is this space which is most commonly used for the insertion of the needle, in spite of the fact that the widest inter-spinous space is that between the fourth and fifth lumbar spines. The spinal cord ends at the disc between the first and second lumbar vertebra; the nerves of the cauda equina are bunched closely together at this level and as far down as the third lumbar vertebra. For these two reasons injection should never be made above the third lumbar vertebra. Malik (1937) advocates, for gastro-jejunostomy, injection between the twelfth dorsal and first lumbar vertebra. This is unnecessary. High injections run the definite risk of touching a nerve root or even the cord itself, possibly resulting in a subsequent paralysis.

The sympathetic outflow, upon which blood pressure depends, is by the white rami communicantes accompanying the anterior roots of the first thoracic nerve to the second or third lumbar

nerves. The distribution of these nerves is briefly as follows :—

1. Anterior limb ..	T 1-3	Constrictor.
2. Posterior limb ..	T12-L2	Constrictor.
3. Head ..	T 2-5	Constrictor.
4. Abdominal viscera	T 6-L5	Constrictor.
5. Coronary vessels	T 1-5	Dilator.
6. Pulmonary vessels	Upper thoracics.	Constrictor.

From this it will be seen that the blood pressure will fall dangerously and vital functions be interfered with if paralysis extends above the fifth thoracic nerve root.

The body of the fifth thoracic lies on the same level as the tip of the fourth thoracic spine, and the fifth nerve issues below the corresponding vertebra.

Technique

It is intended to deal with this in two parts; firstly with the theoretical factors upon which the procedure depends and, secondly, with the practical details adopted.

Diagram to illustrate the use of the dorsal curvature to determine the level of anæsthesia.

The diagram represents the position of the spinal canal in the prone position (1) and in the supine position (2). In the prone position it is obvious that the anæsthetic agent can flow easily up to the highest point to Th. 5; it cannot flow past this as the remainder of the curve is kept definitely downwards. In the supine position, however, the conditions are reversed and the anæsthetic agent will remain at L3 which is now the highest point. To make it rise to Th. 5 the patient must be tilted to the position shown by the dotted line but in this position C3 will be higher than Th. 5 and the anæsthetic agent will therefore flow on upwards. Therefore the height to which it flows is not controlled. By using the dorsal curvature in the prone position the anæsthetic level can be accurately determined. It is only necessary to place the patient in such a position that the uppermost nerve root to be anæsthetized is at the highest level. All other roots cranially are kept at a lower level.

Full aseptic precautions should be observed throughout, the injection area surgically prepared and the anæsthetist should wear cap, gloves, gown and mask. The needle should be as fine as possible so as to cause a minimum amount of trauma. The skin should be anæsthetized with the special novocaine-ephedrine solutions recommended by the makers. The patient is placed in the left lateral position and

as soon as the injection has been made he is turned on to his face for eight minutes. The injection is never made higher than the space between the third and fourth lumbar vertebrae. Directly the patient has been turned on to his face the table is tilted in such a way that the anæsthetic flows up to the height to which anæsthesia is required.

Table showing dosage, barbotage and tilt of the table

Operation	Quantity of spinocaine	Barbotage *	Tilt of the table
Pelvis, legs, etc.	2 c.cm.	Nil	Buttocks up
Lower abdomen	3 c.cm.	1-2 c.cm.	Level
Upper abdomen	3-4 c.cm.	3 c.cm.	Thorax up

* Barbotage is the amount of spinal fluid to be mixed with the anæsthetizing agent.

The above dosage (using spinocaine) is sufficient to give an anæsthesia lasting for at least two hours. The tilt of the table is important, as upon this depends the height of anæsthesia. For upper abdominals the highest point of the dorsal curvature should be about $2\frac{1}{2}$ inches above the level of the buttocks. In all cases the head flap of the table must be dropped slightly and the head of the patient flexed forwards. It is an advantage to place the patient's hands on his occiput. Induction takes place in eight minutes and when it is complete the patient is placed in the supine position.

Determination of the level of anæsthesia is by inspection of the abdomen which shows a characteristic scaphoid appearance due to the relaxation of the abdominal muscles.

Pre-operative treatment

It is not considered that purges or enemas are indicated before any type of anæsthesia as they result in an adverse fluid balance, which is further aggravated by the operation itself, whatever form of anæsthesia is used. The stomach should not be full, as it is important that the diaphragm should in no way be embarrassed.

Some degree of premedication is desirable if the patient is at all nervous, and the following is suggested:—

Nembutal grains 3 one and a half hours before operation followed by omnopon-scopolamine 1 c.cm. three-quarters of an hour before operation. Too much premedication is to be avoided as it tends to depress the medullary centres. Scopolamine is of value for its amnesic properties.

Indications

Spinal anæsthesia is indicated for all major operations below the costal margin and in most cases where an inhalation anæsthetic is contra-indicated. The contra-indications are discussed later.

Relative indications include the perfect relaxation obtained, the collapse of the gut, absence of the neurogenic factor in shock, less bleeding, no systemic reaction of the organism as, for example, the altered acid-base ratio which occurs in ether anæsthesia.

Contra-indications

The only real contra-indications are:—Marked organic disease and the moribund patient. 'Spinal anæsthesia is the sure way of killing the moribund' (Ashworth, 1937).

Lowered blood pressure, perforations of the gut, general peritonitis and widespread sepsis are not contra-indications unless accompanied by toxæmia so profound as to have rendered the patient moribund. Intestinal obstruction (as stated by Malik, 1937) is not a contra-indication as the collapse is passive. Indeed intestinal obstruction is a very definite indication for this type of anæsthesia.

Complications

1. Headache is probably most to be dreaded, but should not occur at all seriously in more than 2 per cent of cases. The causes are said to be escape of the cerebro-spinal fluid, rapid withdrawal of cerebro-spinal fluid for barbotage and effusion of blood into the cerebro-spinal fluid. These chances are reduced by using a very fine needle. Further causes are said to be injection of foreign agents such as iodine, the anæsthetic agent itself, saline, etc. These probably have no effect (Koster, Kasman and Shapiro, 1937). The most likely cause of headaches following interference with the spinal canal is alteration in pressure of the cerebro-spinal fluid.

2. Vomiting is not an important complication; it occurs more than once in only 4 per cent of cases. The writer has never yet had a case of cyclical vomiting nor a case which required any treatment.

3. Flatulence occurs as in any abdominal case and is dealt with in the routine manner.

4. Retention of urine is rare and occurs in the same type of case as with any other anæsthetic.

5. Pain in the shoulders during an operation on the abdomen is due to interference with the diaphragm stimulating the phrenic nerve whose root value is C3-5.

6. Broncho-pneumonia is a negligible complication. Its pathology is probably due more to the manipulations of the surgeon than the anæsthetist (Osborn, 1938).

7. Meningitis or paralysis has never been seen by the writer.

The blood pressure

The fall in blood pressure depends on several factors, the most important being the posture

of the patient and the level of anæsthesia. The most important sympathetic nerves controlling the blood pressure are among the white rami communicantes of the first to fifth thoracic nerves. If these are not interfered with the fall in blood pressure will be minimal.

It is hoped that in a future communication it will be possible to show exactly what occurs to the blood pressure under spinal anæsthesia.

The following case of jejunostomy is illustrative of what appears to occur :—

Mrs. F.

Level of anæsthesia just above the nipples.

Time	Manipulation	Blood pressure	Pulse
11-54	Before giving anæsthetic ..	146/62	62
12-04	Two minutes after giving spinal injection.	140/76	..
12-10	Anæsthesia complete ..	132/80	..
12-35	Fifteen minutes after operation started.	82/62	..
12-41	CO ₂ and O ₂ for one minute. Respirations deepened.	125/75	94
12-45	120/70	90
12-49	O ₂ for one minute. Patient roused.	120/80	108
12-52	105/65	..
12-58	CO ₂ and O ₂ for one minute ..	120/80	108
1-02	105/70	..
1-06	Abdomen closed. Legs raised 90° for two minutes.	130/80	104
1-09	115/75	..
1-10	Head up. Feet down. Groaning and retching.	Unobtainable.	..
1-12	Head down. Feet up ..	135/85	..

(Record of case taken during operation by an independent observer.)

This shows clearly that the remedy for low blood pressure in these cases is posture and CO₂ to breathe.

The writer has had one death in about 200 cases and has observed 200 further cases in which no death occurred. This death occurred at a time when this form of anæsthesia was looked upon more as a massive local than as a general anæsthesia and it was thought that there were no contra-indications. The patient was a moribund man with advanced carcinoma coli invading even the abdominal skin.

INCIDENCE OF PULMONARY TUBERCULOSIS IN THE PUNJAB VILLAGES

By B. L. KAMRA

CAPTAIN, M.B., B.S.

Medical Officer in charge, Sohargarh Rattewala Dispensary, Tehsil Muktsar, District Ferozepore

IN this article an attempt has been made to estimate the prevalence of pulmonary tuberculosis in this rural area of the Punjab. Little apology is due for such an effort as no accurate estimate has so far been possible of the incidence of this disease in Indian villages and if ever such has been tried it has been in a rural area close to a town, thus fully effected as regards urbanization. Purely rural figures, if available, have been collected through vaccinators and village chowkidars, so they are worth very little. Here figures have been collected from the patients attending the outdoor department of the above dispensary and coming from the surrounding villages in the Ferozepore district. The sputa of all the suspicious cases were examined microscopically and only those showing acid-fast bacilli have been included as suffering from the disease. Sputum could not be collected easily from children; those above ten years of age, therefore, have only been taken account of.

This dispensary serves many villages but those situated within an area of about 100 square miles send patients almost daily. The villages within this area are thirty in number. They are all small villages with populations varying from 190 to 1,440. This group is not wholly dependent upon this dispensary for its medical aid; there are four other dispensaries to which many of these villages are nearer than they are to this one. Besides there are many quacks to attract the patients. But this dispensary being the most popular, there cannot be many patients suffering from pulmonary tuberculosis who have not attended here some time during their long illness. Therefore, the figures given below are probably not far below the true incidence.

These villages are inhabited by three classes of people—landlords, cultivators and labourers. Landlords are well-to-do, they can afford better houses and better food but they constitute a negligible part of the total population. Labourers are the poorest financially, they are ill-housed, ill-clad and ill-fed. Cultivators are not better off than the labourers, from their ignorance of the rules of hygiene and dietary. They constitute the majority in the villagers. Total population concerned is 15,884 and according to the revenue records the total income has been estimated at Rs. 10,87,702-8, produced by 48,036 acres of cultivable land per year. About one-half of this produce goes to the landlords. The remaining population, hence, gets about Re. 0-1-6 per head per day. This is the financial condition of the people in fertile areas such as this!

The dietary habits of the people are almost uniform. Most of the Hindus and Sikhs and all

Mohammedans are non-vegetarians but meat is taken only occasionally and in a small quantity at a time. It is taken as a relish rather than as a staple article of diet, which consists mostly of wheat flour. The dietary of the people does not lack in vitamins and salts. Diseases due to their deficiency are not very common and the condition of most of those found with avitaminosis may be attributed to general constitutional defects due to causes other than dietary deficiency. Hindus and Sikhs take food richer in fats than the Mohammedans. Scarcity of milk is increasing. Onions, *sarson ka saag*, green gram and buttermilk, however, with wheat in the adult dietary leave little to be desired.

Open air is nature's best gift to a villager. However, during the winter months the habit is for the family to sleep together, huddled up in one room, ill-ventilated as a rule, giving even rather less cubic space per person than in the towns. The sleeping room is never separate. It is packed up with all sorts of furniture, the store of raw food material is also to be commonly found in the sleeping rooms. The food during the winter and rainy days is also cooked there. Almost every roof in a house is found blackened with smoke.

No latrines are to be found in the premises of the houses. People defecate outside the village in its close vicinity. Young children and infants defecate in the courtyards of their houses and in the streets. There is none to look after the cleanliness of a street. It is usual to find them dirty with refuse. Drains are nowhere to be found.

The respiratory tract is the most frequent avenue of infection, and sputa from infected cases is a great source of the tubercle bacillus. Here we live eight months during the year in an atmosphere thickly laden with street dust—without doubt a fertile source of infection, but thanks to frequent dust-storms, the load of bacilli in the street air is very much diluted. Such in short is the sanitary condition one meets with in the villages around here.

The total area used for residential purposes (streets, ponds, cattle courtyards and places for other village necessities included) in all these villages is 614 acres. The total population is 15,884 men and women and 13,674 cattle. On the average, therefore, 100.5 square yards are used per living animal. This condition of overcrowding may compare well with that in towns, for which I have no figures to quote, but, as mentioned above, during winter months it is the habit to sleep together in closed rooms with very little cubic space per person.

Purdah in its strict sense is practically nowhere to be found except that a few landlord families and those of mosque mullahs are the victims of this practice.

The total number of new cases treated in the outdoor department during the period extending from 13th December, 1935, to 31st March, 1938,

has been 29,464. Amongst these 18,640 patients were above 10 years of age. Out of these 53 were found to be suffering from pulmonary tuberculosis, giving the ratio of 1 to 351.7 patients. The total number of females treated during the period was 7,017 and amongst these 20 were found tuberculous, giving the same ratio. This is what one would expect as purdah and early marriage are almost non-existent here.

The number of tuberculous patients, who attended this dispensary for treatment during the last two years, was 28, giving the incidence of one case per 567.3.

During the years 1936 and 1937 the total number of deaths recorded in these villages was 809, amongst which 274 were deaths in persons above 10 years of age and 22 were amongst tuberculous patients, who were diagnosed to be such by examining their sputa in the laboratory, that is, one death per 12.5 was due to pulmonary tuberculosis.

So far it has been held that the disease is mainly an urban one. 'Urbanization has provided the spark but it will be in the villages where the fire *will eventually burn** most fiercely' says the Editor commenting on the tuberculous problem in India in the *Indian Medical Gazette*, Calcutta, February 1935. The fire is already actively burning in the villages as is shown by the figures given above. The problem elsewhere must be worse than it appears here, as this area is relatively very healthy and better off financially than many others.

I acknowledge my indebtedness to Lieut.-Colonel K. R. Batra, I.M.S., Civil Surgeon, Ferozepore, for useful advice and kind permission to publish this article.

A Mirror of Hospital Practice

TWO CASES OF TREPONEMAL INFECTION TREATED WITH PARITRAN PREPARATIONS

CASE 1

By A. N. MUKHERJI, B.Sc., M.B. (Cal.),
L.R.C.P. (Lond.), F.R.C.S. (Eng. and Edin.)

Visiting Surgeon, Carmichael Medical College Hospital,
Calcutta

Mrs. X, aged 40 years, sought advice for the cure of patches of what she called dry eczema two of which were prominent and unsightly, being situated near the elbows. They gave her little or no trouble beyond a slight irritation in hot and damp weather.

She was married 20 years ago and had five conceptions. Her first child, 19 years old, was born with talipes, cleft palate and other deformities. She has Hutchinson's and Moon's teeth, is physically underdeveloped and wanting in intelligence. There is no

*Italics by the author of this paper.

evidence of congenital syphilis in the remaining three children. Her fifth conception terminated in miscarriage. Her parents are in good health. Her younger sister has pigmentary syphilides; she is mentally 'overstrung' and the Wassermann and Kahn tests are strongly positive. She has had a miscarriage. Her husband's blood gave negative Wassermann and Kahn reactions.

She had four patches of scaly psoriasis with pigmented margins situated in the regions of the elbows and ankles. She complained of unusual dryness of the skin of the lower parts of her legs. The epitrochlear lymph nodes were palpably indurated.

Her Wassermann reaction was 4 to 10 and Kahn test positive. She was given twelve injections of arseno-paritran and bismo-paritran with interruptions, as she had to leave Calcutta for three weeks and discontinue treatment. On her blood being tested one month after the last injection, it was noticed that Wassermann reaction had gone up to 10 to 10 and Kahn still positive though the patches of psoriasis had disappeared leaving the skin smooth. The dry feeling of the skin was also less. She was now put on an intensive course of twelve injections each of arseno-paritran and bismo-paritran bi-weekly. On the blood being tested one month after the completion of this course, Wassermann and Kahn tests were both negative. Psoriasis never returned after its first disappearance though she thinks that there is still a slight dryness of the skin of her leg.

CASE 2

By P. C. SANYAL, M.B. (Cal.), F.R.C.S. (Eng.),
L.R.C.P. (Lond.)

Visiting Surgeon, Medical College Hospitals, Calcutta

C. K. J., aged 40 years, was an assistant to a medical practitioner who has an extensive venereal practice. His wife conceived on six occasions, one resulting in miscarriage and one in death due to neo-natal asphyxia; the four remaining children are apparently healthy. His wife is in fairly good health. He had an exposure sometime before his marriage, resulting in a mild form of urethritis. Neisserian organisms were not found in the discharge which disappeared with local treatment. Some time later he noticed weakness in his control over micturition which developed into incontinence. Later still he suffered from vague nervous symptoms such as insomnia, twitchings of the extremities and loss of concentration.

When he consulted me in March 1937 he said that he never had syphilis and the object of his visit was for the relief of incontinence of urine. His Wassermann reaction was 6 to 10. On examination his prostate was not found enlarged though it was soft and boggy; there were evidences of prostatorrhœa, and his urine collected after prostatic massage yielded streptococci. A full course of autogenous vaccine, lavage, instillations and diathermy gave some relief to the urinary symptom and helped to clear streptococci, but incontinence continued. He was recommended an intensive course of arseno-paritran injection. He took these injections and called in January 1938, some time after the course was completed, to report that though the dribbling and incontinence were definitely less, he has not had complete relief. There was a marked improvement in his general condition. His blood was tested for Wassermann reaction with negative results. He was then given prostatic extracts, orally and by injection, but without relief. He was now given some bismo-paritran injections; thereafter he got further control over his bladder.

A LYMPHO-SARCOMA IN THE BLADDER

By J. F. HENRIQUES, L.M.&S., F.C.P.S., B.M.S.
Civil Surgeon, Bijapur

A boy, age 10, was admitted for a suspected stone in the bladder which appeared to be felt on sounding.

The boy suffered from symptoms like those of stone in the bladder. Litholapaxy was tried, but instead of the stone some part of a fleshy growth seemed to be caught by the blades of the lithotrite. A suprapubic cystotomy was therefore done and the growth appeared to be an enlargement of the prostate. This was unusual in a boy of 10, though later I found, according to Boyd's Pathology, that it does occur in the rarest of circumstances in young people. I shelled it out easily. I did not feel any other growths in the bladder and the boy was in hospital from 7th to 27th January, 1938, and was discharged cured. The growth removed was inadvertently thrown away by the sweeper.

On 13th February, he was readmitted. Whilst playing he fell on his abdomen. He came with a gaping wound at the old operation scar. He was dressed in the usual way and it was thought the wound would heal in a few days. After six days, I was sent for urgently, one night, as there was a sudden severe hæmorrhage through the wound. I performed an exploratory operation and, on dilating the wound, was surprised to find a number of soft growths mostly sessile, in the bladder; these I began to remove with my fingers. They varied in size from small marbles to pigeons' eggs and were about 48 in number. The whole operation took nearly an hour and was a most trying and difficult one. The patient became very low during the operation, but I was able to finish it and as far as I could feel there were no masses left behind in the bladder.

Though the wound seemed to be healing, he looked anæmic and seemed to be going down gradually. He was discharged at the request of his people after about three weeks, with a small sinus still persisting.

The report on the tumours from the Haffkine Institute was as follows:—

'Composed of gelatinous mass. Sections show areas of small cell infiltration separated by bands of connective tissue. The vessels are hypertrophied and at places the tissue is undergoing myxomatous change'. Subsequently, as the laboratory found the case very interesting almost all the masses removed were sent. Their report on these was:—

'The structure is that of malignant lympho-sarcoma, which in the bladder is comparatively rare'.

A CASE OF EXTENSIVE SCALDING TREATED WITH COD-LIVER OIL DRESSING

By K. P. HARE, M.B., B.S. (Lond.), L.M.S.S.A.
Medical Officer, Tingri Medical Association, Assam

DURING the past two years I have used cod-liver oil extensively as a dressing in the treatment of burns, scalds and other wounds involving extensive damage to the skin and have been much impressed by its efficacy. I have, however, been surprised to find that many of my professional colleagues have had no experience of it and am therefore recording the following case which illustrates some of the advantages of this technique, viz, ease of application, painless dressings reducing shock to a minimum, absence of secondary infection and speedy epithelialization.

History.—The patient, a male tea-garden coolie, aged 35 years, was admitted to hospital on 27th February, 1938, suffering from severe scalds sustained the previous night when an earthenware vessel, in which he was cooking rice, burst. He was very shocked.

Fig. 1.

The greater part of the anterior surfaces of the head, neck, chest, abdomen and both arms was scalded. The exact distribution is shown by the shaded area in figure 1 and the general appearance is well seen in the photograph (figure 3) taken two days later.

Fig. 2.

Treatment.—The wounds were cleansed with warm boric lotion and dressed with lint soaked in cod-liver oil. The dressings were held in position by light bandaging. Morphia gr. $\frac{1}{4}$ was administered and complete rest in bed enjoined, the foot of the bed being raised. Subsequently the cod-liver oil dressings were renewed daily.

Progress.—The initial shock was quickly overcome and the daily dressings caused no distress. There was never any tendency towards suppuration and healing

Fig. 3.

proceeded rapidly and steadily. There was no elevation of temperature at any time. The second diagram (figure 2) and the photograph (figure 4) taken on 23rd

Fig. 4.

March show the remaining extent of the wounds on that date. The patient was discharged from hospital with all wounds completely healed on 26th March.

A Correction

In the article '*Bertiella studeri*, a natural tape-worm parasite of monkeys, in a Hindu child', which appeared in the June number of the *Gazette*, p. 346, it is stated Dr. B. M. Das Gupta examined the stool; this is not correct, the contributor, Dr. S. C. Roy, himself made this examination.—Editor, *I. M. G.*

AUGUST

BENZEDRINE : ITS USE AND ABUSE

BENZEDRINE is a trade name given to a synthetic drug known as beta-phenylisopropylamine which is chemically related to ephedrine and to a less extent to adrenaline and is comparable to them in its pharmacological effects. The various curious effects of this substance, which remained unnoticed for two decades after Barger and Dale discovered it in 1910, have recently begun to attract the attention of investigators. Its principal physiological effects are stimulation of the central nervous system, including the higher cerebral centres, pressor effect on the vasomotor system and anti-spasmodic action on the smooth muscles of the gastro-intestinal tract.

Clinically, the sympathomimetic action has been frequently utilized in the treatment of congestion of the nasal mucosa in conditions such as coryza, and vasomotor rhinitis. Benzedrine brand inhalers, supplied in convenient tubes and distributed liberally to the medical profession as free samples, appear to have increased its use in recent years. In hay fever and similar conditions, it may give great relief, but it is doubtful whether the frequent use of vasoconstrictor drugs applied locally is justifiable in inflammatory conditions of the nose and related parts when due to infections. The drug has also been advocated for maintaining blood pressure during spinal anaesthesia and orthostatic hypotension. Its anti-spasmodic action has been utilized, mainly to facilitate x-ray investigation of suspected peptic ulcer or other conditions associated with spasm. The stimulating property of the drug to the higher centres of the brain, which is more marked than that of ephedrine, led to the idea of using it to treat mentally depressed cases in psychopathic institutions, but with little success until oral administration was introduced.

During the past two years a non-volatile salt of benzedrine—the sulphate—has been introduced and extensively exploited as a stimulant to the brain. The present vogue of the drug lies mostly in the treatment of narcolepsy and beneficial results have been obtained. Various

conditions associated with fatigue, depression and lethargy have been benefited by its administration. The distressing symptoms of post-encephalitic Parkinsonism such as drowsiness during the day, oculogyric crisis and the feeling of exhaustion, which are not affected by the administration of atropine and related drugs, are better controlled by the exhibition of benzedrine sulphate. When administered by mouth in 2.5 to 10 mg. doses (occasionally increased to 20 mg.) before breakfast, and lunch if necessary, it relieves the fatigue, increases the capacity for work and gives a feeling of exhilaration. Such stimulation is found to be greater in patients depressed from toxic or organic causes such as alcoholism than in those with purely psychologic disorders. It must be admitted, however, that these results are purely subjective and the stimulation is not permanent.

Benzedrine acts differently in different individuals. Experiments on normal persons have shown that a feeling of well-being, talkativeness and an increase in motor activity are the most frequent changes. But some people develop a state of irritable restlessness and unpleasant sensations. The undesirable effects are dryness of the mouth, anorexia with consequent loss of weight, palpitation, precordial discomfort, tremor and insomnia.

As it prevents drowsiness and depression students began taking it for the purpose of keeping awake and preventing fatigue when preparing for examinations, instead of the old favourites, tea or coffee. Such a practice should obviously be condemned. The relief of fatigue and the stimulation of mental activity cannot be maintained for any appreciable period without subsequent periods of depression. It amounts to 'whipping a tired horse' rather than giving a 'pick-me-up' to a sluggish one. Cases of collapse, fainting and insomnia have been observed as a result of its misuse. The action of the drug is not yet thoroughly understood, and there are undoubtedly risks of severe reactions from its effect on the circulatory system.

Recently, a pharmaceutical student in England, while preparing for the final examination, took the drug in moderate amounts for 19 days. He developed acute aplastic anaemia, and severe cardio-vascular collapse occurred the day after the last dose was taken. Physicians may well keep this drug in mind, when they encounter cases of fainting, exhaustion, and collapse of obscure origin.

At present, benzedrine can be freely purchased from chemists. This will probably lead to its indiscriminate use by the lay public, without medical supervision, a thing to be deprecated,

for caution is clearly advisable, especially in its administration to normal or relatively normal people, as distinct from those suffering from chronic or incurable diseases.

THE VICEREINE MAINTAINS ANTI-TUBERCULOSIS DRIVE

ALTHOUGH Lady Linlithgow is now in England, she has not forgotten the Anti-Tuberculosis Fund and is actively helping the efforts of the Tuberculosis in India Appeal Committee in London to raise money by various means.

Under her distinguished patronage, as well as the patronage of Lord Zetland, Lord Halifax, Lord Willingdon, Lord Hardinge of Penshurst, Lord Stanley, M.P., the Dowager Marchioness of Reading, Sir Atul Chatterjee and Sir Firozkhan Noon, various film and other entertainments are being organized to raise money.

Charity entertainments have been arranged, including a Garden Fête to be held on 7th July, at the High Commissioner's House at 49, Putney Hill. Lady Linlithgow is expected to perform the opening ceremony of this fête, at which Indian ladies will be in charge of the numerous stalls.

The Committee has circulated copies of the appeal for the King-Emperor's Fund to about 170 firms with business connections in India, the majority of which have replied that their Indian branches were making contributions to the Fund in India.

It is learnt that the President of the India League of America is planning to form a Committee composed of both Indians and Americans to bring the appeal to the notice of Indians and other sympathisers residing in America and Canada.

KING-EMPEROR'S ANTI-TUBERCULOSIS FUND

ELEVENTH AND TWELFTH SUBSCRIPTION LISTS
GRAND TOTAL NOW Rs. 42,73,044

THE eleventh and twelfth lists of subscriptions actually received up to 15th May, and 31st May, 1938, in response to Her Excellency the Marchioness of Linlithgow's appeal for the King-Emperor's Anti-Tuberculosis Fund, amount to Rs. 3,20,644-9-6 and Rs. 3,24,114-13-11, respectively, which bring the grand total of cash in hand to Rs. 42,73,044-0-11.

ANTI-EPIDEMIC WORK IN CHINA

TECHNICAL CO-OPERATION WITH THE LEAGUE OF NATIONS
The constitution of the League Epidemic Commission

THE three medical units—the first under Dr. Mooser (Swiss), the second under Dr. R. C. Robertson (British) and the third Dr. (Inspector Général) Lasnet (French)—arrived in Hongkong early in January.

The epidemic commission consists of the three commissioners, together with a representative of the Chinese Government (at first Dr. J. Heng Liu, later replaced by Dr. Robert Lim) and Dr. Borcic (Yugoslav), the League of Nations' Technical Adviser on public health questions to the Chinese Government, who has spent the last six years in China.

In his statement to the epidemic commission, Dr. Liu gave a vivid idea of the consequences of the war in terms of human suffering. The wounded, he said, could be counted by the hundred thousand, the homeless and destitute numbered millions and there were many millions of sick who could get no medical care.

'The migration of the population during the past few months has been unprecedented in the history of the Chinese people. Everywhere in the country, in villages as well as in cities, utilizing every means of communication, including railways, waterways, highways and aeroplanes, people are going and coming in inconceivable numbers. Soldiers are being moved about in millions from one part of the country to the other. There is overcrowding everywhere, and as circumstances make it necessary to ignore even the first principles of hygiene and sanitation, all kinds of sicknesses are spreading rapidly and widely.

The medical services in different parts of the country are already disorganized in the attempt to strengthen the army medical service. Many hospitals, including foreign missionary institutions, have been bombed, or for other reasons had to be evacuated. Private practitioners and nurses are themselves often fleeing refugees.

All of this will result in a series of epidemics in the control of which the most modern methods of preventive medicine and hygiene will be severely tested. I can visualize people, civilians as well as soldiers, dying in millions from influenza, smallpox, typhus, relapsing fever, diphtheria, scarlet fever, typhoid, dysentery, cholera, measles, malaria, tuberculosis and every other infectious disease. Diseases resulting from malnutrition, such as rickets, scurvy, beri-beri, pellagra and others resulting from inanition or vitamin deficiency will add to the number of deaths.'

Dr. Liu went on to promise the epidemic commission the utmost co-operation from the Chinese Government. The war, he said, had made it necessary to cut down many of the health activities which had just been started, but members of the staffs of the National Health Administration and Central Field Health Station were being assigned in large numbers to the anti-epidemic units, as was the personnel recruited from local health services. 'These persons, including health officers, bacteriologists and parasitologists, sanitary engineers, sanitary inspectors and technicians trained abroad and in our own training institute in Nanking during the past few years according to a programme in which both the League of Nations and the Rockefeller Foundation have taken such a great interest and given much support, will be at the full disposal of the commission. China's financial contribution towards the support of the units is already in the hands of the commission. You may rest assured that China will do her part in making the work a success.'

Subsequently the epidemic position in China was discussed, the future location of the league units was decided upon and the laboratory and other medical facilities already existing in the areas covered, transport, budgetary questions and details of the liaison to be established with the Chinese Government, were all considered. In pursuance of the decision taken, no. 1 Unit went by rail through Hankow to Sian-Fu, capital of Shensi, no. 2 Unit to Changsha, capital of Hunan, and no. 3 Unit to Nanning, capital of Kwangsi, and to Canton.

Early in February all three units had reached their stations, established headquarters and were engaged in making the necessary official contacts. At the same time the equipment and stores had arrived at the headquarters of each unit, apart from the base reserve stock which is to be retained at Hong Kong and upon which the units can draw as required. Transport was

provided in the first instance by touring cars purchased in Hong Kong and later by motor lorries, ten of which are attached to each unit. A launch and two out-board engines for attachment to junks were also purchased. Thus in each area is now established an efficient health unit provided with disinfecting material, transport and equipment in each case for one stationary and two mobile bacteriological laboratories.

All the reports received so far emphasize the close liaison that exists between the league units and both the Central and Provincial Governments. In each case the league unit, with the necessary Chinese medical and auxiliary staff, is incorporated in the local health administration, and at the same time is in close touch with the Central Government through a special Chinese liaison officer. In this collaboration every effort is being made to meet present emergencies, and also to strengthen, and where necessary establish, permanent health work, particularly in rural districts. It is hoped that in this way the present league assistance to China will not simply be of a temporary nature, but will serve to continue the medical assistance given prior to hostilities, and thus be a permanent contribution to China's welfare. Moreover, the reports stress the great increase, both amongst the local and central authorities, of interest in anti-epidemic work which has followed the arrival of the league units.

The activities of the league anti-epidemic units were in this way incorporated in the Chinese Government's nation-wide effort to meet the emergency.

Thus a new medical school with a school for sanitary auxiliary personnel has been organized by the Chinese Government in Kweiyang for five hundred medical students and the training of five hundred auxiliary personnel. The central hospital and national field health station established at Nanking by the Chinese Government as part of its plan of technical co-operation with the league in public health matters were badly damaged by Japanese air raids. The new medical school is meant to afford an opportunity to those whose studies were interrupted by military operations, to continue and complete them. The students at the new medical school have been enrolled in teams which are always ready to join in field and hospital work as and when they are needed.

The training institutes for health workers and for workers in rural reconstruction have been transferred from Nanking and Tsining respectively to Kweiyang (Province of Kweichow) and several hundreds of students have been admitted to prepare them for field work during and after the war.

A hundred medical units are being organized to serve in rural districts, both in a teaching and in a working capacity. They are part of the mass education movement which was instituted in the Province of Hunan and has since been extended to Kweichow, Kwantung, Kiangsi, Szechwan and Kwangsi. This movement is attempting to apply the principle that China's national resistance, to be effective, must be backed by a well-informed and well-organized civilian population, able intelligently to co-operate with the army. The movement is enlisting students, teachers, scholars, doctors and technicians for all kinds of social, educational and propaganda activities, as well as for public health work, and is intended not only to help in meeting the present emergency, but to pave the way for post-war reconstruction. Anti-epidemic and sanitary measures are an important part of this movement. The staff of the epidemic commission of the League are actively taking part in this campaign.

The Chinese Red Cross has since December 1937 organized forty units, each consisting of doctors, nurses and dressers, to help in the care of wounded and refugees, as well as in preventive work.

The Chinese Government has organized three big anti-epidemic units, each consisting of from 150 to 250 doctors, nurses, sanitary engineers, sanitary inspectors, etc., to deal with epidemic problems in the Northern, Central and Southern areas of the country respectively. The three League of Nations medical units in these areas are co-operating closely with the

Government organizations, as well as with the local authorities. National Government has also granted 160,000 dollars to the League of Nations' Epidemic Commission for its preventive activities.

The task of each unit after its arrival in its area has been, first, to establish contact with the local health administration, and, secondly, to survey closely not only local epidemic conditions, but also the existing machinery for controlling them. While this is being done, anti-smallpox and anti-cholera vaccination is being carried out and preparations made for the production of typhus vaccine and calf lymph locally.

Meanwhile the purchase of stores for the base supply was completed in Europe and supplies despatched to Hong Kong. These include large quantities of drugs required for the combating of the epidemic feared during the summer. In addition, the stores sent include one and a half tons of quinine, supplies of tetanus and diphtheria antitoxin (the gift of the Danish Red Cross), smallpox lymph, dried milk, cod-liver oil, etc.

DR. H. DE SA SILVER JUBILEE PRIZE

THE Bombay Obstetric and Gynaecological Society has selected the following subject for the thesis for Dr. H. De Sa Silver Jubilee Prize for 1938-39:—

'MEASURES FOR REDUCING THE INFANT MORTALITY'

The prize is open to all registered practitioners of five years' standing. The value of the prize is Rs. 125 in cash. The thesis must be submitted by 15th March, 1939. For further particulars, communications be made to Honorary Secretary of the Society, Sandhurst Road, Bombay, 4.

THE 47TH CHEMISTS' EXHIBITION, LONDON, ENGLAND

THE 47th Chemists' Exhibition will be held from 19th to 23rd September next in the Royal Albert Hall. The management, 'The British and Colonial Pharmacist', is always pleased to welcome members of the drug trade from overseas and they are admitted on presentation of a business card. Solely for the trade, it reflects the advance in the previous 12 months.

THE BIRTH CONTROL RESEARCH COMMITTEE OF VILE PARLE

THE Secretary of the Birth Control Research Committee of Vile Parle informs us that the number of people who visited and sought advice at the Birth Control Centre at 166A, Vincent Road, Dadar, Bombay, conducted by the Birth Control Research Committee of Vile Parle, during the quarter ending 15th June, 1938, was 290 out of which 112 were males and 178 were females. The total number from the first being 565.

SUMMARY OF TUBERCULOSIS NEWS FOR THE MONTH OF JUNE, 1938

1. Hassan Masud Suhrawardy Memorial Anti-Tuberculosis Challenge Shield

THE King George Thanksgiving (Anti-Tuberculosis) Fund annually awards the Hassan Masud Suhrawardy Memorial Anti-Tuberculosis Challenge Shield to the Municipal Corporation, Council or Committee or any other organization (approved by the Central Fund Committee) doing anti-tuberculosis work in British India or in an Indian State. There were nine entries this year from Ahmedabad, Bareilly, Bengal, Bombay, Delhi (2), Mysore, Sholapur and Surat. The fund committee at its meeting held on the 23rd May, 1938, awarded the shield to the Delhi Municipality for its commendable anti-tuberculosis efforts in 1937.

The Delhi Municipality organized anti-tuberculosis campaign through the Public Health Department and through special tuberculosis institutions. It maintains a tuberculosis clinic and 92 beds in the Silver Jubilee Tuberculosis Hospital and helps the Ramakrishna Mission Tuberculosis Clinic with a donation. The work was started in 1936 and in a short period it has made good progress. The total scheme costs the Municipality Rs. 95,000 a year.

The anti-tuberculosis activities are many-sided and are well co-ordinated through the Public Health Department, which is in charge of the educative part of the work. The tuberculosis clinic is the centre of preventive work wherefrom education and propaganda in the homes of tuberculosis patients are carried out through the health visitors. The work of the anti-tuberculosis sub-committee of the local Red Cross in the field of education, health visiting and tracing of contacts with the help of twenty voluntary doctors is a commendable part of the joint effort from the clinic for a co-ordinated preventive work.

The housing schemes in Delhi under the Municipality and the Improvement Trust whereby some slums have been cleared, insanitary *bustees* removed and arrangements made for housing poor people in new areas are bound to have due effect in the anti-tuberculosis movement in this city.

2. Jabli Sanatorium

The Simla Hills are well known for tuberculosis sanatoria. The foundation-stone of a new sanatorium at Jabli was laid by the Raja Sahib of Baghat on the 12th June, 1938. Jabli is on the Kalka-Simla road near Dharampur.

3. H. E. the Marchioness of Linlithgow's Appeal for the King-Emperor's Anti-Tuberculosis Fund

The twelfth list of subscriptions issued by the honorary treasurer of the fund shows that money is steadily coming in and the collections now stand at Rs. 42,73,044-2-11. With Her Excellency at present in England, this Indian question has come prominently before the English public. A lecture was given recently at the Overseas-House, London, on 'Tuberculosis—A Key Problem in India', by Major-General Sir John Megaw. Her Excellency Lady Linlithgow was in the chair.

THE LEISHMAN MEMORIAL PRIZE

LIEUTENANT-COLONEL E. V. WHITBY, M.B., Royal Army Medical Corps, has been awarded the Leishman Memorial Prize for the year 1937, consisting of a silver medal and a sum of £30 (thirty pounds).

The Leishman Prize (Officers) is awarded annually to an officer of the Royal Army Medical Corps or the Army Dental Corps for work of outstanding merit.

NORTH PERSIAN FORCES MEMORIAL MEDAL

EDGAR COCHRANE, M.D., D.P.H., Medical Officer (Health), Gold Coast, has been awarded the North Persian Forces Memorial Medal for the year 1937 for his paper on 'Tuberculosis in the Tropics' published in the *Tropical Diseases Bulletin*, 1937, Vol. XXXIV, nos. 10 and 11.

The North Persian Forces Memorial Medal is awarded annually for the best paper on Tropical Medicine or Hygiene published in any journal during the preceding twelve months by a medical officer, of under twelve years' service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service.

THE ALEXANDER MEMORIAL PRIZE

MAJOR C. V. MACNAMARA, R.A.M.C., has been awarded the Alexander Memorial Prize for the year 1937

consisting of a gold medal and a sum of £40 (forty pounds).

The Alexander Memorial Prize is awarded annually to an officer of the Royal Army Medical Corps for professional work of outstanding merit.

TUBERCULOSIS NEWS FOR THE MONTH OF JULY 1938

(1) AN anti-tuberculosis poster competition will be an important addition to the exhibition of the Simla Fine Arts Society to be held in September. The King George Thanksgiving (Anti-Tuberculosis) Fund has offered a prize of Rs. 100 for the most suitable poster exhibited to help the campaign against tuberculosis in India. If the best exhibit is not considered to be of sufficient merit, the adjudicating committee may divide or withhold the prize at its own discretion. The prize-winning poster or posters will become the property of the fund.

(2) The Bhowali Notified Area Committee has declared the town a 'non-tubercular' area. The public of Bhowali opposed this and the United Provinces Government has decided to appoint a commission under the Inspector-General of Civil Hospitals to enquire into the matter.

(3) A site for the Muzaffarpur tuberculosis clinic has been finally selected. In the meanwhile, a temporary clinic has been started at the Local Sadar Hospital.

Major-General Sir John Megaw, K.C.I.E., I.M.S. (Retd.), delivered a lecture on 'Tuberculosis—A Key Problem in India' at the meeting of the Overseas League on 12th June under the Chairmanship of Her Excellency the Marchioness of Linlithgow. Many eminent physicians, hygienists and administrators who had first-hand knowledge of the conditions in India attended, and spoke at the meeting.

Replanning of life from the point of view of health and saving of life was the dominating idea of Sir John's lecture. He asserted that the unit in every state was the family and prosperous states were those where each family lived a well-planned life. The head of each family must therefore be taught how to plan a satisfactory existence for those dependent on him, apart from the effort to change the public outlook without which better conditions of life were unattainable. The first essential, however, was to prepare a plan, which he suggested could only be done by the co-ordinated effort of those who have experience of agriculture, industry, economics, hygiene and education and the psychology of the Indian people. Once the plan was prepared we should adopt the methods of mass suggestion in promoting the welfare of the people. Sir John Megaw suggested that if one-fourth of the money spent on education was spent on instructions on life-planning, it would solve not only the problem of tuberculosis, but many others now in existence.

The campaign against tuberculosis must, however, include humanitarian effort and relief of the sick. Prevention and cure go hand in hand. Sanatoria and dispensaries have great educative values. The public will insist on having treatment and it is the business of the state to see that they get it. Tuberculosis is a key problem and its solution will mean more than the conquest of a single disease.

General Bradfield, Director-General, Indian Medical Service, while agreeing with the above views urged that one of the urgent necessities was a system of educative persuasion among the humbler classes, seeing that most of them prefer the cheap nostrums to be bought in the bazaar rather than the western medicines.

Major-General Sir Cuthbert Sprawson, I.M.S. (Retd.), endorsed the above views and considered that it was most important to educate the girls of India rather than boys and men, as it was the wives and mothers who allowed or vetoed what was done in a house in the way of medicine and hygiene.

Current Topics

The Debt of Western Medicine to the East

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P., F.C.O.G.

(From the *Bristol Medico-Chirurgical Journal*,
Vol. LIV, 1937, p. 239)

LITTLE did I think when I entered the portals of the Royal Infirmary thirty-five years ago that I should have the honour of being invited to deliver a lecture to commemorate the name of Edward Long Fox, a man of noble character, fully imbued with that spirit of ceaseless inquiry which inspires youth.

Hitherto it has been the pride and fashion of scholars to ascribe to the ancient Greeks the glory of having first conveyed in their own language the foundations of medicine, philosophy and art; but recent research has shown that the genius of the Greeks drew its sap from Phœnicia and Crete, from Babylon and Egypt, and even still farther afield from Sumeria and the dwellers in the Valley of Indus. Indeed, it was from the East and not from Egypt that Greece derived her architecture, her medicine, her sculpture, her science, her philosophy, her mathematical knowledge—in a word, her intellectual stimulus.

This is no idle statement; for though the *Ebers papyrus* carries us back a thousand years before the birth of Christ, it is only within the last fifty years that the scientific world has realized that a high state of civilization existed in Sumeria and the Indus Valley five thousand years ago.

The discoveries of Evans in Crete, of Sir Leonard Woolley at Ur, and of Sir John Marshall in Mohenjodaro and Taxilla have illuminated our darkness, and corrected many of our former 'certainties'.

It has been argued by some that such discoveries are but curiosities demonstrating manual dexterity and the stimulus of environment; but if we believe, as I do, that the history of medicine is the history of civilization, and if we have seen these things as I have seen them, we shall surely agree that the real criterion of their value lies in the extent to which these ancient peoples contributed to human progress, and to that culture which is the heritage of the living world.

Woolley has shown that the earliest graves at Ur, with their wonderful furniture and ornaments of gold and lapis lazuli, are older than the first dynasty of Egypt, four thousand years before Christ, and has stated that the foundation of Egyptian civilization was due to foreign influence; for in Egypt have been found the same cylinder seals, the same architecture, the same vases, the same grotesque animal drawings, the same musical instrument (the sistrum), and above all the same religious mythology as had been familiar to the Sumerians for hundreds, may be thousands, of years.

Nor must it be forgotten that Sumerian arms and Sumerian commerce, under the ægis of Sargon, spread up the valleys of the Tigris and Euphrates, penetrating Syria, Palestine and the Taurus, carrying with them their culture and their codes, the laws of Sumer becoming the code of Babylon, the code of Hammurabi that of Moses, the code of Moses that of Israel and Greece.

Neuburger sums up our knowledge as follows: 'Long before the time when Greece first appeared on the horizon of history the Babylonians were able with marvellous exactitude to undertake astronomical observations and calculations. Indeed, the style of writing, the pictorial and sculptural representation, the military tactics and jurisprudence of many nations were directly or indirectly influenced by Mesopotamia'.

The code of Hammurabi (2500 B.C.), engraved on Diorite stone, regulated medical and surgical practice. Details of operations and fees are given, but the punishment meted out for unsuccessful daunted and

discouraged all but the very expert, with the result that surgical progress was inhibited.

Recent discoveries by Dr. Frankfort of a seal of Indian workmanship depicting the elephant, rhinoceros and fish-eating crocodile in Tell Asmar, and by Woolley, of decorated Carnelian beads and steatite vessels exactly resembling those found by Marshall in Mohenjodaro, also point strongly to the fact that so long ago as 3000 B.C. facilities of trade existed between the people of Mesopotamia and the Indus Valley. It is more than likely that the long land route was traversed, but on the other hand it is possible that the sea route was used then, as it is now, by dhows sailing from the western ports of India, hugging the shores of inhospitable Baluchistan before reaching the Persian Gulf or Aden.

In this connection it is not without interest to observe that Sir Annel Stein has shown that the population of Baluchistan and the Indus Valley was far greater then than it is now, for in that age the climate was good. That the people of the Indus Valley traded with the whole of India, Mesopotamia and Egypt is certain; for in the ruins of their cities we find jadeite from Central Asia, Amazon stone from the Nilgiris, gold from the Deccan, lapis lazuli and silver from Afghanistan, pearls and precious stones from Ceylon.

In those early days, though the art of writing was known, it is important to bear in mind that lack of suitable writing material made any lengthy compilation a difficult task; but modern study of folk-lore readily explains how experience, practice and learning were conveyed from mouth to mouth by the nomadic clans as they travelled along the great trade routes which stretched from India to Persia, Mesopotamia, Syria and Egypt. Those who have served in Sindh or Persia can readily visualize those long, winding caravans of mules and camels toiling and grunting along, those caravans referred to in the Books of Esther and Ezekiel carrying 'ivory and ebony', 'cassia and calamus', 'brodered work and rich apparel' from India to the West. Is it then difficult to picture the elders of these nomads, halted at the hour of the setting sun by riverside or hamlet, telling and retelling of those wonderful things they have seen and heard? Among these assuredly the prevention and treatment of sickness must have had a foremost place.

This is no fanciful image; for medical evolution among the Chaldeans and Babylonians began some six thousand years ago, whereas among the Greeks and Romans it started some three thousand years later. The papyri of the Egyptians, the clay tablets of the Assyrians, and the Vedas of the Indians represent but an epitome of their medical achievement.

It is true that these demonstrate a sacerdotal and theurgical system of medicine, for they possessed many gods, good and evil, male and female, causing or curing disease, the ancients believing that the gods rewarded or punished man for his various acts, reward being in the form of good health and success, punishment in the form of sickness or failure.

The practitioner of medicine, whether priest or layman, was always a man of good family and education. Doubtless superstition and custom marred the palatability of his simples, but ample record exists of the variety of drugs that were in common use for everyday disorders. We read of alum, antimony, arsenic, cantharides, copper, myrrh, turpentine, mercury, iron, zinc, sulphur and fish-liver oil being employed for diseases of the eye and skin. Nor must we forget that by long observance the ancients arrived at deductions of astounding empirical value. Many of these were handed down from generation to generation. Some were observed by the Israelites, as close study of the Old Testament will show; but perhaps the most astonishing, apart from the subject of personal hygiene and preventive medicine, is the law decreeing that man and wife shall live apart until the seventh day after the catamenial period has ceased if the people would multiply as the sands of the seashore. This empirical edict, based upon rabbinical observation, anticipates by four thousand years the recent discovery

that ovulation does not occur before the thirteenth day, and perhaps also accounts for the well-authenticated fact that the orthodox Jewess does not suffer from cancer of the cervix uteri.

The Old Testament, mostly dating from eighteen hundred to five hundred years before Christ, has many references which demonstrate astute clinical observation and training. For instance, we read in Genesis xxxviii. 27 of spontaneous evolution with live uniovular twins and a ruptured amniotic sac. The treatment practised is classical and has not altered since. The condition described is very rare, only forty-four cases being on record. It was first mentioned in our medical literature by Viardel in the seventeenth century, who stated that when twins are of the same sex they are enclosed in a single amnion, whereas when they are of different sexes the Almighty encloses them in separate sacs with a view, shall we say, to guarding their morals *in utero*! Then again we have recognized the extreme dangers of uterine inertia in 2 Kings xix. 3 and in Jeremiah xv. 19, together with the fatality associated with precipitate labour and inversion of postpartum hæmorrhage in 1 Samuel iv. 19. I hope some of you will refer to these passages. But perhaps most wonderful of all is the graphic description (far antedating Hippocrates) of puerperal or pelvic peritonitis in Numbers v. 21-27.

Obstructed midwifery has little or no mention, but that is what one would perhaps expect in a nomad people living a healthy life and feeding on a full vitamin diet. The words 'the obstetric hand shall bring forth the winding serpent', in Job xxvi. 13, would, however, seem to hint at version or manual removal of the placenta.

Remember always that the treatment of disease in Biblical times was not *only* by prayer and sacrifice, for dietetic measures and medicaments were used, including healing springs and oil baths. Oil, wine and balsam were employed in dressing wounds, and bandages were applied to broken limbs. Midwives were obviously esteemed, for we read that 'the Lord dealt well with the midwives and built them houses'.

Though the priests or Levites were health officers, it is wrong to suppose that no professional physicians existed; for wherever there is mention of healing there is no reference to priests, but rather to the 'Rophe' or physician. It will be recalled that Jeremiah held it as inconceivable that there should be no physicians in Gilead, and of course the testimony of Ecclesiasticus xxxviii. stands for all times.

The Talmud gives much useful information, and shows considerable knowledge of the dura and arachnoid membranes. The preparation of food from slaughtered animals gave the Jews insight into the pathology of diseases of the liver, lung, kidneys, etc. Moreover, we read that trephining, amputation and venesection were regularly performed.

It would be indeed erroneous to minimize the medical achievements of the Babylonians and Israelites twenty to thirty centuries before Christ merely because we possess no doctrinal evidence. Admittedly magic, astrology and divination befog the written word but there can be no question that the practice of embalming, together with clinical observation, advanced the knowledge of anatomy, physiology and surgery, so that succeeding generations of Greeks and Romans could build upon it, assisted by speculative philosophy and deductive observation. Should such a statement be challenged one has only to contemplate that masterpiece of Assyrian art, the dying lioness from the palace of Assurbanipal which is in the British Museum. The wounded beast, her spine severed by an arrow, turns snarling on the hunters, dragging her paralyzed limbs. Such a conception could only be depicted by an artist fully acquainted with the physiological effects of spinal injuries.

It is not possible to date the dawn of Indian civilization, but it is probable that the Aryan race, fair in complexion and enterprising in character, originated in the high tableland eastward of the Caspian Sea. That they possessed a co-ordinate system of government

and a religion abounding in moral precepts is certain. As their numbers increased and expansion became necessary one branch spread westwards towards Persia and the Caucasus, the other spread south-eastwards, invading and settling in a country called Aryavarta (the land of the Aryans), which lay east of the River Sindha, the western boundary of India. The letters H and S are convertible in Zend, the ancient Persian language, and so the name of the River Sindha explains the title given by those who first passed its boundaries—the Hindus.

The Book of Kings in our Old Testament speaks of the wisdom of a people who inhabited the east of Asia, and in Genesis xxxvii. 25 we read of the products which were in demand from them. Moreover, we are told that Terah, the father of Abraham, who lived about 1800 B.C., 'dwelt on the other side of the flood and served other gods', the flood, of course, denoting the great Euphrates River.

The Aryan race, possessing both an alphabet and grammar, were the founders of Sanskrit, the purest and most perfect of all languages, from which Zend, Armenian, Greek, Latin, German and Celtic derive their basic origin.

At this point it is not without interest, perhaps, to observe that all the early religions, those of Brahma, the Buddha, Confucius, Mahomet and Christ, together with almost all early civilizations, such as those of Sumeria, Northern India, Babylon, Egypt, Crete and Greece, flourished round about the thirty-fifth degree of latitude; that is to say, where the resources of nature were most abundant and the climate not too enervating.

It has been supposed by some that China can claim priority in knowledge of the arts and sciences owing to the remarkable and enduring character of their civilization, but although there was intimate intercourse with India by means of travellers, ambassadors and Buddhist priests, it is now held that the science of medicine was not introduced into China before the Christian era, for reverence of the dead and ancestor worship forbade dissection. The only medical debt we consciously owe to the Chinese is gold and silver acupuncture, which was immemorial treatment for every ill; though it would be churlish not to admit that they first discovered the art of making paper, an art that later made the intellectual revival of Europe possible.

It is from the Vedas, through the mists of mythology and fogs of superstition, that fifteen hundred years before Christ we can discern the realities of existence in ancient Hindustan. Legend has it that the great god Brahma wrote the Vedas for the guidance of the universe, and that the greatest of these was the Atharva Veda. Subsequently, taking compassion upon sick and suffering man, Brahma produced the Ayur Veda, which is the first great treatise on the Science of Life. Dhanwantari, the father of medicine, was then created to minister to the diseases of mankind, and just as the sages came in later centuries to Hippocrates, so in those early days deputations were sent to Dhanwantari for instruction. The story runs that on their arrival the master asked his pupils, 'On what shall I lecture?' and they answered, 'On surgery, because among the gods there are no diseases, whereas wounds and injuries are the common lot of gods and men'. This reply, so like the story in Homer of Achilles and Machaon, is not without interest, for even to-day many incline to look upon disease in mankind as a retribution for sin.

Susruta and Charaka were among the first disciples of the master, and though some are of the opinion that their Sanskrit compilations belong to the Christian era, it is far more probable that they are pre-Hippocratican, for their elaborate ethical code, written in ancient and purest Sanskrit, was founded on the Laws of Manu, and is purely Brahmanical. These laws date back to 900 B.C. Moreover, a study of their copious Materia Medica reveals the fact that there is not a single mention of any substance of foreign source, whereas the writings of Hippocrates give ample

evidence that many Indian plants, whose properties were well known, were imported into Greece. The Hippocratic oath leads one to the same conclusion, for when it interdicts the performance of lithotomy, except by men who were special practitioners of this operation, it surely suggests that the author's knowledge of anatomy and surgery had been derived from a more enlightened nation, and was imperfect compared with that of his teachers. Moreover, seeing that Hippocrates visited Smyrna, Libya and Scythia, is it not probable that he visited this latter distant and inhospitable northern country because he had heard of the surgical feats performed by an enlightened people?

Dim dates are difficult to be sure of, but at least we know that at the time of India's invasion by Alexander the Great the conqueror enlisted the services of local practitioners, whose wisdom was as proverbial then as it was in the later days of Galen, Pliny and Dioscorides, who frequently used the words *Indi dixerunt*. Susruta taught that the foundation of surgery was excellence or wisdom used the words *Indi dixerunt*. anatomy, and made his pupils do dissections. In those days there was no Brahmin ban against touching a corpse, for the Laws of Manu state that 'mere bathing will purify after touching a dead body, while to stroke with water will remove defilement'.

Thus began the golden age of Hindu surgery. To Susruta we owe the discovery of cataract-couching, skin-grafting and rhinoplasty. From him we possess a precise knowledge of midwifery and learn the positions occupied by the foetus in utero. He states that the expectant mother must be kept in a happy frame of mind and in placid surroundings if her labour is to be easy. He speaks of post-mortem Cæsarean section. He writes of amputations and the necessity of artificial limbs made of iron. Tumours are removed, ruptures reduced and patients laid down for the operating-room, for able, rules are laid down for the surgeon to keep his hair and beard short, his nails clean and wear a sweet-smelling dress. It is not certain what drug was used, but directions are given that the patient was to inhale a substance called *sammohini* before operation. Over a hundred steel instruments are depicted and their uses described. Many of these have their counterparts in the catalogues of every modern firm supplying the needs of the general surgeon.

Reference having been made to the fact that Cæsarean section is mentioned by Susruta, perhaps a digression may be permitted in order to show that this operation is of great antiquity, indeed dating back to the Iliad of Homer; for the legend runs that Coronis, mother of the unborn Aesculapius, was killed by Artemis for her infidelity. When Apollo, the father of her child, saw Coronis on the funeral pyre, he cut the boy from his mother's womb and carried him to the cave of the wise centaur Chiron, where he was instructed in the cure of all disease.

Ovid, *Metamorphoses* ii. 630, obviously refers to this belief in the lines:—
'Natum flammis uteroque parentis
Eripuit geminique telit Chironis in antrum.'

And, of course, we have the evidence of Shakespeare that the operation was well known in his day, for apart from the reference in *Macbeth* to 'Macduff who was from his mother's womb untimely ripped' we have the metaphor in *King John*, V. iii., indicating that his audience was well acquainted with the operation.
'You bloody Neros, ripping up the womb,
Of your dear Mother England, blush for shame.'
There can be no question that the practice of Cæsarean section dates back to the Vedas, for to-day, as from times immemorial, the Hindu is forbidden to burn the body of a pregnant woman who dies before the birth of the child without first excising the foetus. Needless to say such evisceration must have taught the elements of anatomy; for the most frequent cause of premature death in the case of pregnant woman in

the Tropics must have been the same then as now, namely either enormous enlargement of the spleen and liver inhibiting progressive ascent of the uterus or obstruction in the pelvis preventing delivery.

Charaka flourished about 400 B.C. and wrote eight books. He describes about 100 diseases, and tries, and nearly every disease we meet with in common practice to-day. The seventh book details four hundred purgatives alone and their various uses. He classifies food and diet according to disease, and tries, like Freud, to analyse the secret of dreams. He writes of the benefit of steam baths and of stramonium cigarette smoking for asthma. There is an interesting section on climatology, where patients, according to their sufferings, are urged to sojourn in such climates as are suitable to them. The ritual of oral cleanliness is looked upon as of the first importance, and although toothbrushes did not come into use in Europe until about A.D. 1700, it is remarkable to read the rules laid down by Charaka for the selection and use of twelve distinct types of tooth-brush and tooth powder.

He tells us that the practitioner who knows the value of quicksilver and the metals is a god, he who knows the qualities of herbs and roots is a man, he who knows the use of the knife or fire resembles a devil, but he who knows the proper prayers to be offered up in the time of sickness is a prophet.

The mention of the metals is of significance, for the ancient Hindu race were the first to employ mineral drugs internally. Their chemical skill was remarkable. They knew how to prepare sulphuric, nitric and hydrochloric acid. Gold, mercury, silver, copper, lead, tin, zinc, iron, arsenic and antimony, as all described, and their uses, either in pure form or as salts, are indicated. For instance, it is illuminating to read that if sixteen parts of gold and one of lead be mixed with lemon juice and then rubbed together and heated, or if gold be mixed with sulphur and aloe and exposed to the fire twelve times until it is reduced to a powder, either mixture is valuable for chronic diseases of the spleen and lung. Or, again, it is instructive to read of the preparation of the yellow sulphurate of arsenic, which was used for leprosy, skin diseases, mania and fevers.

It would take too long to recount the way they prescribed their medicines in pill, extract, infusion or ointment form, with rules which varied according to the temper, age, constitution and disease of the patient, but historically it is perhaps not without interest to see that medicines were divided into classes, one which increased strength by evacuating bad humours, and the other which lowered the exalted action of the humours, and restored them to a healthy state. For instance, thirty-nine simple drugs are enumerated for curing diseased wind, twenty-three for curing diseased phlegm and twenty for deranged bile. In those days rubbing with oil to relax all tissues of the body was an essential feature of treatment before any drugs were exhibited.

In parenthesis and lighter mood it may not be without interest to the gentler sex to relate that the art of dyeing the hair, the fashion of lipstick, and eye pencilling, the mode of varnishing the finger, and toe nails, together with the music of the bagpipes, all originated in Sumeria and the north-west corner of India some five thousand years ago—imperishable legacies to many.

If such was the wisdom of Aryan India (and I have but given you a passing glimpse of it), what was the reason of its decay? History tells us that it was the rise of pure Brahmanism, with the desire of the priests to maintain all power in their own hands. For it must be remembered that the Brahmins, with their subcaste the Vaidyas, considered themselves persons of divine origin, whose duty it was to perform rites of religion and instruct mankind in the path of learning and duty. They alone had access to the Shastra, and so became learned pundits and skilful physicians.

The priestly office, like that of the ancient Druids, was the road to distinction and power. In the beginning they attained pre-eminence by cultivation of the mind and the practice of virtue, but with power came degeneracy. The despotism of caste, forbidding liberty of thought, laid down rules which subjected a whole continent; for we see that in order to curtail the growing influence of the surgeon they not only prohibited all shedding of blood, but ruled that all who took from or were touched by a surgeon became unclean, and to enhance their own majesty they introduced the treatment of all diseases by *mantras*, incantations and amulets.

The rise of Buddhism and its rapid spread throughout the Far East still further inhibited surgical progress for hundreds of years, for the teaching of the Buddha prohibited the use of the knife and any form of dissection.

One must, however, be fair to the Buddhists, for to them India and the whole world owes a great debt from a sanitary, medical and veterinary point of view. They first established a system of state medicine, one physician being appointed for every ten villages on the great roads of India. They laid down laws regulating burial and sanitation. They prohibited adulteration of food. They established botanical gardens for the special supply of herbs and drugs for medical use. They built bird and animal sanctuaries and even animal hospitals with a reverence worthy of St. Francis of Assisi. Indeed, our debt to the followers of the Buddha is but little appreciated, and I would wish to offer them a professional salute.

It is not easy for the Western mind to enter into that spirit of Buddhist or Hindu philosophy, which deprecates action, for, as Carlyle has said, 'the end of man is an action and not a thought, though it were the noblest'.

The Yogi who practises Yoga with the object of uniting his soul with the divine spirit is highly interesting as an example of the attitude of the Indian mind towards life. His world-weariness causes him to fly from the struggle and pleasures of life to the solitude of the jungle, in order to seek an escape from the activity even of thought itself.

It may be that a philosophy of quietism was natural to the indolence and enervation of Indian life, but such a doctrine was a direct incentive to warlike and materialistic neighbours to harass and invade the country; and so we find that all the learning of centuries subsided, was lost or forgotten in the tides of war and invasion which swept again and again over India from the beginning of the Christian era.

Is it then surprising that the clocks of medicine and of surgery stood still, and that Europeans visiting Hindustan at the time of Shah Jehan marvelled at the lack of any surgical skill? Their wonder is perhaps not so remarkable when one considers that the doctrine of Karma held two hundred million people, a doctrine that taught that 'I am what I am because of my past deeds, I shall be what I shall be because of my present deeds'.

So far it has been my object to portray the intellectual vigour of the primitive eastern branch of Aryans, to whom we owe so much in medicine, law, art and philosophy. It is not my intention to dwell upon that later western branch which built up the Grecian and Roman systems of medicine from the time of Pythagoras till the second century A.D. During this period men of genius conferred glory on their country and imperishable renown upon themselves. Greece became the seat of philosophy, and Greeks the nursemaids of the arts handed down to them by earlier eastern civilizations. But as in India so too in Greece, the clock of progress was stopped by the invasion of rude and hardy races from the north, who destroyed what was most noble and beautiful with relentless barbarism, preserving only what harmonized with their rude manners or administered to their sensual pleasures. Thus persecuted, Europe remained for many centuries in a state of lethargy, the pendulum of learning swinging back again towards Egypt and Syria.

It is to the Caliphs of Baghdad that we owe an imperishable debt. They patronized learning and instigated the translation into Arabic of the most important medical authors, particularly those of Hippocrates, Dioscorides, Galen and Paul of Aegina. This inheritance of Grecian thought awakened the dormant intelligence of the Arabs and sharpened their critical faculties. The Nestorian school at Jondisapur was the cradle of Arabic medicine. From it came wise men who gave the impetus to translation and scientific research which lasted for centuries. To fulfil this statement it is only necessary to mention three great names, Rhazes, Ali Abbas and Avicenna.

Rhazes was born in 850 A.D. He was guided by the principles of Hippocrates, basing his opinions upon observation and laying stress upon hygienic and dietetic measures. He has acquired lasting fame chiefly for his vivid description of smallpox and measles.

Ali Abbas realized that the chief task of the physician was to prevent disease. He was a pioneer in recommending that young physicians should frequent the mental and other hospitals which were first inaugurated by and were the glory of Arabic civilization from Baghdad to Alexandria and from Cairo to Cordova.

Avicenna, who wrote the *Canon of Medicine*, stands out as a monumental figure from the tenth to the fifteenth century. He was a statesman, physician, astronomer, teacher and author. His great work is a landmark, for it stands as an epitome of all precedent development, the final codification of all Græco-Arabic medicine.

For nearly a thousand years Arabic physicians were the teachers of the West, throwing open to the Christians of Europe the portals of scientific medicine and granting to them the privilege of access to the intellectual treasures of antiquity, a privilege of surpassing importance which compels recognition.

With the Renaissance individuals and nations vied with each other in honouring the pursuit of learning. The study of medicine exercised the genius of great men, who constructed it upon a basis of anatomy and physiology, observation and reasoning, not a little assisted by the genius of Leonardo da Vinci, who uplifted the science of descriptive and pictorial anatomy to a height which has never been equalled.

Coming to more modern times, it is very easy to see and appreciate the debt of the West to the East, for civilization, commerce, transport, peace and war, owe an imperishable debt to scientists working under conditions of danger and stress.

If the apothegm of Blaise Pascal, 'Had the nose of Cleopatra been shorter, the whole face of the earth would have been changed', be accepted, how much more truly could it be written, 'Had the cause and treatment of malaria been known, to what heights would not Greek and Roman culture have reached'.

History teaches us that Hippocrates recognized the periodicity of malaria and relapsing fever, for he describes the jaundice, the enlarged spleen and liability to abortion; but it was the tide and pride of wars, with overcrowding of populations in infected areas, that spelt the ultimate decay of Greece and Rome.

The story of Ronald Ross working in Calcutta before the days of modern comforts and modern scientific implements is a romance in itself. It is quite impossible to estimate the benefits that his discoveries and those of Manson have conferred upon mankind—discoveries that have made possible the development of all tropical countries, and which have reduced the death rate of immigrants and indigenous people in those countries to that of London.

Similarly peace and war have demonstrated the debt we owe to the experimental research of Shiga and Leonard Rogers on the treatment of dysentery and cholera; to the work of Obermeyer, Todd and Mackie on the transmission of relapsing fever; to the discoveries by the Japanese investigators Inada, and Ido of the leptospiræ which cause Weil's disease; to the researches of British, Dutch, German and Indian

workers on the causation of beri-beri and epidemic dropsy; to the work of McCarrison on goitre and nutrition; to the finding by Billharz of the parasite which, since time immemorial, has been the cause of colossal mortality and invalidism; to the investigations of Scott, Fairley and Mackie on the etiology of sprue; to the work of Leishman and Donovan upon kala-azar; and to the elucidation of that crippling disease osteomalacia by Maxwell, Stapleton and others. It is not necessary to prolong the list, for these are but a few of the diseases which every European practitioner may meet with in these days of rapid transit and moving populations.

Horace tells us that as we grow older we become *mitior et melior*; therefore, before closing, I should like to touch upon a somewhat sombre side of our debt, one that has a bearing upon the future. Hitherto I have endeavoured to demonstrate what we owe to the East, and have tried to illustrate how, in this century, at least, we have repaid some of that debt in the currency of preventive medicine. But from that that of food production and supply, for a rapidly increasing eastern population with a rapidly decreasing death rate. The burden that preventive medicine has thrown upon the East is an immense one. It is a challenge, for starvation and ultimate decay must occur if food production is inadequate in those countries. It is for us to devise a plan lest the debt of eastern medicine to the West be repaid by lamentation. That science will solve the problem, too, we need not doubt. The productivity of Mother Earth is so great that even in a crowded Europe and America millions of tons of fresh food-stuffs are destroyed deliberately every year for purely economic reasons. 'Poverty amid Plenty' is a commonplace all the world over. But it is a problem which we must solve quickly, especially in the East. If we can solve it, maybe our debt to those 'Wise Men of the East' of whom I have been speaking will be at last repaid in full.

High Calorie Feeding in Gastric and Duodenal Ulcers

By L. J. WITTS, M.D., F.R.C.P.
(From the *Medical Press and Circular*, Vol. CXCVI, 23rd March, 1938, p. 240)

We already know much about the etiology of gastric and duodenal ulcers, and our difficulty is to put our knowledge into practice. We know that they occur only in the presence of acid gastric juice. We know that emotional disturbances such as loss of financial or domestic security can precipitate an attack or a recrudescence of peptic ulceration. Ulcers are common in intense people who overwork and have too much drive. They are infrequent in primitive peoples who do not take much thought for the morrow and who live simple lives in which emotions are vivid but transient, unashamedly expressed and quickly forgotten. Diet has a more obvious influence on the location than on the frequency of peptic ulcers, gastric ulcers being more common in those on coarse diets and duodenal ulcers in those on refined diets. Nevertheless, whenever we see a secular variation in the incidence of a disease we are always tempted to ascribe it to change in diet, and the rise of peptic ulcer as a cause of illness and death in Western Europe can be fairly closely correlated with a fall in the intake of vitamin B. McCarrison has produced gastric ulcer in animals by feeding them on a diet in carbohydrate and deficient in vitamin B, and more recently an anti-hæmorrhagic factor K has been found in foods, which is often closely associated with vitamin B and absence of which may lead to erosions in the alimentary mucosa. For the present there is no proof that peptic ulcers are due to defects in diet, but there is much to suggest that healing may be delayed by lack of essential food principles.

One of the few certain facts about peptic ulcers is that they only occur in the presence of acid gastric juice. They are confined to surfaces which are exposed to concentrated gastric juice, such as the lower end of the oesophagus, the stomach and the first part of the duodenum, and they never occur in pernicious anæmia, a disease which is characterized by gastric anacidity. Experimentally, ulcers can be produced by methods which abolish the natural dilution or neutralization of the gastric juice or which expose the mucosa to a constant drip of dilute hydrochloric acid of a strength comparable with that of normal juice. It is natural to conclude that the healing of ulcers will be promoted by measures designed to neutralize the gastric juice, provided that the diet is not irritating and any drugs used do not themselves damage the mucous membrane. This is the basis of the Sippy treatment, which is still the most rational and most successful medical treatment. Sippy's diet was based on the fact that milk neutralizes approximately its own volume of gastric juice and that fats inhibit the secretion. The normal quantity of gastric juice is 1.5 to 3 litres a day. Fifty ounces of milk will neutralize 1.5 litres of juice. In addition one can give up to 20 grammes a day of alkali (expressed as sodium bicarbonate), the equivalent of 3 litres of juice.

Three ounces of a mixture of equal parts of milk and cream are given every hour from 7 a.m. until 7 p.m. After two or three days soft eggs and well-cooked cereals are gradually added, until at the end of about ten days the patient is receiving approximately the following nourishment: three ounces of the milk and cream mixture every hour from 7 a.m. until 7 p.m. and in addition three soft eggs, one at a time, and nine ounces of a cereal, three ounces at one feeding, may be given each day. The cereal is measured after it is prepared.

Cream soups of various kinds, vegetable purées and other soft foods may be substituted now and then, as desired. The total bulk at any one feeding while food is taken every hour should not exceed six ounces. Many of the feedings will not equal that quantity. The patient should be weighed. If desired, a sufficient quantity of food may be given to cause a gain of two or three pounds each week.

A large variety of soft and palatable foods may be used, such as jellies, marmalades, custards, creams, etc. The basis of the diet, however, should be milk, cream, eggs, cereals and vegetable purées. Lean meat is not given during the period of accurate observation, since it interferes with the tests for occult blood in the stool and aspirated stomach contents.

The acidity is more easily controlled by feeding every hour and giving the alkalis midway between feedings. The acidity may, however, be controlled by feeding every two, three or four hours. I have maintained complete control of the free hydrochloric acidity in several cases by feeding three times daily. In most cases, however, the plan of feeding every hour is best.

A tube was passed at bedtime and the stomach aspirated if more than 10 c.cm. of juice were present. The tube was also passed occasionally at different periods of the day to ensure that neutralization was complete. It is important to note that Sippy's diet was much more generous than many of the modifications which have been suggested. Sippy fed his patients every hour and he expected them to gain weight. If one feeds a patient with watered milk every two hours, especially if the milk is citrated, and the ulcer is rapidly evacuated from the stomach, the full Sippy regime complete neutralization is difficult, and during the hours of sleep the stomach often secretes acid copiously, so that the healing accomplished during the day is broken down again at night.

Various efforts have been made to overcome these difficulties. Alkalis have been introduced which act slowly and which do not produce alkalosis, such as

magnesium trisilicate and aluminium hydroxide. In the method adopted by Winkelstein, a tube is passed into the stomach and the patient is fed by continuous drip. The solution consists of milk containing 5 grammes of sodium bicarbonate to the quart. A flow of thirty drops a minute equals three quarts or 2,400 calories in the twenty-four hours. Such a solution will theoretically neutralize nine quarts of N/10 hydrochloric acid, but in our experience it has not always produced persistent anacidity, and ulcers have not healed appreciably more rapidly than under the Sippy regime. In hot weather the solution tends to clot and will not flow. Alkalosis may occur. The constant presence of the tube is an annoyance and one patient swallowed his completely, to his intense alarm. Similar objections apply to the continuous alkaline drip advocated by Woldman, and to the methods of duodenal feeding and jejunostomy. The more experience one has of peptic ulcer, the less one uses these elaborate methods. The quickest and safest way of bringing under control the symptoms of peptic ulcer is by hourly feedings during the day and a powerful barbiturate such as nembutal at night. Strong alkalis such as sodium bicarbonate and magnesium oxide should only be used—but they certainly should be used—to relieve pain. When strong alkalis are used the blood should be examined every 48 hours for evidence of alkalosis or uræmia. Weak alkalis such

as magnesium trisilicate may be used to promote healing. Atropine and belladonna are rarely of assistance in relieving pain or hyperacidity. As soon as the patient is free from pain the diet should be increased to a level which is adequate in calories and vitamins and which enables him to regain lost weight. It usually does not take more than three days' treatment to reach this stage, and rarely more than a week. If the patient feels hungry between feeds it is probable that the diet is inadequate. Adequate feeding is especially important in preparing patients for operation, for operative mortality is directly proportional to the degree of malnutrition and loss of weight, and a patient who is 25 per cent below his best weight is a very bad operative risk. It is often better for a patient to go to a convalescent home before operation than afterwards.

The original Sippy diet is, in my opinion, far and away the best diet for the medical treatment of peptic ulcer and one can only deprecate modifications in which feedings are too widely spaced, calories inadequate or the diet excessively monotonous. The only real improvements in treatment are the recognition of the frequency and danger of alkaline poisoning and the need for supplementing the diet by added vitamins. The commonest cause of adult scurvy in this country is a gastric diet. Instead of the usual olive oil before some of the feeds I use cod-liver oil,

TABLE
DIETETIC TREATMENT OF GASTRO-DUODENAL HÆMORRHAGE
Arranged for two-hourly feeding

Feeds by day	Food			Day		
				1	2	3 and subsequent
1	Whole milk (fresh or dried) ..	oz.	5	5	5	5
	Patent barley or strained porridge	Portion	Portion	Portion	Portion
2	1 egg beaten up in milk ..	oz.	5	5	5	5
	Buttered rusks or cream crackers	1	2	2
3	Whole milk (fresh or dried) ..	oz.	5	5	5	5
	Marmite to taste
	Barley sugar ..	oz.	1	1	1	1
	Thin crustless white bread and butter ..	slices	..	1	2	2
4	Strained orange or tomato juice ..	oz.	1	1	1	1
	Vegetable purée	Portion	Portion	Portion	Portion
	Pudding
	Cream ..	oz.	1	1	1	1
	Boiled or steamed fish	Portion	Portion
5	1 egg beaten up in milk ..	oz.	5	5	5	5
	Barley sugar ..	oz.	1	1	1	1
	Buttered rusks or cream crackers	1	2	2
6	Whole milk (fresh or dried) ..	oz.	5	5	5	5
	Fruit purée	Portion	Portion	Portion	Portion
	Pudding
	Cream ..	oz.	1	1	1	1
	Thin crustless white bread and butter ..	slices	..	1	2	2
7	1 egg beaten up in milk ..	oz.	5	5	5	5
	Black treacle or barley sugar ..	oz.	1	1	1	1
	Buttered rusks or cream crackers	1	2	2
8	Whole milk (fresh or dried) ..	oz.	5	5	5	5
	Fruit purée	Portion	Portion	Portion	Portion
	Pudding
Feeds at night (when awake).	1. Whole milk (fresh or dried) ..	oz.	5	5	5	5
	2. 1 egg beaten up in milk ..	oz.	5	5	5	5
Between feeds	Strained orange or tomato juice ..	oz.	1	1	1	1
Approximate caloric value	2,545	3,118	3,624	3,624

which not only exercises the inhibiting action of fat on gastric secretion but also supplies vitamins A and D. Vitamin C is supplied as orange or tomato juice and B as Benax and Marmite. Doctor and nurse or dietitian should take a keen interest in the patient's likes and dislikes. Patients who will not take milk in the ordinary way will often take milk soups, proprietary milk foods or milk flavoured with coffee, tea or chocolate. A visit to a milk-bar or an ice-cream counter will often suggest new ideas. The puréed vegetables sold by the canning companies under the titles of homogenized foods (Libby) and strained foods (Heinz) are very helpful, as also are many of the Heudebert foods. Patients on dietetic treatment often suffer from flatulence and dyspepsia which is quite different from their original ulcer pain; it is due to intolerance of the diet and can be relieved by modifying the milk, reducing fats, altering the type of purée or other simple expedients.

The recent great advance in the treatment of ulcer is the policy of immediate feeding in cases of hæmatemesis and mælena. The orthodox treatment in such cases has been starvation for 48 hours, then very small feeds at two-hourly intervals, so that on the tenth day of the illness the patient is receiving only 1,000 calories and he does not get 2,000 until the fifteenth day. These patients are starved not only of food, which might be tolerable, but of water and salts which is intolerable, owing to the large amounts of fluid lost in the hæmorrhage. For any but the most expert it is difficult to replace the water and salts by parenteral administration. Is it any wonder, then, that these patients are dehydrated and toxic, and that about 15 per cent of them die? The orthodox treatment is based on fallacies. One does not rest the stomach by starvation; one merely exposes the ulcer to the pangs of hunger and the action of undiluted gastric juice. Pultaceous food in the stomach does not excite bleeding but acts as a hæmostatic. In any event it would be futile to concentrate on treatment of the bleeding point when the organism is dying of shock and dehydration. The diet which I have now used in nearly fifty successive cases of hæmorrhage from gastroduodenal ulceration without a death is as given in the table.

Between feeds sips of water, glucose solution, or half-strength isotonic saline are allowed in quantities up to 5 ounces an hour. If the patient is hungry he is allowed 5 ounces of milk at the intermediate hours. The total fluid intake averages about 2,750 c.c.m., and allowing for the water of oxidation the patient is probably provided with some $3\frac{1}{2}$ litres of fluid a day. No medication is given other than liquid paraffin or paraffin emulsion, and I deliberately avoid alkalis unless there is epigastric pain—which is, of course, unusual after a hæmatemesis. It is both safe and wise to give treatment with iron from the start. To avoid disturbing the patient or provoking fresh bleeding no purgatives are allowed and enemata are postponed until between the fifth and tenth days. I have described elsewhere how well this deliberate constipation is borne. Unless the patient is collapsed, when, of course, he should be transfused, I allow the head to be moderately raised, because the patient is more comfortable in this position than in the orthodox complete recumbency, and he can take food without swallowing troublesome quantities of air.

Looking back on this diet, which began as a modification of that of Meulengracht, who introduced the treatment of gastro-duodenal hæmorrhage by early feeding, I see I have come round to something very like the original Sippy regime. I have not wanted to change it at too early a stage of my experiments, but it departs in two ways from Sippy and I am not sure that these departures are not faults. The two-hourly feeds are quite alarmingly large, some of them from ten to twelve ounces, and the intermediate milk feeds are permissive and not compulsory. The more faint-hearted may decide that no feed should exceed six ounces, when hourly feeds will be necessary to keep up the calories. I am prepared to admit that

not all my patients have been able to eat all the diet all the time, and when they have not wanted feeds they have not been pressed. I am quite certain that they have been much more comfortable and fitter than patients treated on orthodox lines. Recurrence of bleeding has not been considered an indication to stop treatment by feeding. The great thing is to feed ulcer patients; feed them especially when they have bled or before operation; feed them with a diet of which milk forms the basis; feed them frequently so that the stomach is never empty during the waking hours; and if the patient has pain, ask yourself if you could not feed him oftener.

Treatment of Gonorrhœa with Sulphanilamide: Comparisons with Oral Sulphanilamide, Vaccine and Manganese Butyrate in Males and Females

By K. LEIGH EVANS, M.P.H., L.R.C.P. & S.

(Abstracted from the *Medical Press and Circular*, Vol. CXCVI, 30th March, 1938, p. 269)

THE reports on the use of sulphanilamide in the treatment of gonococcal infections leave no doubt that this compound has the most important place in the routine of gonococcal treatment. The report of Dees and Colston gave results of 47 cases with a complete cessation of symptoms, and a disappearance of gonococci, within five days, in 36 of these cases; they record only three failures and three relapses. Crean is even more optimistic, recording only six failures and three relapses out of 100 cases; Anwyl-Davies, using a low dosage, does not consider the drug satisfactory; Cockkinis gives no exact figures but is enthusiastic about the value of sulphanilamide.

DOSAGES

The sulphanilamide preparation used throughout is p-Benzylamino Benzene Sulphonamide. At first treatment was commenced with a dose of 6 grammes per day. This was found to be too toxic for routine use on clinic patients and a lower standard dose was used. This was 4.5 grammes per day for the first five days, followed by 3 grammes per day for six days. The total treatment lasting for 11 days.

For irrigation a solution containing potassium permanganate 1 per cent, sodium carbonate 10 per cent, and sodium chloride 32 per cent is diluted in the proportion of 2 drachms to 20 ounces.

Douching is done at a level of not more than two feet above the pelvis with a warm solution of sodium bicarbonate 1 : 160. Tampons saturated with solutions of picric acid, mercurochrome and ichthyol in glycerine are changed on alternate days, or daily if the discharge is very profuse.

No prostatic massage or instrumentation was used on the cases treated with sulphanilamide.

The complications noted were prostatitis (very common), orchitis, epididymitis and arthritis. The duration of the disease varied from 24 hours to two years, 41 cases being seen within the first week of onset of the discharge.

Thus of 113 males treated with sulphanilamide 68, or 60 per cent, were clinically cured within two weeks of the commencement of treatment. A further 11 were clinically cured after a second course of sulphanilamide, making a total of 79 per cent well after sulphanilamide treatment. It appears to make little difference whether the sulphanilamide is used with other local or systemic treatment—in fact the best results were obtained when the compound was used alone, 19 well out of 24 in two weeks. In the whole series nine cases relapsed after all discharge had ceased, and two other cases developed epididymitis during treatment.

Of the 32 cases treated with manganese butyrate, alkaline mixture and irrigation (prostatic massage and instrumentation used when indicated) only 11 were clinically cured at the end of three weeks. The cases

treated with gonococcal vaccine showed similar poor results—7 out of 18 in three weeks.

Laboratory tests for cure have been unsatisfactory as it has not been practicable to carry out the Complement-Fixation Test. The routine adopted has been: (a) provocative injection of 500 million gonococci; (b) 24 hours later massage of the urethra over a full-sized bougie, followed by (c) drinking of 72 ounces of beer; (d) 18 hours later the prostate is massaged and the urine deposit examined after centrifugalization at 1,500 revolutions per minute for five minutes. If there are any gonococci (intra or extracellularly), or if the deposit contains an average of more than five pus cells per high-power field, the patient is considered not cured. Only 25 of the patients treated with sulphanilamide have attended for this test for cure, of these 13 have been passed as cured. Some generally accepted standard of cure is an urgent necessity before the results of different observers can be considered comparable.

Females.—In each case there was a vaginal discharge in which the gonococcus was demonstrated. Almost all the 132 cases were of cervicitis and endocervicitis; there were 10 cases of salpingitis. Other conditions present were urethritis, marked vaginitis, Bartholinitis and endometritis. The duration of the disease ranged from one week to three years; there were no cases having a history of less than one week. Most of the cases gave a duration of one to six months. The majority of this group are prostitutes—either part or whole-time—and are very difficult to keep under observation.

Of the 101 females treated with sulphanilamide 49 were clinically cured within two weeks of the commencement of treatment; a further 17 were free of all signs or symptoms after a second course of sulphanilamide—a total of 66 out of 101 in four weeks of treatment with this compound. Here, as in the series of male patients, it appears to make little difference whether the sulphanilamide is used as the only treatment or with local or other systemic methods. The improvement, in cases responding to the drug, has been remarkable and rapid—most rapidly, cervicitis and a fortnight. There were ten relapses reported among the women treated with sulphanilamide, whilst they were still undergoing treatment. Treatment with manganese butyrate, or gonococcal vaccine, combined with local treatment gives poor results when compared to sulphanilamide therapy.

In females, even more than in males, the criterion of Test for Cure remains most unsatisfactory in the absence of the Complement-Fixation Test. Each patient has been observed carefully for at least six weeks after cessation of all treatment—swabs being taken from the cervical canal at weekly or fortnightly intervals. Of the 48 women examined in this way 46 were still free of all signs of the disease at the end of this six-week period of observation. It should be clearly stated, however, that no claim is made for a 'cure' in these cases.

DISCUSSION

A series of 163 males and 132 females have been treated for gonorrhoea. Of these 113 males and 101 females have received sulphanilamide; 32 males and 17 females have received manganese butyrate and local treatment; 18 males and 14 females have received mixed gonococcal vaccine as well as local treatment.

Of the 113 males, 68, or 60 per cent, were clinically cured in a fortnight, and a further 11 after a second course of sulphanilamide, a total of 79 per cent in four weeks. Of the 101 females 49 were free of signs or symptoms in a fortnight, and a total of 66 per cent in four weeks from the commencement of treatment. Sulphanilamide has been used alone, combined with injections of manganese butyrate, and combined with local treatment. In both males and females the compound seems to work as well alone as when used along with other treatments.

The reactions noted have been those previously recorded by other observers—chiefly gastric disturbances, headache and erythematous eruptions. Most of the reactions have been comparatively mild, with few exceptions necessitating cessation of treatment. These reactions have only been recorded with a dosage of 4.5 grammes or more per day.

The results in this series are not as good as those reported by Dees and Colston or by Crean—70 per cent in males, and 66 per cent in females clinically cured, compared with nearly 80 per cent by the former and 90 per cent by the latter observer.

CONCLUSIONS

1. An attempt has been made to standardize the dosage of sulphanilamide in the treatment of gonorrhoea.
2. The use of sulphanilamide, with this routine dosage, has shown the compound to be definitely superior to manganese butyrate or vaccine.
3. The dosage used is not enough to prevent several relapses but a larger dosage is too toxic for routine use.
4. The complicated case of gonorrhoea responds as rapidly as the less advanced case to therapy with sulphanilamide.
5. Sulphanilamide appears to give the same results when used alone as when used in combination with other systemic or local treatment.
6. Much remains to be done before this drug can be used as routine treatment for all cases of gonorrhoea.
7. A generally accepted standard of cure of gonorrhoea is a necessity in order that the results of various observers may be comparable.

The Management of Insomnia

By HENRY COHEN, M.D., F.R.C.P.

(From the *Practitioner*, February 1938,

Vol. CXL, p. 181)

THE rational treatment of a patient has two aims. It seeks in the first place to remove the causes of disease; secondly, it endeavours to restore to normal those disturbances of bodily function resulting from disease. The former will not necessarily accomplish the latter. A burn demands treatment even though the fire which caused it has been extinguished, and this treatment is based on our knowledge of the bodily changes which accompany burns. So with insomnia. A discussion of its causes, and of the physiological mechanisms which result in sleep or wakefulness, is a desirable preliminary to a consideration of the management of insomnia. But these mechanisms are, as yet, imperfectly understood; hence many of the fundamental disturbances resulting in insomnia remain unrevealed. Purely palliative measures are in these circumstances the only therapeutic weapons, and they must be employed also when a cause, though known, is ineradicable.

Despite incomplete knowledge of the physiology of sleep, certain helpful facts are well founded. We know that accompanying sleep is a *depressed activity of the cerebral cortex* and that any factors, physical or mental, which tend to perpetuate cortical activity—for example, pain and dyspnoea, worry and strain—render sleep more difficult to procure. It is known also that there are marked individual variations in the depth of sleep, in the amount of sleep required, and in the ease with which sleep comes.

When, therefore, insomnia is the presenting complaint, the victim's normal *sleep-pattern* should be ascertained and the type of deviation therefrom noted. Sometimes it will be found that he cannot fall asleep for some hours after retiring but when once asleep, he remains undisturbed ('delayed' sleep); if he has to be awakened for work at an early hour he will have less,

sleep than he requires; if he remain undisturbed he will usually secure adequate sleep. Or he may fall asleep as usual but wake fitfully during the night, often disturbed by dreams or nightmares, and rise from his bed unrefreshed ('light' sleep). Or he may fall asleep quickly but wake during the early hours of the morning and be unable to recapture his sleep ('curtailed' sleep). It must be remembered that insomnia is a symptom which some patients tend grossly to exaggerate. Many complain bitterly of insomnia who, on close questioning, are found to have awakened for an occasional short period during the night but who nevertheless have had adequate rest and show no symptoms of sleep-deprivation.

CLINICAL GROUPS

Sufferers from insomnia can be separated into two large groups:—

(1) In the first group are those in whom the insomnia is a symptom of an obvious and dominant ailment which may be (i) physical or (ii) mental. A host of physical discomforts may be quoted as examples—the pains of pleurisy and arthritis, the pruritus of diabetes mellitus and urticaria, the dyspnoea of cardiac failure and asthma, the frequency of micturition of cystitis or chronic Bright's disease, the palpitation of Graves' disease, the cough of chronic bronchitis. Mental factors too are almost limitless—the worries of business, domestic anxieties, financial embarrassments—and these are usually volunteered by the patient, or confessed on sympathetic probing, as the explanation of his insomnia. It is evident that this group of cases of insomnia—sometimes designated *secondary insomnia*, because the sleeplessness is secondary to patent physical or mental causes—demands the removal of the cause for its rational treatment. But even though the cause is known it may be difficult to remove, *e.g.*, the anxieties due to an extravagant wife or an erring child, and sympathetic treatment will be necessary if the ill effects of prolonged insomnia are to be avoided.

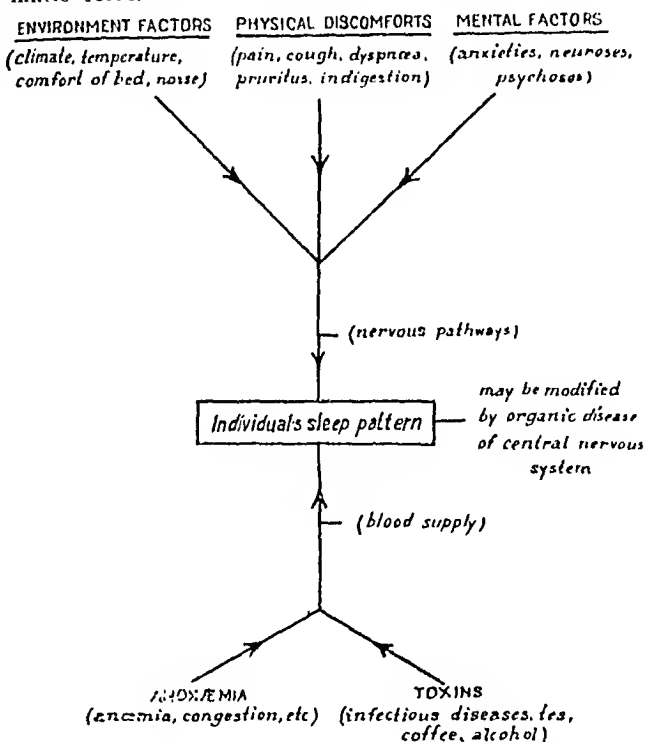

(2) This second group—often referred to as *primary insomnia*—comprises those patients whose principal and presenting complaint is sleeplessness and its accompanying symptoms and signs of exhaustion both physical and mental. A large proportion of these cases will be recognized as secondary after free and careful interrogation has unmasked a cause which the patient in his ignorance had not related to his complaint, *e.g.*, the anxiety and strain of working under an unduly exacting master. If the search for the simpler causes is fruitless after detailed and adequate inquiry, two conditions demand consideration, (a) an anxiety neurosis, the cause of which may be revealed by prolonged analysis, and (b) an early psychosis specially of the manic-depressive type. It may be that once insomnia has resulted from a known cause it is perpetuated as a compulsive or obsessional neurosis, not infrequently associated with fear of losing the reason.

The terms 'primary' and 'secondary' in relation to insomnia should be confined to this purely descriptive sense. In the former the insomnia is the dominant symptom, although its cause may appear after prolonged psychological observation and investigation; in the latter it results from an obvious or easily ascertainable cause.

Notable variations in response to an anxiety of similar type and intensity occur in different individuals and even in the same individual at different periods. In some people, the relatively slight disturbance of fresh surroundings, a strange bed, retiring late, unusual noise, or even unaccustomed silence will cause sleeplessness. Occasionally a very late meal, or coffee, tea, alcohol, or smoking before retiring to bed will be followed by insomnia; at other times they fail to disturb sleep.

Thus, whilst the individual's sleep-pattern varies slightly from time to time, gross disturbances follow those extrinsic influences which have been discussed

above. It is helpful to the understanding of the treatment of insomnia to represent this in simple diagrammatic form.

Variation in sensitivity of the neural mechanism responsible for an individual's sleep-pattern may arise in organic disease of the central nervous system, *e.g.*, in epidemic encephalitis, in cerebral arteriosclerosis, in third-ventricle tumours; if insomnia results it demands treatment.

TREATMENT

A consideration of the diagram indicates the principles of treatment in insomnia. Sleep will be promoted (1) by the removal or allaying of (i) physical and mental discomforts, (ii) disturbing environmental factors, and (iii) offending toxins in the blood stream; and/or (2) by so depressing or modifying nervous activity by drugs, physiotherapeutic or psychotherapeutic measures that disturbing influences cannot reach, and thus affect the neural mechanism of sleep. I have refrained from suggesting that therapeutic measures may directly influence the so-called 'sleep centre' in the floor of the third ventricle as our knowledge of this is meagre.

A comfortable bed, an equable temperature, regular habits, avoidance of late meals, adequate relaxation, assurance that the insomnia will not lead to mental breakdown, a frank discussion of difficulties—business, domestic, social and sexual—all these may suffice to restore sleep. Pain must be relieved, cough alleviated, and other disturbing factors treated by appropriate measures when they cause insomnia. But when the cause is obscure, or when the cause is known but likely to be prolonged, then treatment must be more active if the deleterious effects of insomnia are to be avoided or the vicious circle of insomnia inducing an obsession is to be broken. To this end the three groups of measures at our disposal need more detailed discussion.

Drugs are a most valuable and effective adjunct to treatment, but to use them recklessly is to court disaster. They act by depressing the nervous system and thus shut out from it external influences which may disturb the normal sleep-pattern. It follows that the more potent these factors the more potent must be the drug prescribed. But the potency of these drugs is not without its dangers. They may (i) be habit-forming, (ii) depress the nervous control of vital functions, *e.g.*, respiration, and so endanger life, and (iii) be toxic to certain organs of the body, *e.g.*, the

kidneys. Hence we must be guided in the choice of hypnotics not solely by the intensity of its action but also by (a) how long it is likely to be required; in an illness of a few days' duration, *e.g.*, pleurisy or post-operative pain, the more potent remedies can be used without the risk of addiction developing; (b) associated symptoms, *e.g.*, respiratory or cardiac distress, when if the more potent hypnotics are required appropriate stimulation must be used at the same time; and (c) associated disease, *e.g.*, chronic nephritis.

The drugs available are legion, but the practitioner who knows the effects and indications of a few well-tested remedies will achieve greater success in their use than he who is inveigled into trying those 'new and better preparations for inducing sleep', advertisements or samples of which arrive with each morning's post. Hypnotic drugs vary not only in the intensity but also in the rate of their action; a point to be utilized in the treatment of 'delayed' sleep. Most hypnotics show but slight analgesic properties, and are of little use when pain is responsible for insomnia, though here if a mild analgesic such as aspirin fails to secure sleep, its combination with a mild hypnotic will often succeed. The most commonly used hypnotics are:—

(1) *Bromides*—used as potassium, sodium, or ammonium salts, and sometimes combined with beef tea, or given in effervescing mixtures for greater palatability. Administered in doses of 20-30 grains, they are mildly hypnotic, but scarcely affect pain sensation; they act rapidly (15-30 minutes) and for four to six hours. No habit forms, and undesirable effects, such as acneiform eruptions, mental dullness, or digestive disturbances, ensue only if the drug is administered over prolonged periods. Bromides are excellent in 'delayed' sleep, and in the insomnia resulting from mental worry and strain, and the mild anxiety neuroses.

(2) *Choral hydrate* given orally in a dose of 10-20 grains usually acts in thirty minutes and produces a restful sleep lasting six to eight hours. In large doses—60 grains—the sleep is deeper, pain is dulled, respiration is slowed and, in some cases, the pulse weakens; it tends to depress the respiratory and vasomotor centres and also the heart-muscle, but these effects do not occur with the dose suggested, in which it is an excellent, reliable and non-habit-forming hypnotic. For the light restless sleep of anxiety it is most valuable; it can be combined with bromide for the delayed sleeper.

(3) *The barbiturates*.—Of these *veronal* (barbitonum B. P.) in doses of 5-10 grains was until recent years the most widely used. It has little analgesic effect but produces a restful sleep in $\frac{1}{2}$ -1 hour, lasting six to eight hours. After-effects are rare but addiction is not uncommon if constantly used and may be accompanied by toxic effects, such as impaired mental acuity, diplopia, peripheral neuritis, and erythema. The sodium salt of *veronal-medinal*—in similar doses acts more quickly but is subject to the same disadvantages of habit-formation and chronic poisoning. More commonly used to-day is *luminal* (phenobarbitonum, B. P.); in doses of 1-2 grains it acts in $\frac{1}{2}$ -1 hour, and is more powerfully hypnotic than *veronal*; it has little analgesic action but subdues motor excitability and is especially valuable when motor restlessness prevents sleep. It is but slightly habit-forming but some patients develop pyrexia with an erythematous eruption which may pass into an exfoliative dermatitis; this is probably an evidence of marked susceptibility to the drug. A large number of barbiturates have been synthesized and used as hypnotics, and it is well in a patient who requires them to ring the changes frequently so that tolerance to one preparation is less easily established.

(4) *Paraldehyde* in doses of 60 to 120 minims acts in 15 minutes, for four to six hours. In medicinal doses it rarely produces toxic effects and addiction is rare, though not unknown. It has a repulsive taste and smell which brandy mitigates but little. Its rapid

action and its easy administration rectally make it a useful hypnotic in acute disease, *e.g.*, pneumonia.

(5) *Opium and its derivatives* are the most powerful hypnotics and analgesics, but they are respiratory depressant, and with their more than occasional use there is grave danger of habit-formation. They should thus be used only in acute illnesses of short duration or in incurable disease.

I have not discussed *sulphonal* and its derivatives for their action is so uncertain both in rate and duration that they have no great merits. Moreover toxic effects, *e.g.*, hematuria, are not uncommon. For similar reasons I omit references to the *urethane* group.

The indications for drug treatment in any given case must be carefully weighed and the appropriate remedies chosen. The anxious student before an examination with 'delayed' sleep will be helped by bromides; if sleep is 'light'—small doses of chloral hydrate or a barbiturate may be given; but if the acute pleural pain of lobar pneumonia is preventing sleep, morphine will be necessary and its respiratory depressant action counteracted, especially in the latter stages of the disease, by appropriate stimulants.

OTHER MEASURES

Physiotherapy.—In the milder forms of insomnia, especially when associated with anxiety, soothing massage to the head and neck at bedtime will often induce sleep. If dyspeptic symptoms of the spastic-colon type are present, abdominal massage is a helpful measure. Tepid baths for 20-30 minutes before retiring, followed by a warm drink, induce a relaxation which aids sleep. Spa treatment has advantages not because of its intrinsic merits but because it ensures (i) regular habits of meals and exercise, (ii) a pleasant climate and environment, (iii) freedom from business worries, and (iv) the stimulus of undertaking a defined regime with an assurance of relief.

Psychotherapy, as in the treatment of diseases in general, plays a potent part in all measures designed to overcome insomnia. Sympathetic reassurance and understanding; frank discussion of various troubles all help. Simple measures, both physical and medicinal, must be prescribed with the confident assurance that good will ensue. Doubts about the grave effects of mild sleeplessness on mental activity must be dispelled. The mere presence of a sedative at the bedside to be used in case of need may suffice to induce sleep. But formal psychotherapy is of less value. Hypnosis is at best of temporary benefit only. Psycho-analysis might unmask repressed anxieties but it must be undertaken with caution for the cases in which it is helpful are few in number, and in the psychoses it is not only useless but may be harmful.

CONCLUSION

Insomnia is a symptom which demands treatment *per se* because its effects may be deleterious in both acute and chronic illnesses. But as an essential preliminary to its proper management, all possible etiological factors must be recognized and assessed, for only in this way will rational therapy be achieved.

Otitis Externa : "Hot-Weather Ear"

By G. MORLEY, F.R.C.S.

(Abstracted from the *British Medical Journal*, Vol. I, 19th February, 1938, p. 373)

THE scope of this contribution is limited to inflammation of the external auditory meatus apparently caused by hot humid climatic conditions and associated with an infection with *B. pyocyaneus* in pure culture. At the aural clinic of the Royal Air Force Hospital, Aden, a series of 100 cases was investigated, a line of treatment evolved on a simple practical basis, and search made for a common causative factor.

OCCURRENCE

Infections of the external auditory meatus with *B. pyocyaneus* among the troops in Egypt were described during the Great War, and more recently have been reported from the Seychelles, Canton, Ascension, East Africa, America, and Australia. Inflammations of the meatus are common in the troops generally and are often ascribed to a fungus infection. The conditions appear to be very similar and equally resistant to treatment, but as none of the cases which were bacteriologically examined in this series was found to have a fungus infection or any organism other than *B. pyocyaneus* and *Corynebacterium ceruminis diphtheria*, no attempt is being made here to discuss any other infection.

A record of the monthly total of new cases was kept and it was noted that the majority were affected during the May-June and August-September periods, more particularly the former. At these times—the beginning and the end of the south-west monsoon—the temperature and the relative humidity increase, and there is scarcely any appreciable 'cooling off' during the night. 'Prickly heat' is also very common at this period; both conditions, however, improve under the fresher weather during July and August, and during the cool season they almost entirely disappear.

AETIOLOGY

It has been thought desirable to investigate two popular theories—that of causation by bathing, and that of irritation by sand or interference. Of the 100 cases only forty-six had bathed in the sea within approximately one month previous to the onset of symptoms. Of these, thirty-five were regular bathers, the remainder taking only an occasional swim. Twenty-one used wool plugs in the ears while bathing, and twelve admitted to cleaning the ears with wool wound on match-sticks after bathing. The average number of baths per week among the regular swimmers was 2.85.

While it is admitted that the number of cases is small for the purpose of forming a definite judgment, these figures appear to discredit the sea-bathing theory. Fresh-water shower-baths were taken, on an average of two a day, by ninety-five of the patients, and ordinary slipper-baths by forty. The water used for this purpose is supplied from deep artesian wells and is also used for drinking. It is analysed regularly at the Royal Air Force Laboratory, and no evidence of faecal contamination has been evinced. Only twenty-five of the patients could fairly be considered to have been more exposed than other residents to sand in Aden, where the amount is not great: one or two minor sand-storms may occur in July, August, or September. It was observed that a few individuals had served for some years in India or Iraq and had been unaffected by real sand-storms, while at a time when personnel were encamped locally in bad drift sand the incidence of the condition did not increase. None of the cases had any gross disease of the ear, nose, or throat on examination, other than the meatitis.

The origin of the organism is still in doubt. Faecal contamination has been suspected, but there is hardly any water-borne sanitation in Aden at present, and, as has been noted, there is no evidence of a contaminated water supply. It is, however, a fairly ubiquitous organism, and it appears that certain factors promote its growth and render it pathogenic. No suggestion can be given as to the reason why *B. pyocyaneus* in particular should be the infecting organism. It is believed that the chief of these factors is moisture and maceration of the epithelium, especially if devitalized by trauma. It is well known that these cases present a moist appearance clinically, and that the corollary in treatment is to keep the ear dry. Also it is shown that most cases are infected when the humidity of the climate is greatest.

There is no evidence that all these cases are associated with *B. pyocyaneus* infection. For these reasons, the term 'hot-weather ear' has been maintained—a term used by Lieut.-Colonel Palmer, R.A.M.C., when

he described it as a clinical entity because this appears to be the strongest aetiological factor.

CLINICAL ASPECTS

Otitis externa has been described as clinically divided into two categories—the dry and the moist. This division has not appeared to be at all satisfactory, and for the purpose of description and treatment it has been found desirable to enlarge upon it. The classification adopted here is as follows: (1) acute; (2) subacute; (3) chronic; and (4) relapsing. The first two conditions and usually also the third are 'moist', whilst the fourth is 'dry'. There is, however, considerable overlapping between these classes.

1. *Acute*.—The patient usually complains of acute pain in the ear, often of a throbbing character, that has developed after a variable period during which he will have noticed increasing discomfort and usually some discharge from the ear. Pyrexia of 101°F. to 103°F. and pre- and post-auricular lymphadenitis often occur. Occasionally there is a slight degree of trismus, and mastication is painful. On examination the auricle may be slightly oedematous, and any movement of it becomes acutely painful. The meatus is occluded by swelling of the epithelial walls, which appear white and sodden, and a white curdy covering is often observed externally. The tympanum is not visible by ordinary auriscope examination, and there is moderate diminution of hearing. If the meatus is examined under an anæsthetic the inner part is seen to be covered with sodden white epithelial debris, removal of which shows an inflamed, red, and very angry-looking meatus; but only rarely is there a definite boil to be seen. The tympanum is usually only affected to a slight degree: the normal light reflex is diminished, and the external surface is most frequently granular in appearance. Sometimes there is moderate injection in the region of the malleus, but never any bulging or pulsation. In most cases the tympanum is normal and mobile. As the condition progresses under treatment there comes a point of relief from the acute symptoms which is sometimes associated with the liberation of thin sero-purulent fluid and resolution of the acute phase temporarily. Observation and incision have failed to locate definite pus during this stage.

2. *Subacute*.—The majority of cases are first seen in this stage, and a large number can be prevented from becoming acute. The complaint is of an aching ear, often associated with discharge from the meatus, which causes a yellow stain on the pillow-slip overnight. Slight adenitis may be present, and the auricle is tender on movement but not acutely painful. Hearing is only slightly diminished, but most distressing symptoms are caused in the hot humid atmosphere, and sleep is lost at night. Concentration at work is very difficult, and the condition may well be described as extremely aggravating. On examination the meatal walls are considerably swollen and 'soggy', with plaques of white cheesy debris partly adherent and partly lying in the lumen. The tympanum can usually be seen through a narrow space and is generally normal. One very characteristic pitfall is a curtain of debris immediately lateral to the tympanum, usually incomplete, which very closely resembles a perforated tympanum with acute meningitis, the whole being bathed in purulent exudate. It is only when this has been removed that a normal tympanum is found to exist, and the differentiation of these conditions is largely a matter of familiarity with the appearances on auriscope. For this reason the bright magnified view obtainable with an electric auriscope makes this the most useful method of examination. Removal of the sodden debris leaves excoriations which bleed very readily, and the ear then becomes more painful. Only those pieces which appear already detached can be removed without causing further trauma. There is in addition a thick purulent exudate, which lines the meatus and is very tenacious and difficult to remove efficiently. Most particularly is this true of the antero-inferior recess of the meatus immediately lateral to the tympanum. In long-standing cases this pus has

been observed to assume a yellowish-green coloration with great regularity.

3. *Chronic*.—In this stage without treatment the condition in unfavourable circumstances readily relapses into the subacute phase. With treatment, however, and efficient careful removal of debris, the meatus assumes a slightly thickened red appearance, while scaly flakes of dead epithelium form on the walls. The tympanum is normal, but there is most frequently a sodden 'subacute' area in the recess medial to the elevated floor of the meatus which is extremely difficult to eradicate. The chief symptom of this stage is most profound and distressing irritation, whilst the condition is aggravated by the rubbing and shaking of the auricle which this irritation provokes. There is a variable amount of discharge, which is of very thick greenish-yellow pus. Hearing is almost normal.

4. *Relapsing*.—In this stage the ear is to all intents and purposes normal both to the patient and on inspection. For a week or two after the chronic stage has been cleared after-treatment is necessary, as under very humid conditions the ear sometimes 'feels wet again'. If this is ignored recurrence is likely. In some cases this feeling persists during the hot season, and more acute symptoms can then be precipitated by the injudicious use of glycerinated ear-drops and wool plugs in the meatus, designed to keep out irritating particles of foreign materials such as sand and dust. Cases under the heading are regarded as potential infections and are given prophylactic advice and treatment.

BACTERIOLOGY

Meatal swabs were taken from thirteen typical cases in varying stages. The reports upon each were of Gram-negative, non-sporing, motile bacilli with no evidence of fungus. Eight produced pyocyanine on culture and gave the sugar reactions of *B. pyocyaneus*. All contained *Corynebacterium ceruminis diphtheriae*.

The cases which were examined were selected at random, and presented lesions typical of the condition. It has already been pointed out that the pigmentation of the pus in the later stages and the definite yellow staining of the pillow-slips due to discharge from the meatus are fairly well-marked clinical signs.

In standardizing treatment cases were classified into the clinical groups described, and the routine was strictly followed according to the group.

Acute cases

With this group no effort was made to clean out the meatus; to attempt it is sheer brutality, as the pain is exquisite. The meatus is very gently syringed with boric lotion, as hot as the patient will tolerate. After this the meatus is allowed to drain by posture for a few minutes. The ear is next filled with warm 1 per cent carboglycerin drops and a hot boric foment is applied, large enough to include the pre- and post-auricular glands. This treatment is carried out four-hourly, and is combined with initial purging by 4 grains of calomel in split dosage followed by salts. At first there was considerable diffidence in syringing with really hot lotion, lest vestibular disturbances should be caused. However, this does not appear to occur in these cases; most probably because the lotion does not freely reach the depths of the meatus. The relief is great and almost immediate, whilst the removal of small portions of debris makes the application of the carboglycerin more effective. The latter has been used only in 1 per cent solution, and as such the analgesic effect has proved satisfactory when combined with the hot syringing and fomentation. The question of incision in these cases is interesting. In some earlier cases the pain was so acute that the meatus was examined under an anæsthetic. Sodium evipan was used, but no actual boil could be found. Once or twice the most turgid and inflamed region was incised without the liberation of definite pus. Despite the relief this procedure gives it is considered that incision is contra-indicated. Even if a definite boil is seen, which is unusual, it seems better to allow it to burst

under the conservative treatment described; the pain is relieved speedily by both methods, and convalescence is not hastened by incision. Except for these early cases no occasion to incise the meatus has arisen during the last two years.

Subacute cases

These are cases in which there is partial occlusion of the meatus that is sufficiently painless to permit the introduction of instruments. In this group the object of treatment is to tide over and shorten the gap between acute occlusion and the relative patency of the chronic infection. The meatus is gently cleaned by direct application of dry sterile cotton-wool on malleable wool-carriers, under direct vision with reflected light. The electric auriscope is used only for inspection in this stage. When moderately clear of debris the meatus is packed firmly, but not tightly, with sterile half-inch ribbon gauze soaked in 1 per cent carboglycerin, being retained in position by an external wool plug. This procedure is repeated every twenty-four hours. The steady light pressure lessens the swelling, the glycerin loosens the dead epithelium, and the carbolic acts as a mild antiseptic and analgesic. This stage as a rule lasts only two or three days and leaves a clean but inflamed meatus, while debris persists in the recess near the drumhead.

Chronic cases

The routine adopted has been as follows. First the ear is cleared of obvious gross debris; a day or two on the treatment described for subacute cases have been found most successful for this purpose. The meatus is then dried with either ether or boric and spirit drops. After mopping with dry sterile wool the patient inclines his head right over, to bring the affected ear uppermost, and is warned to keep his eyes tightly closed. A small quantity of boro-iodine powder is tapped well into the meatus and insufflated with a Siegle's speculum into all parts of the meatus. Care is taken to avoid blowing the powder into the operator's eyes. The meatus is then quickly packed with the powder until it is full, the whole being lightly tapped home. Without delay the meatus is now plugged with a firm pledget of wool.

The dressing is left undisturbed for forty-eight hours. It causes slight discomfort for the first hour or two, but in no case has this been intolerable. At the conclusion of this period the ear is very gently syringed to clear away the remains of the powder, the greater quantity of which has usually been dissolved, and the meatus is filled with boro-spirit drops for a few moments, afterwards being drained by posture. It is sometimes necessary to detach dried pieces of dead epithelium with forceps, and occasionally small casts of the meatus are removed in this way; otherwise the use of instruments is avoided at this stage, and the meatus is not kept plugged with wool. Boro-spirit drops are applied twice daily for two days, and the treatment is repeated if it is then found necessary. As a rule only two such applications of boro-iodine powder have been indicated, although repetition has occasionally been necessary after about ten days.

Essential points are the drying of the meatus, speed in the application of the boro-iodine powder as the iodine evaporates rapidly in hot climates, and the subsequent avoidance of any form of plug in the meatus. The reason for the last named is that the cartilaginous portion of the meatus contains sweat glands, and any plugging distal to these must cause increased humidity in the meatus and maceration of the epithelium, conditions which predispose to recurrence. With the use of only a thin film of powder it has been found that the iodine evaporates so quickly in a climate such as that of Aden that the filling of the meatus as described is regarded as essential. In no case has this caused any trouble: within a few hours the powder appears to be dissolved by the moisture of the plugged meatus.

AFTER-TREATMENT

Most cases are now discharged from the clinic with a bottle of boro-spirit drops, a small quantity of which they are advised to insert into the meatus last thing at night. Patients are instructed to dry the ears carefully after bathing, especially after taking a shower-bath, by gently shaking with a towel inserted in the auricle on the tip of the little finger and with the head inclined over on the side. The insertion of wool plugs is strongly discouraged for the reasons mentioned above, although the question of using 'a plug of cotton-wool soaked in olive oil during bathing' frequently arises. Unsterile oil and dirty wool are often used, and the plug is sometimes forgotten. It is of doubtful efficiency, and is needless if the ear is carefully dried.

PREPARATION OF BORO-IODINE POWDER

The method described by Scott Stevenson was taken as a guide and modified to suit the climate of Aden. The following description has been prepared by the dispenser at the Royal Air Force Hospital, Aden:

'For the preparation of iodized boric powder sublimed iodine is used in a strength of 1 per cent in acid. boric. pulv.; the iodine is first broken down with a few drops of alcohol 90 per cent. The boric acid is added in powder form in small quantities as quickly as possible, using a non-porous glass mortar and keeping the mixture moving all the time. As soon as the iodine appears to be evenly distributed the powder is transferred to a wide-mouthed dark glass-stoppered bottle, without waiting for complete drying. Evaporation of the iodine is very rapid; if any delay occurs all the iodine is lost, and the use of a glass-stoppered bottle instead of cork is necessary to preserve the iodine content.'

OTHER METHODS OF TREATMENT

In many papers dealing with this and allied conditions there appears a variety of treatments, a number of which has been tried here in the hope of finding one more satisfactory than the others. At first diligent mopping of the meatus with hydrogen peroxide, then drying with ether, and applying a solution of silver nitrate in spiritus aetheris nitrosi was tried. Then spirit and biniodide of mercury, 1 in 4,000, was substituted for the ether. Argyrol (2 per cent), merurochrome (1 per cent), and liquid iodex packs were given exhaustive trials, with disappointing results. Zinc ionization promised well; a course of five treatments each of 1/2 mA for one-half hour, a stronger current being uncomfortable, produced good results at first, but recurrences were numerous. Vaccine therapy was not tried, although recommended by some observers, because it was felt that a simpler and more practical method of treatment could be evolved which could be practised efficiently at out-stations. Phenyl mercuric nitrate was not used in this series.

Finally one case arose in which all efforts to obtain a cure appeared futile; the condition just continued to

relapse. First one side would improve and the other commence to discharge, then the state would reverse. The man spent fifty-seven days in hospital, in addition to receiving 107 days of out-patient treatment. The organism was a typical *B. pyocyaneus*, and all the methods of treatment described were tried with no avail. In the end the meatuses were treated with boro-iodine powder on the lines now described, and after one application on each side the condition cleared up completely. He has since passed through the whole hot season without recurrence, and only occasionally applies a few boro-spirit drops at night-time. The routine treatment was then evolved and adopted, with results which have been very satisfying, although not always as spectacular as in this case.

RESULTS

Since the treatment described was adopted as a routine and applied to the later sixty-six of this series of cases the average number of daily attendances has been 8.27 per case (maximum, 24; minimum, 2). Previously, under the other forms of treatment, this was considerably greater, and in the earlier thirty-four cases of this series the average was 22.6, or, excluding the exceptional case to which reference has been made, 18.1, with a maximum of 72 and a minimum of 3. Admissions to hospital have totalled five from the earlier thirty-four cases (16.6 per cent) and three from the sixty-six later cases (4.54 per cent).

Published results of vaccine therapy are good after periods of weekly injections extending over some five or six weeks (maximum, 12; minimum, 3). The vaccines used were autogenous, but the suggestion is made that a stock vaccine might prove equally efficacious.

Phenyl mercuric nitrate, used 1 in 1,250 in 95 per cent alcohol, is claimed to have a spectacular effect on the acute stage and to shorten the course and hasten recovery in the chronic and long-standing cases.

SUMMARY

1. A series of 100 cases of otitis externa occurring chiefly during the hot humid seasons of Aden was investigated, and a representative number of cases were found to be infected with *B. pyocyaneus* in pure culture.

2. The influence of sea-bathing and a sandy atmosphere as aetiological factors are discussed and discredited; whilst the seasonal incidence is held to justify the term 'hot-weather ear'.

3. A routine method of treatment with facility of application is described, based upon boro-iodine therapy. The use of cotton-wool plugs in the meatus is discouraged. Prophylaxis and after-treatment are described.

4. The results of this form of treatment as applied to sixty-six cases are given, and are compared as far as possible with those of some recently published methods.

Reviews

THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE.—Edited by Sir Humphry Rolleston, Bart., G.C.V.O., K.C.B., M.D., D.Sc., D.C.L., LL.D. Volume I. Pp. 742 plus xxxiv plus 60. Price, Rs. .25. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta.

In this volume the subjects dealt with range from abdominal pain to appendicitis; there were some 50 articles written by about 40 different contributors. All the contributors are well-known British authorities on the various subjects; those writing on tropical subjects, include Sir Leonard Rogers, the late Colonel Acton, and Colonel V. B. Greu-Armytage.

The volume opens with a masterly introduction from the pen of the editor. Sir Humphry, in his finished yet easy style, discusses the different eras through which medicine has passed, from the pre-Hippocratic to the modern, post-Jenner, period; he asks the question 'What is medicine? Is it an art or a science?' It still remains an art which has been greatly helped by science (so much so that there is a danger of its losing its *being transposed into a science*). The changes in the type of disease, nomenclature and classification, the birth of bacteriology and the surgical revolution, anaesthesia and radiology, and finally specialism and medical practice.

Sir Arthur Hurst has a number of contributions on achlorhydria, on aerophagy, on anorexia nervosa and on achalasia; the last-named chapter is a somewhat unusual one, as it deals with achalasia of such widely separated structures as the pharyngo-oesophageal sphincter and the os uteri.

The chapter on anaemia, a very important one of 64 pages, is written by Dr. J. F. Wilkinson with sections by Dr. L. E. H. Whilby; a good account of the subject, commencing with a classification which is on the modern lines. If we have a criticism, it is that a little too much space is devoted to achrestic anaemia, in view of the doubts that exist about this disease as a separate entity.

Sir Leonard Rogers gives a very good chapter on amebiasis; he does not, however, mention carbarsone in the treatment.

'Appendicitis' is written by Sir David Wilkie and is considered from the point of view of the practitioner, who may be called upon to operate himself.

All the articles are of a very high standard and are, above all, eminently practical.

L. E. N.

FOOD AND PHYSICAL FITNESS.—By E. W. H. Cruickshank, M.D., D.Sc., M.R.C.P., F.R.S.E. 1938. E. and S. Livingstone, Edinburgh. Pp. xi plus 148. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 3-12

This book is based on a series of public lectures delivered by Professor Cruickshank at Aberdeen. It is a type of book for which there is plenty of room, though it is in no way unique. The writer is a physiologist and nutrition worker of repute and the book has received the blessing of Sir John Orr, so we need not hesitate to accept the facts that are presented.

The book is a plain straightforward statement of the body requirements of food and of the means by which they may be provided. It was written, or rather the lectures on which it is based were delivered, for a Scottish public, but the facts presented will be found as useful for an Indian public, and the writer has gone to India and other foreign countries for many of the examples that he quotes to illustrate his points. In the section on 'some false ideas concerning foods' he provides a much needed corrective to the spate of food advertisements and the ridiculous statements of 'stunt' writers on weight reducing dietaries.

Though the book is based on a series of public lectures the information given will be found of great value to the practitioner, who will probably find much in it he ought to have known but does not know, and to the health worker, as well as to the housewife for whom it is primarily intended.

TROPICAL NUTRITION AND DIETETICS.—By Lucius Nicholls, M.D., B.C., B.A. (Cantab.). 1938. Baillière, Tindall and Cox, London. Pp. xi plus 164. Illustrated. Price, 7s. 6d.

Tropical medicine owes much to parasitology, but the debt is mutual, and in fact both studies have grown side by side during the last fifty years. It is not surprising, therefore, that in the study of tropical diseases the greatest emphasis should have been laid on the parasitological aspect of them. There has, however, during the last few years, been a distinct shifting of the centre of gravity from the parasitological to the biochemical aspect—in this latter is included the dietetic.

Dr. Lucius Nicholls' book is a welcome addition to the growing but still rather scanty literature on dietetics as applicable to tropical conditions. All the information he gives can easily be obtained elsewhere, but he has collected it and summarized it in a way that will be very useful to the tropical worker whose library is limited. The book might well be looked upon as a 'primer' in tropical dietetics as it is written in a way that not only the medical man but the layman can benefit from it; on the other hand, the

man who has studied the subject will not find much of value in the book.

Dr. Lucius Nicholls has himself made an important contribution to the study of deficiency diseases and the papers in which he first described the condition he called phrynoderma appeared in this journal, it is natural, therefore, that he should be particularly interested in vitamin-A deficiency and his section on this subject is very complete. He has not been quite so far to the vitamin-B deficiencies and there is no mention of the macrocytic anaemia associated with vitamin-B-complex deficiency. The only mention of anaemia is a statement that the common anaemia of the tropics is a microcytic anaemia which is mainly caused by hookworm infection and malaria. This is not, we believe, quite true, and the typical anaemia of malaria is not microcytic. A great deal of work has recently been done on vitamin-C estimations; some of these are given, but not the most useful.

A knowledge of dietetics is far more important to the practitioner in the tropics than it is to his opposite number in England, and this applies particularly to those who have to deal with labour forces. This useful little book fills a distinct want and should be in great demand.

L. E. N.

CLINICAL ATLAS OF BLOOD DISEASES.—By A. Piney, M.D., M.R.C.P., and S. Wyard, M.D., M.R.C.P. Fourth Edition. 1938. J. and A. Churchill Limited, London. Pp. xvi plus 127, with 42 illustrations, 38 in colour. Price, 12s. 6d.

We are pleased to see another edition of this useful little book which has always been deservedly popular with students and practitioners. It gives the student visual impressions which they often find easier to retain than those received by other methods—for example, the plate of sickle-celled anaemia will fix a picture in his mind which no description would, and he may find this useful in an examination though the chances against his ever seeing a case will be about a thousand to one. The short descriptions are for the most part accurate and helpful, but quite naturally there are statements with which everyone will not agree.

The illustrations are on the whole good. In places they are a little crude and the 'diagnostic' points have been over-emphasized so that the student may be a little disappointed that in practice the different cells are not, so to speak, labelled as they are in this book. The reviewer does not like his illustrations of megaloblasts but then he does not like his definition of megaloblasts and erythroblasts either, and these are points about which no two hematologists are agreed.

Every book on a specialist subject should contain a glossary, as this book does. Altogether it is a book we can thoroughly recommend for the class of reader for which it was written.

L. E. N.

MAJOR ENDOCRINE DISORDERS.—By S. L. Simpson, M.A., M.D. (Cantab.), M.R.C.P. (Lond.). 1938. John Bale Medical Publications, Limited (85, Great Titchfield Street, W.1), London. Pp. x plus 184. Illustrated. Price, 10s. 6d.

This little book contains a concise statement of our present knowledge regarding endocrinology. It will be very useful to the student or examiner as the writer prefers to call him, assuming that we are all still students, and the practitioner. It is not a complete treatise on the subject; this is a distinct advantage as far as this class of reader is concerned, as treatises often contain much speculative matter which may help the specialist but is liable to lead the practical worker astray.

Despite the title of this book certain glandular disorders that cannot be considered major are included; there is, for example, a section on menstrual disorders. It is cheerful for the woman who may regret certain of the disadvantages that are associated with the menopause to think that she may attain 'greater

resolution, command, initiative, originality and administrative capacity'.

The writer points out that familial obesity is often due to a familial habit of overeating. It is extraordinary how difficult it is to persuade the obese individual that he is overeating, because he can usually quote someone who eats much more than he does, but when he has the moral support of his family it is almost impossible.

It is a useful little book which we have no hesitation in recommending.

INFANTS IN HEALTH AND SICKNESS.—By R. E. Steen, M.D., F.R.C.P.I. 1937. Oxford University Press, London. Humphrey Milford. Pp. x plus 127. Illustrated. Price, 5s. Obtainable from Oxford University Press, Bombay and Calcutta

More than half this book is devoted to the feeding of infants in health, breast feeding under normal circumstances and under difficulties, and artificial feeding. There is next a chapter on gastro-intestinal disturbances. There are two short chapters on abnormalities and diseases in infancy and a final one on hygiene.

It is a very useful little book and the teaching is orthodox and quite up to date, but the title is, we consider, misleading—'Infant Feeding in Health and Disease' would have been better.

The author's style is not faultless. The preface opens with these lines:—

'This book, except for a few minor additions, is identical with the Infant Section as it appears in Tweedy's *Practical Obstetrics*. It was written and printed solely with this object in view, and it was only as an afterthought that the decision was made to publish it separately.'

With what object? And we should have thought that decision to publish the book would have been made *before* it was printed: our publishers are always adamant on this point.

We can think of no more inappropriate book in which to introduce, as does the author at the beginning of this book, the overworked—and certainly untrue in its present form—quotation about diagnosis, diagnosis and then diagnosis being the three important things in treatment, than one that deals mainly with infants in health and the way to maintain them in this state.

Nevertheless, we can strongly recommend the book as a sound and practical statement on the subject of infant feeding.

CLIMATE AND ACCLIMATIZATION.—By Sir Aldo Castellani, K.C.M.G., D.Sc., M.D., F.R.C.P. Second Edition. 1938. John Bale Sons and Curnow, Limited, London. Pp. x plus 198. Illustrated. Price, 10 shillings

THIS is not presumed to be a comprehensive work dealing with all the branches of the subject but is a collection of notes on some features of the problem, particularly on those which have a bearing on white settlement in the tropics. The work is based chiefly on personal experiences of the author in his long sojourns in many different tropical countries and he has endeavoured to emphasize the fact that climate *per se* has an important influence on the health of Europeans living in the tropics, apart from the rôle played by parasites and hygienic conditions. The text is divided in four chapters. In the first chapter there are short notes on the classification of climate, climate and man, climate and animals, climate and vegetation, the divisions of warm climates, and on temperature and humidity. The second chapter deals with the effects of climate and discusses the effects on body temperature, respiration, circulation, blood, blood-pressure, digestion, general metabolism, nervous system, urinary system, endocrine glands, fertility, growth, skin, tissues and on general sickness and mortality. The subjects of heat-stroke, heat-exhaustion, heat-cramp, sun traumatism, heat-low fever, heat-œdema, chills and cold-stroke have also been discussed in this

chapter. The third chapter begins with a discussion of the effects of high and low atmospheric pressure, such as caisson disease and mountain sickness. The different kinds of wind, permanent, periodical and local, and their effects, and the different kinds of rays given out by the sun and their influence upon our health and complexion are discussed in this chapter. The fourth chapter deals with acclimatization, suitable head-gear, clothing, housing, etc., the adaptation of European women and children to tropical climates, white troops in tropical climates either for garrison duties or for military operations, and finally a few notes on the experimental researches on the influence of climate and adaptability to climate. A fairly long list of references to various textbooks, monographs and reports on meteorology, and the literature dealing with the effects of climate and acclimatization is appended at the end of the book. Written as it is by an author of very wide experience, this excellent handy volume will be read with great interest by a large circle of readers, both medical and non-medical.

ANNUAL REVIEW OF BIOCHEMICAL AND ALLIED RESEARCH IN INDIA. Vol. VIII, 1937. Published by the Society of Biological Chemists, Bangalore, India. Pp. 185. Price, Rs. 3 or 6s. (Inclusive of postage)

THE review has been discussed under the following heads: Vitamins, Proteins, Enzymes, Pharmacology, Human Physiology, Human Pathology and Bacteriology, Foods and Nutrition, Microbiology and Fermentation, Plant Physiology, Chemistry of Plant Products, Phytopathology-Mycology, Phytopathology-Entomology, Soils, Fertilizers and Manures, Animal Nutrition and Dairy Science, and Veterinary Science. Each section has been reviewed by some worker experienced in it and references to almost all the work done in India during the year have been given. The Society of Biological Chemists, India, deserve to be congratulated on this well-produced and useful publication and the volume will be welcome not only to all the research workers on Biochemistry and allied subjects but also to all those who are interested in the progress of science in India.

S. G.

A TEXTBOOK OF OPHTHALMOLOGY.—By Sanford R. Gifford, M.A., M.D., F.A.C.S. 1938. W. B. Saunders Company, Philadelphia and London. Pp. 492 and 249 illustrations. Price, 18s.

THE book is a good short reference book for the general practitioner for the treatment of eye diseases inasmuch as it lays stress on facts of real importance and systematically describes the most modern practical points in diagnosis and treatment.

The book will prove to be of value for medical students as well. The arrangement is very satisfactory for their training. In chapters I to IV containing methods of examination even short notes on transillumination and slit-lamp microscopy have been given. Chapter V deals with refraction where first of all the basic ideas of physical optics have been given and the chapter has been finished with a short outline of special optical appliances which might rouse the interest of the inquisitive student. In chapters VI to VIII, dealing with the various diseases, the anatomy and congenital anomalies have been described, so that the student is able to grasp what the actual disease picture is like. In chapter XVII, dealing with the disturbances of ocular motility, the latest methods of orthoptic treatment have been briefly mentioned, with systematized practical points which is a real advancement over older textbooks. Chapter XIX deals with 'Injury to the Globe'. This is rather short but this seems unavoidable in consideration of keeping down the size of the book. In chapter XX a good, but short, account of the therapeutic agents employed in ophthalmology is given. In chapter XXI we find 'Eye—General Disease', a subject quite important for the general practitioner, has been dealt with rather

too briefly. In the appendix useful reference has been made to the standard methods of computing compensations and the regulations thereof.

The author has on the whole omitted pathology. The coloured plates have been very well reproduced but are few in number and the ordinary illustrations though numerous are rather indistinct.

S. K. M.

TREATMENT IN GENERAL PRACTICE.—By H. Beckman, M.D. Third Edition. 1938. W. B. Saunders Company, Philadelphia and London. Pp. 787. Price, 42s.

It is just four years ago since we had the pleasure of reviewing the second edition of this book. In that we said it was 'a well-arranged and eminently practical book'. It is now still just as practical and is better arranged. As a result of this, combined with judicious pruning of matter perhaps better dealt with in larger books on special subjects, the author has been enabled to add a great deal of new matter from the many advances in treatment that have occurred in the past four years and still to keep his book approximately the same size as the second edition.

Much of the information is necessarily condensed but a list of approximately 2,300 references provides ample opportunity to the reader of amplifying almost every subject discussed.

This book maintains its character of having kept right up to date so that it can be just as strongly recommended as the second edition as a book of reference for the busy practitioner, to find out the most modern methods of treatment in vogue in practically all diseases.

P. A. M.

DISEASES OF INFANCY AND CHILDHOOD.—By W. Sheldon, M.D. (Lond.), F.R.C.P. (Lond.). Second Edition. 1938. J. and A. Churchill, Limited, London. Pp. xii plus 739, with 125 text-figures and 13 plates. Price, 21s.

The appearance of the second edition of Dr. Sheldon's book on 'Diseases of Infancy and Childhood' in less than two years shows its popularity and demand. It proves that there is room for yet another book on diseases of children, as expressed by Dr. F. Still in a foreword; for the progress of knowledge in this particular department of medicine has been rapid during the past few years.

After an introductory chapter on the physical examination of children and their normal development, the book deals with the affections of the newborn and the management of the premature child. Next comes a chapter on the diet of the healthy infant, followed by an account of digestive disorders in infancy. Thereafter, the book deals with various diseases including mental deficiency and skin diseases. It covers the field of pædiatrics in a complete manner, allotting space to various conditions proportionate to their importance.

Several additions and alterations have been made in this edition. The chapter on intra-thoracic tuberculosis has been re-cast, and a distinction is no longer made between hilum tuberculosis and tuberculosis of the mediastinal glands. An attempt has also been made to clarify the part played in this disease by hypersensitivity to tuberculin. Recent therapeutic measures, such as the use of mandelic acid salts, sulphanilamide drugs, oxygen tent, etc., have been added.

An appendix has also been incorporated giving a table of common drugs and their appropriate dosage at the various ages of childhood. The illustrations are many and vivid, the index is complete and the production is good.

The book is useful and suitable for students and post-graduates. One comment may be made, that is, tropical diseases have not received sufficient consideration. Diseases, such as malaria and kala-azar, might perhaps

have been included to the advantage of practitioners in the tropics.

R. C.

ARTIFICIAL FEVER PRODUCED BY PHYSICAL MEANS: ITS DEVELOPMENT AND APPLICATION.—By C. A. Neymann, A.B., M.D., F.R.S.M. 1938. Baillière, Tindall and Cox, London. Pp. xv plus 294. Illustrated. Price, 27s.

DR. NEYMANN has reviewed in an excellent manner the result of researches in the treatment of diseases with artificial fever, a new and rather limited part of therapeutic medicine. The therapy concerns itself with the beneficial effects of raising the temperature of the human body by means of heat. Since these fevers are now usually produced by high frequency electric currents, instead of the older methods, the term *electropyræxia* has been coined. This is effected by supplying heat from without to the body, which is insulated to prevent its loss.

After a discussion on the basic theories and principles in the therapy, the book deals with the history of the development of the method. It is followed by detailed descriptions of the physiology and then the technique on electropyræxia. The rest of the book refers to its use in diseases, such as dementia paralytica, syphilis, multiple sclerosis, chorea minor, arthritis, gonorrhoea and asthma with a chapter on other diseases.

The book will be of considerable value to those interested in radiothermic treatment. The reader will obtain an easier insight into this subject than by reading the many articles that comprise the bibliography at the end of the volume. There are numerous illustrations, and the get-up of the book is excellent.

R. C.

SURGICAL ERRORS AND SAFEGUARDS.—By Max Thorek, M.D., K.L.H. (France), K.C.I. 1937. Third Revised Edition. J. B. Lippincott Company, Philadelphia and London. Pp. xvi plus 696. With 668 illustrations, many in colour. Price, 45s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 33-12

To say that Professor Max Thorek has written a valuable book is, at best, poor appraisal for a notable work, which now appears in its third edition. Despite the noble traditions of the medical profession, there is no denying the fact that there is a large body of opinion which is sometimes passively but more often manifestly hostile to the present-day teaching and practice of the medical sciences. The reasons for this sad state of affairs are not far to seek. As Dr. Bevan rightly points out, in his foreword, 'the great increase in surgical procedures has brought with it two new and serious problems, i.e., the doing of some unnecessary operations and the performance of operations by men who are relatively incompetent'. This disquieting statement may not apply to any one country in particular, but it should engage the serious attention of the controlling bodies.

Humility, in a surgeon, is of no less importance than technical skill and self-confidence. The author feels that a 'personal experience of over twenty-five years in the practice and teaching of surgery justifies him in acting without presumption or vanity as a mentor to those who are entering on the perilous path of surgical practice which he has trodden'. We venture to assure the author that it is not only the neophyte who is likely to profit by his experiences, but also many a hardened surgeon will remember with advantage his aphorisms and dicta. There will be general agreement with the statement that 'operation is not synonymous with surgery and that primary object of surgery is not operation, but the cure of the patient'. It is true that the devastating criticism of the past that 'the operation was in every way successful but the patient died', is no longer tenable, but it has now been replaced by the case of the successful operation

followed by chronic invalidism. The author has done well, therefore, to emphasize again that in dealing with the patient the surgeon is expected to follow the golden rule. He should never perform an operation on a patient which he would not want to have done on himself under the same circumstances.

The making of a surgeon is a comparatively slow and gradual process, dependent on the assimilation of experience and mastery of technique. Preventable catastrophes and other infractions in surgery are usually due to three fundamental causes, 'ignorance, dishonesty, and bad judgment'. This is forceful language, but justifiable. That foreign bodies like surgical instruments, sponges and dressings are at times accidentally left within the abdominal cavity during surgical operations is a well-known fact. Surgeons are only human and therefore they 'do not like to confess mistakes and there are reasons, legal and otherwise, why the error of leaving a foreign body in the abdomen, or elsewhere, during an operation should be hidden'. It is common knowledge that 'the accident occurs with much greater frequency than one would suspect on the basis of statistics', yet the author's references run to several hundred cases. We do not remember ever having seen an instance mentioned in the published annual returns of our larger hospitals!

Enough has already been said in praise of this book. The author certainly deserves our thanks for his courageous advocacy of conservatism in surgery, strictly consistent with efficiency and simplicity of technique. Volumes, it is true, are now and again published, for the laity, with a pseudo-scientific flavour conforming to the requirements of sensational journalism, thus bringing the honourable medical profession into disrepute for the sins of the few. This book has the great merit of not belonging to this category. Within the compass of 700 pages and 16 chapters there is a store-house of experience and sagacity which the practising surgeon and the post-graduate student of surgery can ill afford to ignore. This book should find a place in the library of every surgeon.

The printing, binding, and illustrations are excellent. Each section has an adequate bibliography and the book concludes with an exhaustive index.

P. N. R.

SURGICAL HANDBOOK FOR HOSPITAL ASSISTANTS IN THE TROPICS.—By W. K. Connell, M.B., Ch.B. (Glas.), F.R.C.S. (Eng.), D.T.M. & H. (Lond.). 1938. John Bale Medical Publications, Limited, London. Pp. xvi plus 440. With 177 illustrations. Price, 12s. 6d.

THIS book is apparently not intended for medical students, practitioners, or nurses. It is therefore difficult to place it in any of the usual categories. It would be easy to find faults in such a book but there are some glaring ones which cannot be overlooked. On septicaemia the author says that 'the medical departments of Tanganyika and Kenya have been so impressed by the anti-streptococcal power of "Prontosil" that they are now using it to the entire exclusion of anti-streptococcal serum which is no longer purchased' (p. 19). Yet (on p. 31) it is stated that 'the anti-streptococcal serum is of great value in erysipelas, cellulitis, etc.' Referring to vaccines, the author declares with emphasis that his own personal experience has been *disappointing* (p. 25), yet he goes on to say that 'all cases of erysipelas, most cases of cellulitis, and many cases of whitlow are due to streptococci and may be benefited by streptococcal vaccine' (p. 31). The author has expressed the hope, in a foreword, that he is looking forward to achieving standardization of treatment in the tropical hospitals and also to the time when he can say to his dispenser 'this patient is suffering from so-and-so, I wish you to give him the treatment, which is described on page such-and-such of my textbook'. The many palpable inconsistencies, we are afraid, will, at once, dash his hopes to the ground. In any case such a method of surgical practice is certainly liable to shock the feelings

of medical practitioners, but the author declares that he is unrepentant.

The African dispenser is expected to perform minor operations like tapping a hydrocele under aseptic conditions. There is, however, an illustration depicting the performance of this operation with the surgeon's hands in position, the scalpel ready, but the diseased organ displaying a luxuriant growth of pubic hair (p. 356)! One may wonder why the prospective surgeon is not aware of shaving as a first principle of asepsis. The author has been particularly mindful of simplicity of language in imparting surgical knowledge. We are not very sure that he has achieved the desired success when we read that 'it is extremely dangerous to kiss a patient suffering from the secondary stage of syphilis' (p. 92). The italics are ours. As we are unfamiliar with the conditions prevailing in East Africa, it is difficult to give an opinion as to the utility of this book. But it seems to us that efficient practical training would be more important and beneficial for this type of hospital assistant than a smattering of book knowledge.

P. N. R.

SICK CHILDREN: DIAGNOSIS AND TREATMENT.

By Donald Paterson, B.A. (Manitoba), M.D. (Edin.), F.R.C.P. (Lond.). Third Edition. 1938. Cassell and Company, Limited, London. Pp. 604. With 15 half-tone plates and 75 figures in the text. Price, 12s. 6d.

THE second edition of this book on children's diseases, published in 1937, was reviewed in the columns of the April issue of this journal last year. The demand for a third edition within so short a period is sufficient testimony to the excellence of the matter and the clear and concise nature of its presentation.

The book deals with facts, not theories; its compactness and the fact that the description of rarer diseases are printed in smaller type make it very suitable for the medical student and general practitioner, while the student reader will find in the copious footnotes and references material for wider reading and investigation.

Complete revision has been done and recent advances particularly in the field of chemotherapy, infections of the accessory nasal sinuses, Sonne dysentery, epidemic jaundice and diabetes have been incorporated in the text. The useful table showing the normal composition of cerebrospinal fluid, faeces and blood in children, printed inside the cover, is repeated, and for the use of those going up for examinations in child health the examination papers in appendix 2 have been brought up to date.

The growth, development and diet of the normal child is the proper starting point for the study of sick children, and it is fitting that the care of the normal child as well as nutritional disorders should receive detailed attention. Altogether the book can be confidently recommended as an excellent introduction to paediatrics.

J. M. O.

CUTANEOUS CANCER AND PRECANCER: A

PRACTICAL MONOGRAPH.—By G. M. Mackee, M.D., and A. C. Cipollaro, M.D. The American Journal of Cancer, New York. Pp. xv plus 222, with 245 illustrations. Price not stated.

THIS is a valuable monograph as it collects in a remarkably condensed form nearly all the information available on the subject of cutaneous cancer. The book is only of 212 pages several of which are occupied by bibliography. In these pages there are 231 photographs and microphotographs many of which occupy a whole page so it is clear the reading matter is not great. Nevertheless the essentials are given and theoretical discussions avoided, thus making it a book for the practitioner rather than the laboratory worker. Treatment is also only indicated, it being left for the reader to acquire the detail elsewhere; this we look on as an advantage.

The illustrations are beautifully clear and well selected, and the photomicrographs without exception show what the descriptive captions state is demonstrated in the figure, a thing which cannot be said of all photomicrographs. They are so good and the descriptions so adequate that if published in the form of an atlas without any amplification by printed matter they would be of great educational value.

A remarkable omission in the book is that there is no mention of the work of Paul and other Australian dermatologists who have contributed largely to the subject of solar dermatitis and epitheliomata, on account of the high incidence of these conditions in that country.

P. A. M.

SPEECH TRAINING FOR CASES OF CLEFT PALATE.—By M. C. Oldfield, M.Ch. (Oxon.), F.R.C.S. 1938. H. K. Lewis and Company, Limited, London. Pp. 18, with 38 illustrations. Price, 4s. 6d.

THE book deals with the problem of educating a child to speak correctly after an operation for cleft palate. It is a fact that in India, in almost all cases, a child after an operation is left to adjust for himself. There is no properly organized speech-clinic to help him to overcome his speech disabilities. In India such

cases are extremely difficult to handle if we remember that most of the patients have already formed bad habits of speaking through the nose before an operation takes place. With younger children the task is much easier.

Dr. Oldfield has rightly stressed the value of daily and systematic practice in corrective exercises under the guidance of a competent speech-trainer. He has, of course, invited the co-operation of the parents. But the matter is so highly technical that too much dependence upon the home will not bear any good result.

The main principle dealing with speech-correction of a case with a false palate lies in the exercise of the soft palate. The different games suggested by the author will enable such children to get the necessary exercise through games. For older patients such games will not, however, have any appeal. Besides the games suggested I would advise active and direct exercise of the soft palate by moving it and keeping it stationary to command.

The description of the speech sounds given by the author is very elementary and the reviewer is also rather sceptical as to how far the parents may be benefited by it.

The book is well printed and bound and has 38 illustrations.

Abstracts from Reports

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (UNIVERSITY OF LONDON) INCORPORATING THE ROSS INSTITUTE: REPORT ON THE WORK OF THE SCHOOL FOR THE YEAR 1936-37

THIS report has grown so much in size with the ever-increasing scope of this institution that now it is not possible to abstract it adequately in the space available. We have accordingly had to be content this year with quoting a few paragraphs from the general report of the Dean which give an outline of the more important work carried on at the London School.

A new departure is the issue of the report of the Ross Institute of Tropical Hygiene in the same volume. Hitherto this appeared as a separate report. Our abstract of this report is confined to a few passages from the work of this Institute which refers to the work in India only, but it should be recognized that similar work is being carried on by it in many other parts of the world.

The Medical Research Council have renewed the fellowship held by Professor Sir Rickard Christophers until September 1938, thereby enabling the board to maintain the malaria research unit in its present form for a further year. Another of the Medical Research Council's workers, Dr. T. Bedford, who last year was granted academic status as a lecturer in the School, has been recognized as a teacher of the University. We have welcomed the opportunity during the year of arranging a preliminary period of study for a junior fellow appointed under the Council's scheme for fostering research in tropical medicine through their Tropical Medicine Research Committee.

In July the Department of Scientific and Industrial Research offered to the School a substantial annual grant towards the cost of the researches in progress in Professor Raistrick's division on the biochemistry of moulds. The offer was gladly accepted, not only because it ensures the continuation of an important piece of work, but also because it establishes contacts which may be of the utmost value to the School.

The School was greatly honoured by the presence of the Right Hon. the Earl of Athlone, K.G., at a Reception held on Wednesday, 9th June, to commemorate Sir Patrick Manson and Sir Ronald Ross. A

collection of original notebooks and similar material relating to Manson and Ross was displayed, and members of the staff arranged an interesting series of exhibits illustrative of the work of various divisions. The School has been honoured during the year by visits from H.H. the Sultan of Selangor and the Maharaja of Darbhanga. Other visitors have included a party of scientists from South America (Professor Sordelli, Professor Eugenio Suarez, and Drs. Hormaeche and Gerardo Varela), who spent a week in the School in the course of their tour of Institutes of Hygiene.

A course on mental deficiency, designed to enable medical practitioners to secure recognition by the Board of Education as certifying officers under the Mental Deficiency Acts so far as elementary school children are concerned, was held in the School for the first time in February, with the co-operation of the Central Association for Mental Welfare. It was open to members of the public health class, and to other persons such as school medical officers employed by local authorities. All available places were filled. The course was an unqualified success, and it is hoped to repeat it in future years. The thanks of the School are due to the Central Association for Mental Welfare, particularly for their assistance in arranging the practical work of the course; and to the lecturers who assisted—Dr. Tredgold, Dr. Williams, Dr. May Smith, and Miss Fildes. Two new courses in psychology and physiology applied to industry have been sanctioned by the board and one, a short intensive course for persons already engaged in industry, will be held between 7th and 18th February, 1938. It is intended primarily for members of the supervisory staff of industrial firms, but it is hoped that it may be of interest also to probationary factory inspectors and post-graduate students in engineering. The other course will last a full academic year, and is designed for persons who desire to study some of the applications of psychology and physiology to industrial problems with a view to preparing themselves for appointments in connection with personnel management, welfare work or factory inspection.

The usual course on tropical hygiene for non-medical men and women was held in December, and the course for naval surgeons in January. A course for laymen on

the control of malaria was organized by the Ross Institute in June, and was attended by 113 persons, chiefly planters and mining engineers. One aspect of the co-operation between the Ross Institute and laymen in matters of health in the tropics is well illustrated by the fact that, in each of three years, this course has been attended by an average of considerably more than a hundred persons. The Trustees of the Pilgrim Trust in their annual report for 1936, in connection with the grant which they had made to the School in aid of special researches, referred to this side of the work of the Ross Institute in the following terms: 'Since 1933 the Ross Institute has been incorporated in the London School of Hygiene and Tropical Medicine (University of London), and its work at home as well as overseas has already offered striking illustrations of successful co-operation between scientist and layman through its Industrial Advisory Committee'.

Professor G. S. Wilson was a member of a group organized by the Health Section of the League of Nations to study the conditions governing the production and distribution of milk in the countries of Western Europe with a view to discovering how far it is possible to implement the recommendations of the League Nutrition Committee that more milk should be made available for infants and for other sections of the population. A report on the investigation is in the press, and will be issued as a League publication. In June Dr. G. P. Crowden attended a conference at Geneva organized by the League of Nations Commission on the hygiene of housing. With the assistance of a grant from the Board of Management, Dr. Hamilton Fairley and Mr. R. J. Bromfield spent six weeks during November and December studying blackwater fever in Macedonia. Dr. Fairley found blackwater fever to be remarkably prevalent, and he reports that Macedonia is a peculiarly favourable area for the study of this disease. His work has confirmed the presence of a new blood pigment in cases of blackwater fever, the discovery of which was mentioned in last year's report. Dr. V. B. Wigglesworth was enabled by the award of a Fellowship from the Rockefeller Foundation to spend six months working in the laboratory of Professor A. Krogh in Copenhagen; and Dr. A. E. Oxford spent some weeks in the laboratories of Professor Ph. Biorge at the Institut Carnoy, University of Louvain, Belgium. Dr. J. J. C. Buckley, Milner Research Fellow, has continued in the Malay States his investigations on the life history of onchocerciasis in cattle; and Dr. Alan Mozley, Wadsworth Scholar, began in January a survey of the molluscan carriers of bilharzia in East Africa. Dr. G. C. Ramsay, Principal of the India Branch of the Ross Institute, spent the greater part of the year in India; and Major H. Lockwood Stevens, Organizing Secretary of the Ross Institute, proceeded to India in order to explore the possibility of reorganizing and extending the India Branch. Dr. R. Svensson visited Nyasaland under the auspices of the Ross Institute, and in July he started on an extensive tour of West Africa in order to study the use of anti-larval oil in that area.

Dr. G. Carmichael Low, Senior Physician to the Hospital for Tropical Diseases, and Director of the Division of Clinical Tropical Medicine in the School, retired on 30th September, 1937. Dr. Carmichael Low joined the former London School of Tropical Medicine, which then occupied premises at the Albert Docks, in 1899, and he has been continuously associated since that date with the School of Tropical Medicine and with its successor, the present School. He will be greatly missed, and his colleagues hope that he may continue to enjoy a long period of fruitful activity.

The School has sustained a great loss in the death of Professor J. G. Thomson, a member of the staff of the old London School of Tropical Medicine since 1914, and Director of the Department of Protozoology in this School since its foundation. Professor Thomson's scientific attainments were everywhere recognized, and he had a great and well-deserved reputation as a teacher. No member of the staff was held in higher regard by the students.

Reports contributed by the heads of divisions and departments give an account of the teaching and research work undertaken in the School during the year. The joint researches of the Divisions of Bacteriology and Biochemistry have made satisfactory progress. Chemical fractions which appear to have effective immunizing powers have been isolated from the organisms of typhoid fever, of whooping cough, and of cholera, and from certain strains of hemolytic streptococci, and a point has been reached where the practical application of the results obtained with some of these organisms is within view. The work appears to be of the utmost importance, and indeed it is not too much to say that it will give a new direction to practice in relation to the whole group of infectious diseases. Collaborative work between the Divisions of Bacteriology and Epidemiology has been continued on experimental epidemics in mice. Experiments at present in progress are designed to study the effects of variations in the duration of exposure to risk. The work is linked with that of Dr. Marion Watson, who, with the assistance of a grant from the Medical Research Council, is studying the effect of diet on the fertility, survival, and growth of mice and on their resistance to infection.

Experiments with various diets have confirmed the previous finding that the resistance of mice to infection by *Bact. typhimurium* is influenced by the diet on which mice are bred and reared.

The report of the Department of Entomology includes an account of work on the biology of the bed-bug. The investigation is being financed by the Medical Research Council, who have appointed a committee to study the insect with a view to devising means of controlling it.

Among matters referred to in the report of the Division of Bacteriology may be mentioned a study carried out by Professor Wilson in collaboration with Dr. F. C. Minett, of the Royal Veterinary College, and Mr. H. F. Carling, of the Berks and Bucks Joint Sanatorium, on the relative value of raw and of pasteurized milk for the feeding of calves. The results suggest that pasteurized milk is not inferior in nutritive value to raw milk. Professor Wilson has been responsible during the year on behalf of the Ministry of Health for examining samples of methylene blue specially prepared for the purpose by Imperial Chemical Industries, Ltd., with a view to discovering how far the chemical and the biological methods of standardization are in agreement. The work has been undertaken in connection with the new methylene blue test for the grading of raw milk. Dr. I. M. Asheshov, working in the Division of Bacteriology with a grant from the Medical Research Council, has pursued his investigation of the effect of bacteriophage in experimental infections. His findings constitute the first clear demonstration that a bacteriophage may exert an effective protective action in an experimentally infected animal. Dr. Asheshov left the School in September on his appointment as Associate Professor of Bacteriology in the University of Western Ontario.

In the Division of Biochemistry research, which is of considerable industrial importance, has been continued on the biochemistry of the lower fungi. Dr. Lucy Wills, the holder of a Lady Tata Memorial Fellowship, has extended her studies in anæmia in collaboration with Dr. Clutterbuck. They have been able to separate a factor curative in nutritional macrocytic anæmia from the liver principle curative in pernicious anæmia, and have studied its chemical nature and its relation to the vitamin-B complex.

In the section of Industrial Physiology work, which is likely to be of considerable practical importance, has been carried out on an air-conditioned cubicle suitable for use in tropical bungalows. The cubicle, which is portable, is constructed of light-weight material effectively insulated and, with a small air-conditioning plant, is capable of reducing tropical temperatures and humidities to reasonably comfortable conditions.

The Institute of Agricultural Parasitology has continued, at Winches Farm, St. Albans, and elsewhere,

investigations on the prevention and treatment of helminth diseases: parasites of plants of economic importance, including potatoes, oats, tea; parasites of farm stock, of poultry and game, and of horses.

REPORT OF THE ROSS INSTITUTE OF TROPICAL HYGIENE

Since the publication of the last report, the Ross Institute Standing Committee has lost its Chairman and Vice-Chairman, Sir Austen Chamberlain and Sir Charles Campbell McLeod. The passing of these two great men was a loss not only to this Institution as a whole, but to the Empire. However great the calls from other quarters, they always found time to meet the members of the staff of the Institute, and their advice on our problems and difficulties was invaluable. This close contact has made their loss something very personal to the Institute.

Sir Harcourt Butler accepted the office of Vice-Chairman of the Standing Committee, and at his request the selection of a Chairman has been delayed for the time being.

During the year the Committee has been strengthened by two new members, Sir Thomas Stanton, Medical Adviser to the Colonial Office, and Sir John Megaw, Medical Adviser to the India Office.

The director was responsible for the course in tropical hygiene given to candidates for the Diploma in Tropical Medicine and Hygiene.

ROSS INSTITUTE IN INDIA

During the past year the Deputy Director, Dr. G. C. Ramsay, occupied himself, as usual, mainly with visiting tea estates in Northern India, but he also found time to visit a number of tea estates in Southern India, jute mills in Bengal, sugar factories in Bihar, cotton ginning factories in Sind, and a manganese mine in the Bombay Presidency. It is gratifying to record that in January 1937, Dr. G. C. Ramsay was created a Companion of the Indian Empire.

To place the work of the Ross Institute in India on a solid scientific foundation, the Ross Institute has financed, wholly or in part, and for longer or shorter periods, a number of field research stations. They have been placed under medical men engaged in estate practice. For their supervision, the Institute is specially indebted to Drs. D. Manson, G. Fraser, C. C. Hamilton in Northern India, and Dr. Measham in Southern India. The success of the work of the Ross Institute in India is to no small extent due to the valuable co-operation received from these and other medical men. Since the India Branch was formed, no fewer than 350 Indian malaria surveyors and laboratory workers have been trained at our centres, and absorbed in industry.

There are some 40 known anopheles in India, yet only a few are of economic importance. In Northern Bengal and Assam, the only malaria-carrying mosquito of importance is *A. minimus*, which lives in slow running water. In the jute mill areas near Calcutta, the harmful mosquito is *A. philippinensis*, which breeds in tanks. In Bihar *A. culicifacies*, which breeds in pools, is the principal carrier of malaria. In Southern India *A. fluviatilis*, which breeds in the grassy edges of hill streams, is the important carrier of malaria in the higher malarial areas, up to say 3,000 feet. But at 1,000 feet *A. culicifacies*, breeding in pools, in river beds, has been found infected in numbers great enough to make its control a necessity. Investigation is being carried on in eight different centres, and in time it is hoped the problem may be clearly defined. It will then be possible to control malaria with certainty and at a minimum cost. Fortunately both *A. minimus* and *A. fluviatilis* can be controlled by preserving jungle or growing shade, methods which are inexpensive and permanent.

It has been felt for some time that the Ross Institute in India should have a larger staff so as to ensure one man being available at all times. In order to see how far Indian industry, which has not hesitated to ask assistance, would be prepared to finance an extension of the staff and work of the Ross Institute and place

it on a permanent basis, Major H. Lockwood Stevens visited India and interviewed the heads of many of the leading firms in Calcutta and Bombay. Although most of the heads of firms had changed since he was last in India, his visit was welcomed, and the discussions helped to define the position. The plan suggested received so much favourable support that there is reasonable hope that the remaining difficulties will be overcome once a permanent Ross Institute Committee has been created in Calcutta.

BENGAL ANTI-MALARIA CO-OPERATIVE SOCIETIES

The excellent work which is being done in villages in Bengal under the pioneer of the movement, Rai Dr. G. C. Chatterjee Bahadur, has been mentioned in previous reports. During his visit to India, Major Lockwood Stevens had an opportunity of revisiting some villages in Bengal where the society is operating, and of having several discussions with Dr. Chatterjee. Major Stevens also presided at the Annual General Meeting of the Societies in Calcutta, held on 24th January, 1937. The late Sir Charles McLeod presided on two occasions at the Annual Meeting, as also has Sir Malcolm Watson. Sir Ronald Ross himself attended the Annual General Meeting in 1926.

The result of fostering interest in the prevention of malaria in villages by the Societies has been general uplift of the village community, and it has led to the development of small holdings to such an extent that compared with a few years ago the whole outlook of some villages has changed. At Sukchar, a few miles from Calcutta, Dr. Chatterjee maintains a model farm in which he demonstrates the control of mosquitoes in village tanks by breeding fish for food, and the conversion of all waste products into manure by a simple process of composting. He also shows how a large family can be maintained on a relatively small garden. In teaching the villagers he shows that the prevention of malaria in rural areas, village uplift, rural sanitation, and agriculture naturally go hand in hand.

The thanks and appreciation of all members of the Societies are due to Dr. A. N. Mitra, Assistant Secretary of the central body, who has helped Dr. Chatterjee for many years. In the Director's opinion, work such as Dr. Chatterjee has stimulated in Bengal is one of the methods by which the rural problems of India could be solved.

The Director has renewed pleasure in recording the happy relationship that exists between the Calcutta School of Tropical Medicine and the Institute. Not only have we collaborated and so avoided overlapping of work, but it has been suggested that accommodation will be made available for our staff in India to make its headquarters in the School. Various members of the staff have had the pleasure of seeing Colonel Chopra, Director of the Calcutta School, on several occasions when he has been on leave; the discussions have been of the most cordial kind, and animated by a keen desire that each and every department of the two Schools should work together and give each other every possible help. It is hardly necessary to stress the value of co-operation between these two bodies in their work for the welfare of India.

ANNUAL REPORT OF THE DIRECTOR OF THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH FOR THE YEAR ENDED 31ST DECEMBER, 1936

THE past year has been one of more than usual activity, with the result that several departments are finding increasing difficulty in carrying on their work in the space at their disposal, and no relief is possible in the present buildings.

DEPARTMENT OF BACTERIOLOGY

Pneumonia.—The bacteriology and epidemiology of pneumonia and other allied acute respiratory diseases occurring in local mine natives are the subjects of continuous study. As a result of these investigations, the pneumonia vaccine issued for prophylactic purposes

comprises the prevailing bacterial flora on the Witwatersrand. Each mine desiring to employ the prophylactic vaccine is studied as a separate entity to ensure the provision of a representative 'community autogenous vaccine' for that particular mining community of natives. It was found this year, however, that the bacterial divergences in the various communities were not sufficiently marked to warrant the issue of special and separate vaccines. The general vaccine as issued has been sufficiently comprehensive for the purpose.

The use of prophylactic pneumonia vaccine is increasing on the mines, and a number of satisfactory results continue to be recorded.

Opportunity was taken of their presence in Johannesburg to examine a number of Bushmen who were brought to the Empire Exhibition; the bacterial flora of a number of these people, who were suffering from minor respiratory maladies, was investigated. No unusual finding was recorded.

Pneumococcus infection in Europeans and non-mining natives.—In addition to the work on mine natives, a study was made of the pneumococcus type distribution in the European population as well as in the non-mining natives. The specimens examined in this connexion were derived from sufferers from the various forms of pneumonia as well as from pneumococcus infections other than pneumonia. This pneumococcus type survey is being continued.

Pneumococcus meningitis.—Specimens of cerebro-spinal fluid in cases of pneumococcus meningitis, both in Europeans and natives, provided a relatively large number of specimens submitted for special study. These were investigated from the pneumococcus type-distribution point of view. From sixty specimens of cerebro-spinal fluid in cases of pneumococcus meningitis, the pneumococcus was recovered and typed, 43.3 per cent of the pneumococci belonged to Groups 'C', 'B' and 'E' (= types I, II and III), and 56.7 per cent to other groups.

Typing of the pneumococcus.—The 'Quellung' phenomenon is now being utilized for identifying the different types. By this means a rapid 'pneumococcus-typing service' for clinicians is now provided, a service which is being used by an increasing number of medical men who have cases of pneumonia in their care.

Streptococcus studies.—The question of the streptococcus types occurring locally has been given much consideration. A considerable number of strains of the hemolytic streptococcus isolated from a variety of human sources have been typed, and all have been shown to belong Lancefield's group 'A'.

Cerebro-spinal meningitis and the meningococcus.—A study has been made this year of meningococcus meningitis from the bacteriological standpoint. A portion of every specimen of cerebro-spinal fluid received for routine examination at the Institute is diverted to these laboratories for special investigation.

Strains of the meningococcus are now being typed under another system. This has been done to simplify the classification of the meningococcus with its ill-defined type-divisions. The simple agglutination test has been substituted for the more laborious agglutination-absorption test, which for many years was carried out in these laboratories. This latter test has not, in recent years, been found to give the more clear-cut results which were at one time obtained. The more complicated test, therefore, does not seem to be warranted any longer. This curious change in the meningococcus has been also noted in other countries where the question has been studied.

The relation of the meningococcus strains to therapeutic serum production is of considerable importance to the Institute serum department and much careful study has been undertaken in collaboration with that department in the selection of suitable organisms to provide the most adequate antigen for the preparation of an antigenically comprehensive polyvalent anti-serum in horses. These efforts have been justified, as,

at present, the anti-meningococcus serum produced is satisfactory in its agglutinating power against meningococcus strains isolated from current cases of the disease; but more important, the case-mortality rate in cerebro-spinal meningitis locally has shown a significant drop.

Plague.—A noteworthy feature in the plague position is an apparently steady diminution in the virulence of the strains of *B. pestis* obtained from both human and animal sources. One line of evidence pointing in this direction is as follows: All positive results are originally obtained either by guinea-pig inoculation or by culture from material received; these are checked by guinea-pig scarification; a few years ago such guinea-pigs usually died in from five to seven days, now they usually live ten or twelve days before succumbing to the disease or, not infrequently, they survive and recover, after development of a bubo, but without further spread of the disease.

South African strains have never been obtained with a virulence equal to that of some Indian strains, of which it has been reported that a dose of less than 100 organisms is regularly fatal for rats in three days, nevertheless, until a couple of years ago, almost any local strain could be counted upon to be fatal for a rat within that period in a dose of about five million organisms. Now few strains are ever fatal in such a dose and none are regularly so.

It might be thought that recently increased resistance in the local rate was the key to the loss of virulence, but the easy explanation of postulating increased resistance in the rats cannot be accounted for by race immunity through infection, because there has never been plague amongst the rats of Johannesburg which have been used throughout for test purposes here.

Tuberculosis.—What part does infection with bovine tubercle bacilli play here in the production of tuberculosis in human beings?

In attempting to answer this question by the identification of the type of tubercle bacilli present in tissues or discharges, an appeal has been made to practitioners throughout the Union to send material from suitable sources for investigation. As infection with bovine strains of bacilli is most commonly met with in young subjects and in gland, bone or joint tuberculosis rather than in pulmonary tuberculosis, material from such sources has been mainly solicited. The response to the appeal has not been as large as had been hoped for.

So far, the investigation is entirely negative as regards indication of infection of human beings from bovine sources. The number of cases is, however, too small to be of any great significance.

DEPARTMENT OF INDUSTRIAL HYGIENE

Dust from the lungs and mass distribution of particles.—The recovery of dust from the lungs of those who have been exposed to the underground air-borne dust of the Witwatersrand gold-field has been continued. No advanced cases have been studied, and those dealt with fall into three types: (1) Early clinical silicosis; (2) Fibrosis of silicotic type found on examination of lungs after autopsy; (3) No evidence of silicosis either during life or after autopsy.

When there is simple silicosis there is a relation between the mass of dust recovered and the amount of fibrosis. As great a mass of dust may be recovered from lungs showing no evidence of silicosis as from lungs showing a mild clinical silicosis. In the absence of silicosis there is no obvious relation between duration of exposure and mass of dust recovered. One cannot but be impressed by the experience that, over a considerable number of cases, one finds a relation between the mass of dust recovered and the amount of damage done to the lungs.

It is possible that overmuch importance is being attached to the ultra-small particle, say, particles of 0.8 microns and less which contribute the main number of the particles in the air-borne dust. The requirements for an index of dust-hazard are determined by physiological criteria and not by deductions based on physical and chemical characters or by the results of

experiments on animals secured under conditions remote from those experienced underground. It is our experience on the Witwatersrand that a reduction in the mass of the air-borne dust, a mass chiefly contributed by particles of round about 2 microns, is associated with a fall in the dust-hazard. Our gravimetric sampling, which takes no account of ultra-small particles, and our konimeter sampling, which take but little account of them, yet appear to afford a tolerable assay of our dust-hazard. Present experience suggests that if we had only ultra-small particles in their present concentration in our underground air, there would be very little silicosis, and what there was would take a long time in the making and be almost confined to the particularly susceptible subjects.

It has been the experience of the Miners' Phthisis Medical Bureau that 'susceptibility' is related rather to an infective element coming into play early than to special sensitivity to dust invasion.

BIOCHEMICAL DEPARTMENT

The inquiry into native edible plants has been continued, and though the number of new specimens received has been far less than in the previous year, it included a few of considerable interest. Most of the plants have now been identified, and progress is being made with the preparation of a detailed report.

At the present time there is a widespread impression that vitamins are very delicate substances, and are almost totally destroyed when a foodstuff is cooked.

Our own conclusions, based mainly on work done in this laboratory, are as follows:—It is known that the effect of heat in itself on solutions of ascorbic acid in distilled water, even after 15 minutes' boiling, is comparatively small, but contact with iron or copper salts leads to considerable destruction even in the cold. This is probably one reason why finely chopped raw green leaves may lose so much of their activity, even without any cooking at all, if they are allowed to stand.

It was found that even under the best conditions of cooking, very considerable losses of activity may occur when green vegetables are allowed to stand before being consumed; this loss is presumably due to atmospheric oxidation and to the destructive action of the metals already referred to.

The practical conclusions to be drawn from all this are that when it is desired to conserve antiscorbutic activity, green vegetables should be cooked in the minimum of water or preferably steamed, potatoes should be cooked in their jackets, aluminium or enamelled ware should be used in preference to copper or iron, and cooked and even raw vegetables should not be allowed to stand for longer than is absolutely necessary before being served. Pressure cooking was also found to be destructive of ascorbic acid.

The unavailability and expense of fresh clean milk in certain areas of this country, more especially during the dry season, led us to consider whether any possible alternatives might be available. Soya bean 'milk' has attracted a considerable amount of attention in some countries, but it seems unlikely that it would attain much popularity here. Experiments made with a view to utilizing commercial quality dried milk powders met with fair success, the difficulty, of course, being to secure satisfactory emulsification; it was concluded that quite a satisfactory and nourishing drink can be made from this source at a cost, when supplied in bulk, approximating to half that of fresh milk. The liquid replaces milk in cooking, and preliminary reports of its use by several authorities who agreed to give it a trial have been favourable. It is not, of course, claimed that such a product is the equal of clean fresh milk, but it is certainly palatable, safe and inexpensive, whilst the nutritional value still remains at a high level.

[The work of the Pathological Research Department appears to have been occupied in experimental cancer research.]

DEPARTMENT OF ENTOMOLOGY

Further evidence on the effect of anti-adult measures on salivary infection rates in mosquitoes.—The lack of

vectors and comparative absence of malaria during the season 1935-1936 has prevented a continuation of experiments on the effect of anti-adult measures in the control of malaria. In the extreme north of Zululand, however, an area was found with some malaria, and it was decided to test the effect of spraying on glandular infections in *Anopheles gambiae* and *A. funestus*. No control work had been done here before. The area was divided into two parts, one half was sprayed with an insecticide three times a week for one month and then five times a week for another two months; the other half was left as a control. The two areas were some five miles apart, but intervening huts did exist and there was undoubtedly some over-flow of infected insects into the treated area.

The results of infections in the two areas for the period March-May were as follows:—

		UNTREATED AREA		TREATED AREA	
		Number dissected	Glandular infections	Number dissected	Glandular infections
<i>gambiae</i>	..	372	19	130	1
<i>funestus</i>	..	594	12	268	4

It is to be noted that all the infected insects in the treated zone came from the extreme boundary of the area where overflow from the untreated area presumably took place. No infected insects were ever found on the opposite boundary beyond which there were no huts at all. Taking these facts into consideration, the results are encouraging.

Carry-over of malaria from season to season in Natal and Zululand.—The question of the carry-over of malaria from one season to another is of some importance. It is quite possible that measures founded on a sound knowledge of what happens during the off-season may conceivably reduce the chances of infection in summer.

From information so far gathered it is concluded that there is probably a complete cessation of mosquito-borne malaria in winter in purely *gambiae* areas and that malaria is carried over from one season to another in the human host. A very low infection rate amongst *gambiae* in winter is not to be entirely discounted. Lack of material sent in for dissection prevents us from being definite on this point.

Mosquito infections.—*Funestus* has been found infected all the year round as in the Transvaal.

Spleen rates.—These are relatively much higher at the end of winter. Moreover, it is possible to show that children near the breeding places have a higher rate than those living away from streams and rivers. From these considerations it is obvious that there is active mosquito-borne malaria in winter in *funestus* areas.

ANNUAL REPORT ON THE CIVIL HOSPITALS AND DISPENSARIES IN THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1936. BY LIEUT.-COL. J. M. R. HENNESSY, I.M.S., OFFG. INSPECTOR-GENERAL

At the close of the year 1935 there were actually 338 hospitals and dispensaries at work, and not 339 as wrongly shown in last year's statement. During the year under report, seven dispensaries were opened, four closed and one transferred, leaving 340—164 rural and 176 urban—dispensaries at work on the 31st December, 1936.

Taking into account the number of dispensaries at which the public ask for free attendance, the average

area covered by a dispensary comes to 467 [476]* square miles while the average population works out to 72,466 [73,846]*. Classifying the figures further into urban and rural areas, the average population served by a dispensary comes to 15,990 and 126,869, respectively. These figures speak for themselves about the inadequacy of medical relief, especially in rural areas in the province. Financial depression, however, precludes the possibility of undertaking schemes for opening new dispensaries, and, as stated by my predecessor in last year's report, unless the condition of raising a local contribution of Rs. 8,500 on account of endowment fund and half building charges is relaxed, no substantial progress is possible.

Mayo hospital.—The comments on the general condition of the hospital buildings and other necessities made in the last year's report still hold good. The entire institution requires re-building and enlarging to bring it up to modern standards. Necessary proposals have already been submitted and are under the consideration of Government.

Schemes financed from the Government of India grant for rural development.—During the year 1935-36 a sum of Rs. 15,000 was allotted for cheap-plan dispensary buildings in villages. The schemes sanctioned amounted to Rs. 14,750 and they include cheap-plan dispensaries at Atnair and Mohita in the Betul district, Kurkheda and Bhamragarh in the Chanda district, and Mounda in the Nagpur district. The scheme for the opening of the dispensary at Mohita was sanctioned after the close of the year under report. The expenditure generally represents non-recurring grants to the district councils to meet half of the cost of construction of these cheap-plan dispensary buildings.

The total number of patients treated, both in- and out-door, stands at 3,332,292 [3,107,107], showing an increase of 225,185 over the past year. The increase is noticed in all the districts excepting Mandla, Hoshangabad, Nimar and Raipur. Of the total number treated, 3,210,934 [3,024,565] were treated in the general hospitals and dispensaries and 91,308 [82,542] in the female hospitals. The above statistics of attendance and work done in the medical institution referred to give further indication of the growing appreciation by the public of their activities.

The number of cases treated for malaria during the year showed an increase of 97,950 over the figure of the past year and the increase was noticed in all the districts, excepting Jubbulpore and Nimar. The other diseases showing an increase over the figures of the past year were chiefly as follows:—

Diseases of the ear (18,196), diseases of the eye (17,318), diseases of the teeth and gums, excluding tumours (15,585), diseases of the respiratory system other than pneumonia and tuberculosis (15,522), diseases of the intestines, excluding diarrhoea, dysentery and tumours (11,366), diarrhoea (9,758), diseases of nervous system (9,740), pyrexia of uncertain origin and other diseases due to infection (9,166), injuries, general and local (8,663), amoebic dysentery (5,971) and scabies (5,803).

The number of cases treated for smallpox during the year was 460 [462], of which 105 were vaccinated, 170 not vaccinated, while the vaccinal condition of the remainder was not known.

Deputy Commissioners comment on the progressive reduction and unpunctual payment of contributions by local bodies. The Commissioner, Nagpur Division, states that he agrees to the suggestion made by the Deputy Commissioner, Wardha, that it should be made obligatory on local bodies to devote a certain percentage of their income to medical relief and that a contribution once fixed for a local hospital should not be varied without the sanction of Government.

Anti-rabic treatment was carried out as usual at the six existing centres at Nagpur, Jubbulpore, Raipur, Saugor, Hoshangabad and Akola and a new centre was opened at the Main Hospital, Wardha. The number of patients treated at all these centres during the year

was 1,564 [1,730]*. The local Government was also pleased to sanction the opening of an anti-rabic treatment centre at Chhindwara which is expected to start functioning shortly.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF THE CITY OF RANGOON FOR THE YEAR 1936

CLIMATIC conditions throughout the year were more or less the same as in previous years with the exception of rainfall which was the highest for the last 30 years. The city was comparatively free from infectious or notifiable diseases when compared with the previous year. There were 232 deaths from these diseases against 425 in the previous year and against the average of 469 deaths from such diseases for the last ten years. The position in regard to cholera, plague and smallpox was satisfactory. There were only 18 deaths from cholera which accounted for 69 deaths during the previous year, the average number of deaths for the last ten years being 49. Two deaths from cholera occurred amongst the imported cases. Similarly the number of deaths from smallpox was only 21 as compared with 172 deaths in the previous year and the average of 142 deaths for the last ten years. The number of deaths that occurred from smallpox in imported cases was 8. The incidence of plague continued to be low—14 during the year under review. There were 17 deaths from plague during the year 1935, the average number of deaths during the last ten years being 90. One death from plague occurred amongst cases imported from outside.

There was no mortality from measles or chicken-pox, 123 cases of the former and 699 cases of the latter having been reported during the year as against 295 and 1,150 respectively during the previous year.

The number of deaths from cerebro-spinal fever was 5 as against 6 of the previous year, the average number of deaths during the last ten years being 5.

Sixty-two deaths were attributable to enteric fever as against 49 in the previous year, the average for the last ten years being 64. The number of persons attacked with this disease during the year was 183 as against 186 in 1935.

Diphtheria and puerperal septicæmia accounted for 14 deaths and 12 deaths as against 7 and 23 respectively during the previous year.

There were no deaths from typhus fever, 7 cases having been reported during the year as compared with 16 during the last year. Malarial fever caused 81 deaths as against 80 deaths in 1935.

The number of deaths from diarrhoea and dysentery increased from 444 in 1935 to 669 during the year under report, the average number of deaths from these diseases during the last ten years being 783.

The number of persons attacked with epidemic dropsy (including beri-beri) was 199 as against 610 during the last year. There were 86 deaths from these diseases during the year as compared with 81 during the previous year.

Tuberculosis continued to exact a heavy toll of mortality in the city, the number of deaths having increased from 952 in the previous year to 1,115 during the year under report, the average number of deaths during the last ten years being 873. The Buddhist community suffered the most, the Hindus and Mohammedans were the next and the Christians the last.

The decrease in the number of persons suffering from tuberculosis with rising incomes when considered with the facts as disclosed by the examination of the profession or occupation of those dying from tuberculosis is too significant to allow the effects of poverty and lack of nutrition to be ignored in any scheme that may be promoted for checking the ravages of this disease. The peak of the mortality curve of phthisis in Rangoon was reached in the year 1925. The years 1926 to 1930, which were marked by a downward trend, seem to coincide with the period when there were increased

* Figures in square brackets refer to previous year.

* Figures in square brackets refer to previous year.

opportunities for employment. The mortality curve has been again rising from 1931 and this coincides with the period of depression and unemployment. It,

concerned. The following table illustrates the point better and shows how the death-rate fluctuates near this hypothetical standard:—

	1932	1933	1934	1935	1936
Calcutta	25.0	29.4	28.7	28.5	31.0
Bombay	19.7	23.4	23.6	25.2	25.8
Madras	34.4	37.9	36.6	38.6	36.5
Colombo	24.6	27.1	28.6	29.9	27.2
Singapore	20.12	19.66	20.99	23.10	23.55
Rangoon	24.66	22.11	23.66	25.14	25.64
Burma (urban)	28.85	27.22	30.03	30.18	30.81

therefore, appears that the growth of anti-tuberculosis institutions (dispensaries, hospitals and sanatoria) alone will not completely solve the problem of tuberculosis in Rangoon unless at the same time the social and economic aspects of the disease receive attention. An anti-tuberculosis society or association has long been overdue in Rangoon and it is earnestly hoped that public sympathy and charity will not long allow the postponement of the day when such a society comes into being.

The total number of deaths during the year increased by 198, there being 10,265 deaths during the year under report as compared with 10,067 deaths in the previous year. The death-rate was 25.64 as against 25.14 in the year 1935. The most important causes that contributed towards the rise of the death-rate were tuberculosis (+ 163), diarrhoea and dysentery (+ 225) and diseases of the respiratory system (+ 84).

Some of the foregoing remarks with regard to tuberculosis apply with equal force to respiratory diseases. Exposure and failure to have proper treatment in the early stages were additional factors in the causation of higher death-rate from these diseases. The increase in the number of deaths from diarrhoea and dysentery was to some extent attributable to the abnormal rainfall during last year. As death-rate is generally regarded as the criterion of the state of health of a community or locality, some comment with regard to the factors influencing it will not be out of place here.

Many cities in the East, particularly those in India and Burma, were, during the early part of this century, marked by a high death-rate chiefly owing to the prevalence of such dangerous diseases as smallpox, plague, cholera, malaria, diarrhoea and dysentery in epidemic forms. With the introduction of sanitary measures and the organization of public health services, the fall in death-rate has been phenomenal in some towns, chiefly those which happened to be situated at the gateways of trade and commerce, as the diseases already mentioned loomed large in the death returns and were definitely preventable. In Rangoon the death-rate came down from 47.57 per 1,000 in the year 1906 to 22.11 in 1933, the number of deaths from cholera having decreased from 330 in 1907 to 3 in 1932. Similarly, the number of deaths from plague decreased from 2,974 in 1906 to 9 in 1933. Although there have been periodic visitations of smallpox, the number of deaths in the various epidemics has been low. The epidemic of 1906 caused 1,035 deaths whereas the average number of deaths during the last five years was 155 and during the last year there were only 21. The number of deaths from diarrhoea and dysentery declined from 1,494 in 1908 to 444 last year. It will thus be seen that most of the diseases which accounted for a large number of deaths have been brought under control; at any rate the mortality they now cause is so low as hardly to have any appreciable influence on the death-rate which in port towns may be said to have reached a standard about which it will keep on fluctuating. This standard will naturally vary in different towns depending upon the climatic conditions, racial predisposition, composition and density of population, and economic status of the people

It will be seen that in spite of more attention being paid to public health matters in these places there has been a tendency for the death-rate to rise, thereby suggesting that there are some general factors operating all over these places such as trade depression, unemployment, malnutrition and lowered resistance to disease. This uniformity in the rise of death-rate at such distant places would be hard to explain on the theory of local causes alone.

With the control or elimination of the dangerous diseases that were responsible for a large number of deaths, by improvement in environmental sanitation, it appears that future reduction in death-rate to any marked extent can only be brought about by paying more attention to the social side of preventive medicine as envisaged in the maternity and child-welfare schemes, school hygiene and nutrition of the school child, anti-tuberculosis organizations for the relief of sufferers from tuberculosis, promotion of social hygiene, housing schemes particularly for labourers and working people, improved milk supply, the care of the aged and the unemployed, birth-control clinics, practical eugenic policy and sterilization of the mentally defective. Extension of water supply and underground sewerage system to the outlying parts and the closure of rubbish tips in the city will in their turn bring about improvement when these respective schemes come to fruition.

The infantile mortality rate (243.02) was lower than that of the last year (251.35) and was in fact the lowest on record. The mortality amongst the infants under the care of lady health visitors was 145.66 in spite of the fact that their activities were confined to those parts of the town where the standard of sanitation is low and the people poor. This indicates that the scope of maternity and infant welfare work can be profitably extended to those parts of the town not at present served by the health visitors.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER OF THE CITY OF BOMBAY FOR 1936

THE number of live births registered during the year was more by 5,971 than the number of deaths that took place in the city. This excess of births over deaths was equivalent to 5.1 per 1,000 population calculated on the census of 1931 and was recorded six times in succession. Before 1931 there was no such excess since 1866, the year in which birth records were instituted.

The number of live births registered was 35,905 being 1,477 more than in 1935 and 9,856 more than the average of the last ten years 1926-1935 and the highest on record since 1866. The birth-rate calculated on the census population of 1931 was 30.9 births per 1,000.

The total number of deaths from all causes was 29,934 being 645 more than in 1935, 3,575 more than the average of the last five years (1931-1935) and 2,650 more than that of the preceding decennium (1926-35). The death-rate per 1,000 of census population of 1931 was 25.8 as against 25.2 in 1935 and 22.2 the rate recorded for the decennium 1926-1935.

There were only two deaths from plague during the year as against 1 in 1935 and 72 the average of the last ten years (1926-1935).

Smallpox was in epidemic form and caused 906 deaths as against 1,248 in 1935 and 913, the average of the last decennium (1926-1935).

Cholera was registered as the cause of five deaths (including three imported) against 13 in 1935 and 25 less than the average of the ten years 1926-1935.

Influenza was prevalent in a mild form in the city during the year and caused 71 deaths as against 72 in the preceding year and 84 the average of the last decennium (1926-1935).

The deaths from diseases of the respiratory system numbered 10,601 being 40 less than in 1935 and 726 more than the average of the last ten years (1926-1935).

Tuberculosis accounted for 1,993 deaths as against 1,929 in 1935 and 1,667 the average of the preceding decennium (1926-1935).

Ninety-one deaths were due to malaria, being six less than in 1935 and 127 less than the average of the last decennium (1926-1935). There were 1,332 deaths from ague and remittent fever as against 1,389 in 1935. The average number of deaths for the last ten years (1926-1935) from malaria was 218 and from ague and remittent fever 1,474.

The deaths among infants under one year of age numbered 8,946 against 8,455 in 1935 and 7,598 the average for the last ten years (1926-1935). The rate of infant deaths per 1,000 births registered was 249.1 as against 291.7 the mean of the preceding decennium.

Compared with the decennial average (1926-1935) the total number of deaths shows an increase of 2,650, the principal increase in the mortality being 726 under respiratory diseases, 601 under congenital debility and diseases of early infancy, 326 under tuberculosis, 202 under cerebro-spinal fever, 160 under diseases of the nervous system, 106 under enteric fever, 72 under dysentery, 54 under diarrhoea and enteritis and 44 under deaths due to violence.

On the other hand there was a decrease in the deaths under ague and remittent fever by 142, under malarial fever by 127, under plague by 70, under leprosy by 54, under puerperal state by 31, under cholera by 25 and under influenza by 13.

PREVENTION OF INFANTILE MORTALITY

The work which is being done in Bombay for the reduction of infant mortality may be described under the following heads:—

(i) Visits by the municipal district nurses for the purpose of getting into touch with prospective mothers and for discovering cases of sickness especially among women and children and unvaccinated children; for enquiry into the condition of new-born infants; and for giving instructions by homely talks as to the care and rearing of children.

(ii) Attendance on confinements.

(iii) Provision of necessaries and comforts during the lying-in period.

(iv) Maternity homes.

(v) Infant welfare centres and infant milk depôts.

Municipal nurses.—The number of municipal nurses employed is ten, one being attached to each of the ten district registrars' offices. They visit daily the localities and the chawls inhabited by the poor and help to diffuse and popularize elementary knowledge of the principles of health and hygiene and to carry such knowledge into the homes and lives of the ignorant; they give advice on the prevention of disease and the care and up-bringing of infants and bring to the notice of the authorities unregistered births, unvaccinated children and cases of sickness; they also persuade prospective mothers to go to the maternity homes provided for them free. Where this provision is not taken advantage of, they attend on the women in their own houses providing them with bedding for their confinement, and with food in shape of milk and bread during the first seven days of the puerperal period. The visits of the nurses are frequently the

means of bringing to the municipal dispensaries sick persons who would otherwise either not know the existence of the facilities provided or knowing would, through indifference and apathy, neglect to benefit by them. These visits are doing much good and are welcomed and appreciated by those for whose benefit they are paid.

THE ANTI-TUBERCULOSIS MEASURES

There are two special tuberculosis dispensaries for out-patients—one at the Sanitary Institute, Princess Street, and the other at 143, Foras Road.

The Turner Sanatorium at Bhoiwada Hill, Parel, has accommodation for 32 patients. Only early cases are admitted to this institution.

Each dispensary is in charge of a qualified tuberculosis officer, with a fully-trained nurse working under his direction. In addition to her duties at the dispensary, the nurse visits the homes of patients attending the dispensary and reports on the following form which is subsequently attached to the patient's case sheet:—

		Good	Fair	Bad
HOUSE	Situation ..			
	General condition ..			
	Ventilation ..			
		Male	Female	Children
FAMILY	Number ..			
	State of health ..			
	Previous deaths ..			
PATIENT	Living ..			
	Diet ..			
	Habits ..			

Income of the household.

Number of inmates dependent on the patient.

During her domiciliary visits, the nurse distributes printed propaganda leaflets and advises patients and their relatives about ventilation, diet, clothing and general sanitation. The 'contacts' are brought to the dispensary for examination. Their record is entered on a special printed 'contact card'. The investigation of contacts is one of the most important functions of the dispensary.

STEGOMYIA INDEX

Routine work of the malaria branch is not only confined to the control of anopheline variety of mosquitoes but it also devotes its attention to the breeding of all varieties of mosquitoes in the city. Since the commencement of the department, the record of breeding places of anopheline mosquitoes has been maintained throughout. No such record was kept in respect of other varieties until recently when on account of the importance of *Aedes aegypti* which is known to be the carrier of yellow fever a regular record of the breeding places of this variety of mosquito has been kept since June 1936. The stegomyia index which was found to be 0.1 in the beginning of June, reached its maximum which is 0.5 in the month of August and gradually declined and came to 0.03 by the end of December 1936. Thus the index is below 2 per cent which is the standard considered by the Government of India to be sufficient to ensure safety against an epidemic of yellow fever. It will be noticed that the breeding of stegomyia increases during the monsoon partly owing to the favourable conditions and partly on account of the increase in the number of temporary breeding places due to the collection of water in odd receptacles, in open yards, etc.

REPORT OF THE HAFKINE INSTITUTE, BOMBAY, FOR THE YEAR 1936. By LIEUT.-COL. S. S. SOKHEY, I.M.S., DIRECTOR

General review

The institute continued to function during the year as (a) the centre for the manufacture of plague vaccine for the whole of India and of other prophylactic

vaccines for the Presidency, (b) the Provincial Bacteriological Laboratory for the Bombay Presidency, (c) the centre for the manufacture of anti-rabic vaccine for Bombay Presidency and adjoining areas and treatment centres for Bombay city, and (d) a centre for research in plague and pharmacology were carried out with the generous assistance of the Indian Research Fund Association.

The demand for plague vaccine dropped somewhat during the year; 881,054 doses (i.e., 2,643,162 c.c.) were issued as compared with 1,017,044 doses during the previous year. The lowered demand happily is due to lessened incidence of the disease, and not to any falling off in the popularity of the vaccine as a prophylactic measure. There were 23,873 attacks of plague in 1936 against 41,042 attacks in 1935. The demand for the vaccine continues to be high in relation to the incidence of plague.

The outbreak of cholera in the Presidency necessitated heavy demands on the institute for the supply of cholera vaccine and put a serious strain on the reduced staff. 705,621 doses of the vaccine were issued during the year. In addition, 16,381 doses of meningococcal vaccine and 5,746 doses of typhoid vaccine were issued.

The supply of reliable sera to Government hospitals at moderate prices has been a problem demanding solution for some time. About the middle of the year, the institute was called upon to undertake this supply. To meet the immediate needs, the institute has been fortunate enough in obtaining sera at very moderate prices from one of the leading serum institutes—State Serum Institute of Copenhagen. To keep the costs down still further sera are obtained in bulk and bottled at the institute. The problem can be met finally only by the institute producing its own sera. The matter is under investigation.

PLAQUE RESEARCHES

Plague vaccine.—Using his standardized quantitative method for measuring the virulence of the plague bacillus and his method for measuring the protective value of plague vaccines, Sokhey continued the researches on plague vaccine. The work has yielded some very interesting results. After confirming, by further work, his previous observation that broth vaccines incubated at 27°C. are more potent than those incubated at 37°C., he proceeded to investigate the problem as it affects agar vaccines. He finds that agar vaccines incubated at 37°C. are more potent than agar vaccines incubated at 27°C. He points out that the difference to a large extent is only apparent. Certain observations have led him to believe that the potency of a vaccine depends largely on the number of organisms and their size, i.e., the bulk of organisms, in a vaccine. In the case of broth, the growth of organisms is self-limited, and the growth of the plague bacillus at 37°C. is much less than at 27°C. In the case of agar vaccines the number of organisms are varied at will and in all the experiments reported here the agar vaccines had equal numbers of organisms. But the size of the organism at 37°C. is larger than at 27°C. He does not think that the presence or absence of capsular material affects the issue, because Sokhey and Maurice have been able to show by staining that the capsule is present even when organisms are incubated at as low a temperature as 5°C.

Comparison of live avirulent vaccines and heat-killed vaccines has also yielded interesting results. In the case of broth vaccines, heat-killed vaccines incubated at 27°C. have proved to be more potent than live avirulent vaccines incubated at 27°C. or at 37°C. but in the case of agar vaccines, live avirulent vaccines incubated at 37°C. have proved to be much more potent than heat-killed vaccines. It is, however, to be noted that the order of potency of the best live avirulent agar vaccine incubated at 27°C. is the same as that of the heat-killed broth vaccines incubated at 27°C.

The study of the effect of the method of killing of cultures on the potency of the resultant vaccines has produced results of biological significance besides providing indications of great practical value. Here

broth and agar vaccines behave exactly alike and the temperature of incubation is the important factor. In the case of vaccines incubated at 27°C. the best results are obtained when killing is done by the application of heat at 55°C. for 15 minutes. Such a vaccine is about twice as potent as a vaccine killed by the addition of phenol (0.5 per cent) without the application of heat and about four times as good as a vaccine killed by the addition of formalin (0.025 per cent). Killing by the application of heat at 60°C. for one hour reduces the potency of the resultant vaccine to about $\frac{1}{4}$ th of the potency of the vaccine killed at 55°C. for 15 minutes. The extraordinary phenomenon is that if the cultures are incubated at 37°C., the method of killing does not affect the potency of the resultant vaccines. This phenomenon is being studied further for a possible explanation. Indications are that the state of the bacterial protein is responsible for this phenomenon. When cultures are incubated at 27°C., the bacterial protein, in solution or otherwise, is still largely in a coagulable form, but when the cultures are incubated at 37°C., the protein breaks up into a form in which it is no longer easily coagulable. But if this process of breaking up goes further, as in the case of lysis with bacteriophage, it loses its antigenic property entirely, as was shown in the last report.

These are observations of considerable theoretical and practical significance and indicate further experimental work to finally decide the method of obtaining the most potent plague vaccine. It will be noticed that Sokhey has not been able to compare broth vaccines directly with agar vaccines, as he has not yet successfully solved the problem of measuring the bacterial content of a broth vaccine, because during the long period of incubation organisms continue to go into solution. However, from the practical point of view, such a comparison is perhaps not necessary. The question of a vaccine having the greatest possible protective power and the minimum of toxicity. This work offers hope of a final solution of the problem.

The work already indicates that when vaccines are made by growing the organisms in broth, whether a virulent strain of organisms is used or an avirulent one, whether the growths are incubated at 27°C. or 37°C. and whether the growths are killed by the application of heat (55°C. for 15 minutes), or by the addition of phenol (0.5 per cent) or by the addition of formalin (0.025 per cent) or by the addition of the best and the worst vaccine tends to be low, 1 to 7.5 (0.002 c.c. to 0.015 c.c.). But when the vaccines are made from growths on agar, and the same strains, the same temperatures of incubation and the same methods of killing are employed as in the case of broth vaccines, the difference between the best vaccine and the worst tends to be high, 1 to 100 (0.001 c.c. to 1 c.c.), and the best agar vaccine is not much better than the best broth vaccine. The issue will be decided by a measurement of toxicity of the vaccines.

This work raises another issue of interest, that is, the relationship between the serological reactions and the phenomenon of active immunity. Schutze, by serological studies, came to the conclusions that the incubation of plague cultures at 37°C. produced an antigen which was more readily effected by incubation at 27°C. Measurement of active immunity by the biological method shows that incubation of cultures at 37°C. produces more heat-stable vaccines than incubation at 27°C. In the case of cultures of killing, i.e., 27°C., 5°C. rise in the temperature of the resultant vaccine to 60°C., reduces the potency of the killing temperature does not affect at all the vaccines incubated at 37°C. Preliminary experiments show that a vaccine made from a culture incubated at 37°C. even when heated at 100°C. for one hour retains considerable protective power.

The view that 'no dead vaccine whatever conferred satisfactory protection on guinea-pigs and wild rats'

has also been investigated by Sokhey. He finds that this view also arose from defective experimental work and that heat-killed vaccines do confer a very high degree of immunity on those animals. Using a heat-killed vaccine, he has found that very high protection in the case of the guinea-pig, the wild rat and the white rat can be obtained with doses of 0.01 c.c., 0.025 c.c., and 0.025 c.c. respectively, and that even these doses are not the minimum protective doses, which, it appears, will be still smaller.

Anti-plague serum.—Work has been continued and the use of better methods of immunization has resulted in the production of a serum twice as potent as the serum produced last year which gave such encouraging results in the field test at the beginning of the year. Opportunity is awaited to test this new serum in the field.

Epidemiology of plague.—Pandemic of plague separated by four centuries or so is a well authenticated phenomenon. These pandemics have ravaged the world, have smouldered here and there for long or short periods and have then come to an end, as they started, of natural causes. The explanation of this phenomenon has always intrigued observers, but no adequate explanation has been forthcoming. The susceptibility of rats to plague was rightly believed to be an important factor, but no exact measurements could be made for lack of the knowledge necessary to prepare a constant standardized infective dose of plague for suitable laboratory experiments. The success at evolving a constant infective dose for the purpose and the present comparatively quiescent period after a severe pandemic in India offered a suitable opportunity of studying the phenomenon.

The results already reported have clearly indicated that the rats in localities where serious epidemics have raged are highly resistant to plague infection. In fact the resistance of the rats seems to be roughly proportional to the intensity of the epidemic of the locality. This resistance can be attributed to several factors. It has been believed that even when plague among human beings has come to an end in a particular locality, the disease continues to smoulder among rats and this continued mild epizootic gives the rats high resistance to plague. But the daily examination of a large number of rats caught in the city of Bombay has shown that this explanation is not correct. For the last two years, no rats have been found in the city that showed any signs of infection, yet the rat population of Bombay is very highly resistant. The other hypothesis was that rats during an epidemic in a locality acquired immunity and transmitted it to their young. Sokhey has investigated this phenomenon by using white mice. This animal has no natural resistance to plague and the young born to parents which had been fully protected against plague showed no immunity, indicating that acquired immunity is not transmitted.

During their observations, Sokhey and Chitre obtained rats from Dharamsala, a hill station in the Himalayas, where plague has not been known to have occurred during the present pandemic. Some of the rats obtained from this place showed high resistance to plague, indicating that there exist in nature strains of rats which are naturally immune or resistant to plague. The probable explanation of the end of an epidemic in a locality would seem to be that all or most of the susceptible strains of rats die out leaving behind naturally resistant strains. How do fresh pandemics or epidemics start? During the year these workers have made one observation which throws some light on this problem. During this investigation they worked entirely with the house rat (*Rattus rattus*) as it had been observed that this species of rat was the one chiefly responsible for the spread of plague to human beings. However, some workers had observed that in some localities the small field rat (*Gunomys varius*) had been responsible for the spread of the disease. Therefore a batch of *Gunomys varius* obtained from the city of Bombay was examined, and they were surprised to find that this species of rats was highly susceptible though the Bombay *Rattus rattus* was

highly resistant. This observation is of great significance. If and when this species of rat becomes more numerous or replaces the house rat in human habitations, the stage would be set for a fresh epidemic. These workers consider it highly desirable that this question should be studied further. The fact cannot be overstressed that the phenomenon of plague is not yet fully understood and the present time is the most suitable one for further study. It is a comparatively quiescent period after a severe pandemic with just a few cases of plague here and there. These factors make the present period an ideal one for further study and any expenditure that may be incurred would be well worth it.

DEPARTMENT OF PHARMACOLOGY

During the year the department has been responsible for important research work. New synthetic anti-malarials have been in use for the treatment of malaria for some time. Plasmoquine was the first of these and though a large number of papers describing the clinical use of plasmoquine have been published, a complete study of the pharmacology of the drug had not been made. Dikshit investigated the pharmacological action of this drug and described the effects produced on different organs of the body after administration of large doses to experimental animals. His results show that plasmoquine affects most of the systems of the body but more particularly the circulatory and the digestive systems. The important action is the formation of methæmoglobin which leads to cyanosis and fatty degeneration of the liver. These actions are produced by administration of toxic doses of the drug.

As in the case of quinine, treatment of malaria during pregnancy by plasmoquine has raised a certain amount of controversy. Dikshit undertook to investigate this problem and his preliminary results tend to show that plasmoquine does not produce abortion in experimental animals, even when given in doses which are considerably higher than those used in therapeutics. It appears from his studies that, as far as continuation of pregnancy is concerned, plasmoquine would not in any way interrupt the normal course.

In view of the intended enactment of the necessary legislation for the control of the sale and manufacture of drugs, in India, the department has been making arrangements for the biological assay of drugs. Standards maintained at the National Institute for Medical Research, Hampstead, have been obtained and from them standards have been established for the institute. Some samples of tincture of digitalis were examined during the year. One sample was only 25 per cent of the standard strength. A sample of tincture of strophanthus examined had a potency of only 1/10th of what it should possess.

The department is still on a temporary basis and is maintained by the Indian Research Fund Association. The value to the Presidency of such a department cannot be overstated and it is hoped Government will find means to put it on a permanent basis.

DEPARTMENT OF BIOCHEMISTRY

The department continued to be of value both to the workers in the institute for chemical aid in their work as well as to practitioners and hospitals for the examination of clinical material. In addition, the department has continued to work on establishing the normal clinical standards for Indians and is now engaged on nutritional research work.

DIAGNOSTIC DEPARTMENT AND DEPARTMENT OF PUBLIC HEALTH CHEMISTRY AND BACTERIOLOGY

As some of the city hospitals are now well equipped with their own laboratories, these departments are entrusted only with the work that they cannot carry out. Though the work is considerably less than before, these departments are still proving of great value. During the year the department examined over 8,000 specimens sent by hospitals and dispensaries and of these examinations for Wassermann reaction were 4,000.

ANTI-RABIC DEPARTMENT

Since the Anti-rabic Department was opened in 1922, the popularity of the anti-rabic treatment has grown and in keeping with the policy of making the treatment freely available to the public there are now 69 treatment centres in the Presidency. Five of these were opened during the year. In 1922, 243 treatments were issued to the out-centres and 429 persons were fully treated at this institute, while during 1936, 5,259 treatments were issued to the out-stations and 2,331 persons were fully treated at the institute. All this has meant enormously increased work which has now grown beyond the capacity of the present staff.

A TIME LIMIT FOR USING BACTERIOPHAGES

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Various laboratories in Calcutta are nowadays manufacturing bacteriophages for use in bowel diseases especially. Some foreign made are also available. The time limit for their use is very puzzling. Majority put two years as their time limit for use whereas two do not put any date at all, with the idea that their products can be used with benefit, after any length of time. Considering the mean average temperature of India, and also the manner in which they are stocked (they are not stocked in refrigerators), I think in some cases the bacteriophages are liable to deteriorate and lose their potency, before the time limit of two years. An independent test done by me entirely corroborates the report, published by Major Pasricha and others on this subject, that some preparations lose their potency before the time limit (*I. M. G.*, November 1937). I think, to the interest of the medical profession, the dates should be put in such a way as to maintain the maximum potency up to that time, and, moreover, it is wholly unscientific to declare that bacteriophages remain active and potent for years together, whatever may be the condition in which they are kept. Colonel Morrison was of opinion that 12 months should be the maximum length of time up to which the phages remain potent, if kept in cold storage. I shall be highly obliged if research workers on this line can throw light as to what should be the maximum time limit for use of bacteriophages in India; also whether it is scientific at all to believe that bacteriophages may be used after any length of time.

Yours, etc.,

A. N. SEN, M.B.,
Bacteriophage Worker,
The Lister Antiseptic and Dressings
Company (1928), Limited.

P. O. COSSIPORE,
CALCUTTA,
2nd July, 1938.

Notes

MAINTENANCE OF HEALTH

HOW TO PREVENT MOST ILLNESSES IN CHILDREN

ALTHOUGH scientific research has given the world effective cures for almost every illness the old proverb, 'Prevention is better than cure', is still as weighty as it ever was—especially in regard to children's ailments. For it is in the immature stages of the growth of the human body that the foundation of future health and success is laid.

It is a medical fact that a great percentage of children's illnesses is due to constipation and could be prevented by ensuring complete and regular bowel

movement. When their bowels are acting properly, clearing the system of all poisonous waste, children are at their best in health and spirits.

It is also a fact, however, that this happy state of affairs cannot be achieved by harsh purgatives. They act once or twice and then leave the bowels more bound than ever. What is indeed a gentle liquid laxative—California Syrup of Figs, for example—which sets up a natural movement and results in a thorough internal cleansing, doses being diminished when the bowels begin to act properly. Such a laxative is perfectly safe, for it is composed solely of carefully selected vegetable extracts with ripe fruit juice.

'ULERON'

HAVERO TRADING COMPANY, LIMITED, the sole representatives of 'Bayer' Laboratories at Elberfeld, Germany, beg to announce to the profession that Disseptal some time ago referred to in British medical papers is now introduced in India under the trade name 'Uleron'. It is the first successful chemotherapeutic against gonococcal infections. Up to date clinical results show that its curative action is best seen in sub-acute and chronic gonorrhoea and its complications, i.e., when the patient has developed a certain amount of specific resistance. A course of treatment lasts for 3 to 4 days only and has been found sufficient in a large percentage of cases. Only in resistant cases is a second course of treatment necessary after an interval of at least 6 to 8 days. Relapses are comparatively very few. Such a short course of treatment with a very high percentage of successful results in a disease which has so far baffled all kinds of treatment is a unique achievement indeed.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A STUDY OF THE ANTI-TUBERCULOSIS ACTIVITIES IN THE WEST, WITH SOME SUGGESTIONS FOR THE CAMPAIGN AGAINST TUBERCULOSIS IN INDIA

By C. FRIMODT-MÖLLER, C.B.E. (Hon.), M.B.,
ch.B. (Copenhagen)

*Medical Superintendent, Union Mission Tuberculosis
Sanatorium, Arogyavaram, near Madanapalle,
South India*

IN thinking about the campaign against tuberculosis in India, one is almost paralysed by the immensity of the task that lies ahead, by the ignorance of so many factors concerning the disease, the number of problems which have to be solved, and the lack of resources for carrying out the work. So overwhelming is the task that one is nearly tempted to let things take their own course, and do nothing, except to treat the individual patients seeking help. Yet, if the doctors, who are to a large extent the guardians of the health of the nation, do not take a lead in such a campaign, it will be a vain effort, and the situation will be the worse for its failure, even apart from the disease increasing.

Few doctors in India have had the opportunity to study and see in person the anti-tuberculosis activities in the west, and a review of these is, therefore, now called for, as it would be very unwise to start a campaign, leaving out of account the experiences gained in the west during the last fifty years.

I. THE VARIOUS ANTI-TUBERCULOSIS ACTIVITIES IN THE WEST AND THEIR CORRELATION

It is of great interest that the anti-tuberculosis activities were begun differently in different countries in the west, while the measures now in force form a more or less uniform scheme in all of them.

In several countries in Europe, the activities began by establishing sanatoria, as in Germany, Denmark, Norway, Sweden and Finland. In France, the emphasis was laid on the establishment of tuberculosis clinics. In England, the modern activities began also by establishment of sanatoria, in addition to a considerable number of special hospitals for tuberculous patients, some existing from a time as far back as 1791, but mostly established in the middle of the nineteenth century. In Scotland, the activities began with the establishment of tuberculosis clinics and open-air hospitals and sanatoria.

(a) *The emphasis on tuberculosis clinics*

In no country in the west was the campaign against tuberculosis begun with such an em-

phasis on tuberculosis clinics as in France. The first anti-tuberculosis measure which was deliberately introduced in that country was the tuberculosis clinic advocated in 1896 by Calmette (Hazemann, 1936). Six years later he opened the first tuberculosis clinic in Lille where he worked, and he strongly advocated the establishment of similar clinics in each important centre in France. The object of these clinics was to carry out anti-tuberculosis education, to give advice concerning prophylaxis and hygiene, to see disinfection carried out in houses rendered unhealthy by patients, and to arrange free consultation and distribution of medicines for patients without means. The establishment of these clinics took place at such a speed that by the end of 1905 there were no less than 62 in France, of which about half the number were in or near Paris (Kayne, 1937). The facilities for institutional treatment, however, were up to 1914 only ten publicly supported sanatoria with a total of 862 beds. Then came the war, and the enormous number of soldiers invalided with tuberculosis aroused France. An act was passed in 1916 establishing clinics all over the country, and in 1919 another act was passed establishing sanatoria and the maintenance of patients in them. The result of these efforts was that in 1934 France, with a population of 42 millions, had 821 clinics, 156 sanatoria, 19 hospital sanatoria, 54 seaside sanatoria and 214 preventoria, with a total number of 71,632 beds set aside for treatment of tuberculous patients (Hazemann, 1936). This number is far greater than the corresponding figures for England and Wales, although France has only about 5 million more people than England. In England and Wales, in 1934, there were 478 clinics and 587 residential institutions with 28,900 beds. The tuberculosis death-rate in France in 1934 was 151 per 100,000 population, and in England and Wales only 76. The tuberculosis mortality for the age period of 20 to 39 years was in 1927 in France, double that of England and Wales (Hazemann, 1936).

In 1935, eight Departments in France, including Paris, the Lower Seine and the whole of Brittany, had a tuberculosis death-rate of over 200 per 100,000, a figure not seen in Great Britain in the last 30 years (*B.M.J.*, 1936). Although during the last decade France has had less unemployment and better economic conditions than other countries, yet the tuberculosis death-rate in Paris in 1930 was more than double that in London and more than three times that in New York. Paris still continues to have more deaths from tuberculosis than any other of the great cities in Europe (*B.M.J.*, 1932). May this state of affairs in France not be due to some extent to the emphasis in the beginning of the campaign on clinics as an isolated measure, without correlating them with facilities for institutional treatment? Rather late in the campaign, they are now certainly trying to remedy this.

(b) *The emphasis on institutional treatment*

It would probably be a serious exaggeration to attribute to certain anti-tuberculosis measures the whole decline of tuberculosis in a country, but it cannot be overlooked or minimized that in those countries in the west where from the very beginning of the campaign the emphasis was laid on the importance of facilities for institutional treatment of the disease, the tuberculosis death-rate has declined most.

Long before any other country had dreamt of anti-tuberculosis activities, England had already introduced a considerable amount of institutional facilities for treatment of poor tuberculous patients.

The decline in the death-rate from tuberculosis in England began about 1840 and has since steadily been going on, but it is more marked after the period 1860-70. In Ireland, from about 1865, there was a steady increase in the death-rate from tuberculosis which continued until after 1900. This difference in regard to the tuberculosis death-rate during the same period has been explained by Newsholme (Faber, 1926) by the fact that from 1860-70 the pauper consumptives in England were advised treatment in special hospitals, while in Ireland they were treated in their own homes by public support.

It is doubtful whether this explanation of Newsholme covers the whole cause of the decline in England and the simultaneous increase of the tuberculosis death-rate in Ireland. But an interesting calculation concerning the fall of the death-rate has been made by Crockett (1934) who draws attention to the fact that the countries with tuberculosis death-rate ranging from 46 to 90 per 100,000 of population have an average of 0.97 beds per death—beds provided for the treatment of the disease—those with medium death-rates ranging from 91 to 133 have an average of 0.40 beds per death, while those countries with death-rates ranging from 161 to 199 have an average of 0.20 beds per death. Of the countries in Europe in 1932, the extremes were Denmark with a death-rate of 72 per 100,000 and 107 beds per 100,000 population, and 1.50 bed per death, and Portugal with a death-rate of 199, and 35 beds per 100,000, and 0.18 beds per death.

(c) *The emphasis on a co-ordinated scheme*

In Scotland, from the very beginning of the campaign, the emphasis was laid on the clinic and open-air hospitals and sanatoria. In Edinburgh, Sir Robert Philip established in 1887 the first tuberculosis dispensary in the world, and worked out the so-called 'Edinburgh system' of combating tuberculosis. It is very significant that from the first days of the campaign Sir Robert emphasized that the clinic was to be considered only as a link in a chain of measures of which institutional treatment was a very important part. The Victoria hospital

for consumptives in Edinburgh was at the very beginning established as a part of the scheme. In 1906, Sir Robert Philip expressed 'The Dispensary Ideal' as follows: 'The tuberculosis dispensary should be, for every city or district, the uniting point of all agencies. It should not be an isolated institution, but form an integral part, indeed *the centre of a great network of operations*' (Philip, 1937) (the italics are Sir Robert's). Later, in 1908, he stated that 'the dispensary cannot afford to be an isolated institution. Its strength and success will depend, first, on the thoroughness of its internal organization, and, secondly, on the closeness of its relationship with other institutions concerned in the prevention and treatment of tuberculosis (Philip, 1937).

The result of this has been a correlated, well-planned campaign with which practically all countries in the west have now fallen into line. While in France in 1913 there were only very few facilities for institutional treatment in connection with the tuberculosis clinics, there were in Scotland at that time, per 100,000 of the population, not less than 44 beds available, which in 1932 had been increased to 104 (in France, to 67). In 1932, Scotland was second highest of all countries in Europe in tuberculosis beds per 100,000 population, and also second highest in beds per annual tuberculosis deaths. Denmark was leading, while England and Wales were behind Scotland in both respects by a large margin (Kayne, 1937). The mortality from tuberculosis in Scotland in 1875, shortly before the campaign began, was 361 per 100,000, while in 1936 it had fallen to 74. During the thirty-five years previous to 1933, the mortality from tuberculosis had, in England and Wales, been reduced by 56 per cent, and in Scotland by 64 per cent (Philip, 1937).

While the campaign in Germany and the Scandinavian countries began with the sanatorium movement, they have since seen the absolute necessity of combining this measure with the clinic system and other measures later adopted. Some of the most efficient clinics are now found in Germany, Norway and Denmark.

(d) *Colonies for ex-patients and village settlements*

It did not take many years after the introduction of the anti-tuberculosis activities mentioned, before it was found necessary to add to them other measures. Already, in 1904, Sir Robert Philip began to advocate the establishment of tuberculosis colonies, specially for patients leaving sanatoria, but not yet able to return to ordinary occupations, without fear of relapse of the disease.

The pioneer institution in England in this line is the Papworth Village Settlement established in 1916 by Sir Pendrill Varrier-Jones.

Few movements have been more misunderstood than 'village settlements' and 'ex-patients' colonies'. Many would think of them

as colonies in village style, where some poor patients can settle down and earn their living by gardening or other light outdoor occupations. Papworth is, however, quite a different thing. In considering the nature of service rendered at Papworth and the needs which require to be fulfilled, Sir Pendrill writes (Papworth: Annual Report, 1936): 'First and foremost, there is prolonged medical and surgical treatment. . . . Prolonged treatment—so different from the sanatorium treatment of 25 years ago—may include surgical interference'. Another description which reveals the thorough treatment at Papworth is given by Brieger (1937) who writes: 'The medical services of the village settlement are developed from the hospitals; and it may be divided for purposes of description into the following units: ante-natal, ophthalmic, dental, ear, nose and throat, orthopaedic, collapse therapy, two radiological units, the psychology unit, and industrial physiology (research) unit. The research units are developed into the following departments: bacteriological and pathological and biochemical'.

Papworth is a complete institution beginning with a hospital section of 180 beds fully equipped with operating theatres, laboratory and research departments, going on to a sanatorium section with 137 beds, then a hostel section with 155 beds, and ending with a village section of 120 cottages and factories equipped with modern machinery run on competitive business lines. Only carefully selected ex-patients from their own or other institutions, who have had full experience of institutional treatment, are admitted to the village to continue to live there, because only such ex-patients have learnt, by the regime of sanatorium treatment, the limitations of their physical health and discipline of mind and will necessary to live, work and thrive in a colony.

(e) Care and after-care organizations

In the modern anti-tuberculosis activities, in some countries in the west, there have not only been established colonies for ex-patients, but there have also been added other organizations for the after-care of tuberculous patients, and even organizations for the care of dependent relatives, before and during the institutional treatment of the patients. In recent years there has rightly been a general tendency to lay special emphasis on the care and after-care as one of the most important of the anti-tuberculosis activities in connection with the clinics.

The main objects of the care and after-care organization are: (1) helping patients to take advantage of institutional treatment by enabling a sick bread-winner to secure food or clothing for his family from charitable or public bodies during his absence for treatment; (2) assisting patients, when they cease to have institutional treatment, to find suitable work and occupation which will not produce relapse of the disease; (3) assisting in the prevention of the spread of

the disease both within the home and from the home, as, for instance, by removing young children from the infected home or by arranging for a separate sleeping place for the patient, and by improving the sanitary conditions of the home.

(f) Tuberculosis surveys

One of the most important developments in the campaign against tuberculosis in the west is the modern extensive surveys carried out by various skin tests for tuberculosis and by x-ray examinations. In addition to dealing with patients and contacts of patients, the modern clinic has developed a wider field of work and is examining whole groups of people and communities, such as students in colleges and schools, special professions and occupations, and age groups, in order to weed out from among them the non-clinical yet frequently infectious persons, and to detect those who ultimately would break down and only seek medical help when the disease was fairly advanced. The following is an example of the type of work. Among 1,180 medical students in Copenhagen, who were positive reactors to the skin test, 19 were found to be suffering from various forms of tuberculosis, and 12 of these from pulmonary tuberculosis, all of them feeling absolutely fit and healthy. In 5 of the 12 with lung disease, tubercle bacilli were found in the sputum, and in 2 more in the water from a stomach lavage (Holm and Helweg-Larsen, 1938). Through such surveys the spread of the disease has been found to be very different in different communities and occupations, and in different areas and age groups. The whole epidemiology of the disease is now far better understood, and the spread of the disease has been studied in relation to many of the factors which might influence this spread. These surveys have widened the activities and usefulness of the tuberculosis clinic and have given it a new significance and brought it still further to occupy a foremost position in preventive work against tuberculosis.

(g) Research work bearing on the campaign

In connection with the campaign against tuberculosis in the west, there has been and still is, in increasing measure, a great deal of research work going on about factors influencing the spread of the disease. It is impossible here to go into much detail about this research work, but some of the important lines may be mentioned.

(i) *Acquired immunity*.—One of the problems is to what extent is acquired or induced immunity a factor to be considered in practice with regard to prevention of the disease. Skin tests among nurses and medical students in many places have shown that without doubt a positive skin test can be interpreted as a sign of effective immunity against later exogenous infection with tuberculosis (Heimbeck, 1938). The result

is that, in several countries in Europe, probationary nurses and medical students who react negatively to tuberculin are being prohibited from working in the wards for tuberculous patients only, unless they have been first vaccinated with B. C. G. vaccine.

On the other hand, in South Africa it has been found that among the negroes coming for work to the mines in the Rand, those who react positively to tuberculin develop tuberculous disease much more than the negative reactors (Wilcocks, 1935). So, a positive reaction among these negroes is certainly not a sign of effective immunity. Cummins (1935) explains this by saying that the negroes are in a child-like stage, living a very primitive life, without contact with tuberculous infection. They are, therefore, so susceptible to the tubercle bacillus, that—to use his own words—‘the mere fact of latent infection, as revealed by tuberculin tests, has for African adults the same rather sinister significance as it has for infants and young children in this country (i.e., England), and sounds a note of warning that any undue stress or intercurrent illness may determine generalization of the disease’.

This experience shows it is not always possible to transfer conclusions arrived at in Europe to other parts of the world and build on them without finding whether they hold good for those parts.

(ii) *Virgin soil*.—The conception of ‘virgin soil’ which was so prominent a few years ago is being considerably modified, as research, again among the African, has shown that when tuberculosis is introduced among negroes living in their natural surroundings, it does not appear as a rapid epidemic, but has a slow propagation, as in a village in England (Cummins, 1929). But when tuberculosis is introduced among negroes living out of their natural environment and under conditions of stress or strain, it appears rather like an epidemic disease with enormous mortality, as seen, for instance, among the non-European South African troops serving in France during the war, where the incidence of tuberculosis was fifteen times greater than among the British troops serving in the same area, and with a death-rate of 56.0 per cent of the former sick against 5.7 per cent of British troops. This has its bearing on the spread of tuberculosis in towns whose population is largely drawn from people coming temporarily from the villages to live under completely new and trying surroundings.

(iii) *Race susceptibility*.—As regards the relationship between race and susceptibility to tuberculosis, recent investigation points to a lower natural resistance in coloured races to the disease, as judged by the different and more dangerous type of tuberculosis found in them, as compared with what is found in the western races.

(iv) *Inheritance*.—The question of direct inheritance of tuberculosis has been found to be

of no consequence with regard to the spread of the disease. Hereditary disposition to the disease in a family is still under discussion. It has been found to be direct infection of the children after birth from parents with open tuberculosis, which has given rise to the theory of inheritance. Removal of children from such homes has, specially in France, become one of the great measures in the prevention of tuberculosis, as well as vaccination with B. C. G. vaccine of such children; over one million children have been vaccinated in France.

(v) *House infection*.—As regards the question of house infection, it has now been proved that it is not the house which is infectious, but the infection comes only from the tuberculous person living in the house. As soon as he is removed, the house ceases to be dangerous.

(vi) *Climate*.—The question of the influence of climatic conditions on the incidence of tuberculosis and on the tuberculous person is complicated.

It has been frequently demonstrated that excessive heat and exposure to rain-bearing winds are detrimental. It is not humidity nor elevation in themselves which have great influence. Many of the sanatoria in Great Britain and Denmark and elsewhere are situated on the sea-coast and have as good results as those situated inland or in the high mountains in Switzerland.

Good climatic conditions are no protection against the spread of tuberculosis, as, for example, in many of the sunny southern European towns, such as Athens, Seville and Lisbon, the tuberculosis mortality is even five to ten times greater than in towns situated in less favourable climatic conditions in the northern countries (Morland, 1936).

(vii) *Poverty and malnutrition*.—The question of the influence of poverty on the development of tuberculosis is not so simple a question as one would naturally believe, and its influence has undoubtedly been much exaggerated. If poverty were one of the chief factors in causing an increase in the tuberculosis mortality-rate, why is it that this mortality-rate never declined so much and so rapidly in Germany as during the years after the Great War when there was an unprecedented period of poverty and unemployment (Frölich and Overland, 1932). In 1932, Germany had 15 million of its 64½ million people living on the dole or other forms of public relief, and even this was severely cut in that year. Yet the death-rate from tuberculosis, which was considerably higher than in England before the war, drew level with it in 1926 and in 1928 actually crossed it, the figure for England and Wales being 91, and for Germany 88 (Royal Institute of Public Health, 1933).

In spite of the prolonged economic depression, the death-rate from tuberculosis in New York during 1931 was the lowest recorded there up to that time (Wynne, 1932). An investigation in Norway draws attention to the fact that the

spread of tuberculosis in the area surveyed seemed not to have any relationship to economic, sanitary and dwelling conditions (Lunde, 1933).

It has often been pointed out how the mortality-rate from tuberculosis increased in all countries engaged in the Great War during the time food shortage was very marked. It is, however, a question whether the shortage that had the effect on the tuberculosis mortality-rate was not rather a shortage of the right kind of food, than a shortage of quantity of food.

It cannot be doubted that malnutrition is of great importance in relation to the development of tuberculosis. A very striking proof of this is supplied by an investigation among soldiers in Norway (Overland, 1937). In Trondheim, the soldiers who were called up for long service lived in small lodgings in the town, and a high incidence of tuberculous disease was found among them. To remedy this, a modern barracks was built in 1911. To the greatest surprise it was found that the incidence of the disease among the soldiers now living under the best hygienic conditions, increased, instead of decreased. In 1925 the diet was changed, according to the modern experiences of nutrition, and in the four-year period from 1925 to 1928, the incidence of tuberculosis fell from 6 per cent to about a $\frac{1}{2}$ per cent.

That tuberculosis is more prevalent in the slums than in other places is no proof that poverty as such, and not malnutrition, under these circumstances, is the most important factor. A recent investigation in England in a crowded area has shown a relationship between tuberculosis and undernourishment, as judged by deficient dietary (Hart, 1937).

If the increase in tuberculosis is due more to malnutrition than to poverty, it might be possible that a campaign for the right choice of food without increase, or only a little increase in the cost, would have a far greater effect on the decline of tuberculosis than a raising of the general standard of living and an improvement in the hygienic conditions which are tasks far more difficult to tackle.

II. SUGGESTIONS FOR THE CAMPAIGN IN INDIA

(a) *The present position in India*

Turning to India, the prevalence of tuberculosis is something about which we can say nothing definite. Megaw (Jolly, 1936) says that there are probably over 2,000,000 cases of tuberculosis in India, while Ukil (1938) estimates that there are about 1,000,000 in Bengal alone. Lankester (1920) stated that there were more than 10,000 cases of active tuberculosis in Bombay city, and there are good reasons to believe other cities are equally infected.

Sir Leonard Rogers (1925) writes that post-mortem examinations in the Medical College Hospitals, Calcutta, show a higher mortality in Calcutta from tuberculosis than from any of the so-called tropical diseases. One thing is certain, however, and that is, that tuberculosis

is exceedingly widespread in India, and, moreover, is increasing and spreading, specially with improved communications, to previously comparatively isolated areas.

In spite of the paucity of our knowledge about the prevalence of tuberculosis in India, our knowledge is more than sufficient to make us see the absolute necessity of seriously tackling what is a menace to the whole country, a danger from which no class or community, high-born or low-born, rich or poor, is protected. To meet the attack of this enemy, it is necessary to pool the resources of the whole country, the means at the disposal of the Government, and the means at the disposal of private societies and individuals. The situation is so serious that only the united efforts of all can hope to be able to make any headway against the disease.

(b) *The existing anti-tuberculosis activities in India*

In the past there has been but little organized effort to deal with the tuberculosis problem as a whole; the anti-tuberculosis activities that there have been, have been mostly isolated efforts, either Government or private, which have resulted in the treatment of a comparatively few sick individuals. The facilities for institutional treatment, when we consider the size and population in India, are practically nothing, there being only about 2,000 beds for tuberculous patients in about twenty sanatoria and in various hospitals, for the whole of the Indian Empire. If the people of India should have the same opportunity for institutional treatment of tuberculous patients, as, for example, the people in Scotland, there should be not 2,000 beds, but 390,000, that is, one bed for every 900 of the population.

In addition to the sanatoria and hospitals mentioned above, there have been in some of the main cities tuberculosis clinics, but their work has been terribly handicapped by there being no place to which they could send patients found to be in urgent need of institutional treatment. Nevertheless, the need for and the usefulness of clinics in India has been amply demonstrated.

Such institutions as there are in India for the treatment of tuberculosis have not materially influenced the situation as regards tuberculosis in general nor could they be expected to do so. But apart from their treatment of individual patients, they have abundantly justified their existence by showing what can be done in the treatment of tuberculosis. In those institutions where the modern treatment of tuberculosis is carried out in all its aspects, this treatment, both immediate and in its after-results, has been found to be equal to that in the west.

(c) *The situation in India in the light of the campaign in the west*

In India, we now stand where tuberculosis workers stood in England and other western

countries thirty to fifty years ago, and we cannot expect in a year or two to be in the position that those countries are in now, after nearly half a century of careful thinking, painstaking research, much hard toil and enormous expenditure of money. But, we do have the advantage that we can begin our campaign in India with the experience of all that has been found most useful in the west before us, and we need not make the same mistakes as have been made in the west in the earlier phases of the campaign.

From what has been said in the earlier part of this paper, it will have been seen that, although different countries began their campaign with emphasis on different measures, all have tended to adopt a more or less uniform scheme, combining all the various measures duly co-ordinated. Although this is so, a wholesale transference of all the links of the western co-ordinated scheme for the whole of India is, of course, at present totally out of the question. The general poverty of the country, the shortage of specially trained tuberculosis doctors and other tuberculosis workers, the absence of health insurance schemes and other social schemes for helping the sick, the absence of voluntary or compulsory notification of tuberculosis, all stand in the way.

Moreover, no scheme, however perfect, will work, if imposed without the good-will and co-operation of a people who will be willing, even at sacrifice to themselves, to bear the burden of such a scheme. Such good-will and co-operation can only follow a thorough education of the public from childhood upwards in the dangers, problems and measures associated with the disease which is such a menace to all.

On the other hand, even if we could introduce all the links of any western scheme into India, it is not at all certain that it would be right to do so. It might be wiser, for instance, to emphasize a particular part of the scheme at the beginning of the campaign and at the same time have in mind the necessity for changing the emphasis later, as the campaign advanced, than to try to introduce all parts of the scheme at the same time and weaken the whole campaign by overtraining it.

(d) *The tuberculosis clinic in India*

In the present conditions in the west, as already described in the paragraphs dealing with the emphasis on tuberculosis clinics, care and after-care organizations, and tuberculosis surveys in Europe, the tuberculosis clinic has come to occupy a very important place as the connecting link in the various measures of the whole campaign. In order to be better able to understand the position of the tuberculosis clinic in India, it may be worth while to amplify a little some of the various activities of the modern tuberculosis clinic in the west. It is not only a clearing house for detecting and passing on patients to treatment institutions, but, by its

work among family and other contacts in close co-operation with the private practitioners, it is more and more coming not only to detect the disease in those who have already detected it in themselves and have sought help at the clinic, but also to detect the disease in what is called the pre-clinical stage. Further, by its survey work, it is finding out some of the more dangerous sources of infection, namely, apparently healthy persons, themselves unaware of their sickness and living a normal life and doing their work, and yet spreading infection widely, because they have open tuberculosis. In order to carry out such activities, the modern clinic is equipped with all facilities for diagnosis, such as x-ray facilities, a laboratory enabling it to carry out all the cultural and other methods now used for detecting tubercle bacilli, and blood and other examinations also used in diagnosis. Such a clinic has become indispensable to the general practitioner who has usually not the time, the facilities, nor the specialized experience to come to a definite diagnosis in many of his doubtful cases. In earlier years the clinic gave little treatment, but the tendency is now to give certain treatments, such as pneumothorax treatment, chiefly because this is a particularly preventive measure, making many patients sputum- and bacilli-free or keeping them free over long periods. In some clinics gold and light treatments are also given.

From what has been described of the work and activities of a modern clinic as found in large centres, it will be understood that such a clinic needs a full-time and specially trained technical staff, including one or more tuberculosis specialists, a nurse, x-ray and laboratory technicians, clerks and tuberculosis health visitors; in addition, there has to be organized in connection with the clinic an influential care and after-care committee with whom the medical officer in charge of the clinic and the health visitors should work in close connection.

In a campaign in India, the tuberculosis clinic must occupy the forefront in the campaign, as it has come to do in the west. But experience from the west has taught us that the clinic will be a failure if it is worked as a completely isolated unit. When Tattersall, chief clinical tuberculosis officer of Leeds, England, writes about the modern clinic in England (Tattersall, 1936): 'Dispensary organization cannot be discussed as a separate entity; it is only one part of the complete tuberculosis scheme, and apart from its indispensable complement—institution beds—would be a feeble weapon' his remark is as true of the clinic in India as it is of the clinic in England.

In India it is at present out of the question to start to provide immediately a great number of beds for patients detected by the clinics. But a right beginning can be made by establishing clinics in connection with existing institutions, such as headquarters hospitals where the special tuberculosis officer in charge of the clinic should

have a certain number of beds at his disposal. In a few of the clinics already in existence in India, this has been done. The purpose of these beds should not be for accommodating a few chronic and possibly hopeless cases, but should be used for beginning pneumothorax treatment or for patients needing special observation for establishing a final diagnosis. Patients in whom pneumothorax has been induced, will have to come to the clinic, if possible, for subsequent refills, unless there are specially trained private practitioners who are willing and able to give them.

When sufficient properly trained staff becomes available, it will be possible to establish smaller clinics, such as in *taluk* headquarters and elsewhere, but such smaller clinics should be under the direct control and supervision of the central clinic, and be able to use all the facilities of the central clinic, when necessary.

The great danger in India is that in the eagerness to do something against tuberculosis, a large number of clinics may be established which will be completely unable, through lack of personnel and equipment, to do the work a clinic ought to do, if it is to take any effective part in the campaign. In the present state in India, the watchword of the campaign should be concentration of effort and not diffusion. A little done properly will ultimately be of far greater importance for the tuberculosis campaign than efforts which might touch a greater number of people but which would be, by the very fact of their being so widespread, really inefficient and practically useless, a waste of money and energy, discrediting the campaign itself.

(e) *Establishing of tuberculosis hospitals and sanatoria in India*

In every place where a central clinic has been established, it follows, if the full value of the clinic is to be obtained, that some kind of provision, apart from the few beds already mentioned, should be made for the treatment and isolation of patients. It might be that for the sake of economy a section for tuberculosis could be added to an already existing hospital, with a tuberculosis specialist in charge. It would be better, however, wherever possible, to provide small separate hospitals for tuberculous patients outside but not far away from the larger towns. The climate in most places in India and the customs of the people make it possible for such small hospitals to be of very simple and open construction and comparatively inexpensive. These hospitals should be built in places with room for expansion, if later found necessary, and also with sufficient space to prevent the hospital being hemmed in too closely by unsuitable buildings, if the town expands, and to provide the necessary room for the first stages of graded exercise of the patients.

While these small hospitals outside the larger towns will meet a part of the immediate need for places for treatment, the whole campaign

would suffer, if there were not at least one sanatorium with more than 100 beds and all modern facilities for treatment and research, and training of doctors in tuberculosis, in each province. Ultimately, there ought to be one sanatorium for each district of two or three million people, but in the beginning several districts might combine in the running of one sanatorium. Like the special hospitals mentioned above, these sanatoria too need be only of very simple construction, which the Indian climate renders possible. The value of a sanatorium does not lie in the grandeur of its buildings, but in the treatment carried out, and it is much more reasonable to put the money into the medical outfit and equipment, than into buildings of grand architectural style. The medical equipment should, however, be of the very best, because the treatment of tuberculosis has advanced far beyond the open-air rest cure of the early sanatoria in the west. A modern sanatorium admits cases which the early sanatorium would never have dreamt of admitting, because now it is often possible to do something for such patients and to do it best in a sanatorium. But such modern treatment demands the highest medical and surgical knowledge and equipment with x-rays and laboratories to be used not only for diagnosis, but also for the control of the treatment. In the west it was in the sanatoria that the whole modern conception of tuberculosis and its treatment was worked out, and in India, too, it is in such sanatoria that the treatment best suited to the type of tuberculosis in India and to Indian patients, will have to be worked out.

The latest stage in the campaign will be the establishing of ex-patients' colonies and after-care centres, run in connection with already existing tuberculosis sanatoria. These colonies, too, should be in simple style with a village type of house adapted to the needs of ex-patients, and the industries should be on as simple lines as possible.

(f) *The training of tuberculosis doctors*

While clinics, hospitals, sanatoria and ex-patients' colonies will probably in the end form part of the campaign against tuberculosis in India, all these institutions will be useless without properly trained tuberculosis doctors to run them. Therefore, the first and most important step in the campaign is to train such doctors.

There must be a centre in each of the larger provinces for the special training of doctors in tuberculosis. Such training is necessary for all doctors who are going to specialize in the treatment of tuberculosis, but it is above all necessary for the doctors who are going to work in the clinics. These doctors cannot be trained in the clinics themselves, but must have a complete all-round training in tuberculosis in a central well-equipped institution of some considerable size, where they can become thoroughly conversant with modern methods of diagnosis and treatment. The tuberculosis officer in charge of

a clinic, by the very nature of his front position in the campaign, must be one with a thorough knowledge of all the links in the campaign or else his work will tend to become isolated, and the more it is isolated, not only will the work of the clinic itself be less effective, but it will also become a stumbling-block in the whole campaign. If we have learnt anything from Europe, it is that the campaign must be correlated and co-ordinated in all its links.

It must be understood that a clinic will never develop to what it should be if the doctor in charge is one who has only one month's theoretical training with a few demonstrations of patients and methods of treatment. This is a totally inadequate preparation for doctors who shall lead the tuberculosis campaign. These short courses of a month's duration are, of course, valuable to general practitioners to give them a glimpse into what is being done and can be done in the modern treatment of tuberculosis. These courses are, therefore, of some value to the whole campaign.

(g) *Necessity for tuberculosis research in India*

While the efforts hitherto described are being developed for the general population, there ought to be selected special areas or groups of people for intensive research with a view to working out experimentally the best way in India to tackle the whole tuberculosis problem. This could well be done in, for example, one or more of the large industrial concerns such as has been done in the Michelin works near Paris (*The Lancet*, 1937). About thirty years ago this industry with 22,000 people dependent on it, began to do away with all the slum houses of its workers and then began first a tuberculosis dispensary and afterwards a sanatorium and its own care and after-care organization. In 1922, as many as 13 per cent of the attendants at the dispensary were advanced cases, in 1935 only 1.5 per cent; in 1931 there were 181 new cases of tuberculosis, in 1936 only 84, a fall from 8.2 to 3.8 per 1,000 inhabitants.

In addition to research among a particular group of people like those employed in one industrial concern, certain areas should also be chosen for survey and research into social and epidemiological problems of tuberculosis in a general mixed population, with all the anti-tuberculosis measures in full force. These problems can only be solved by working in such concentrated areas and not by working loosely over the whole of India. It is such surveys and intensive work in Europe and elsewhere which have brought to light most of our present knowledge of tuberculosis problems. India has its own problems which need their own investigation and solution, such as the type of tuberculosis in India and its particular treatment, the rôle of acquired immunity and natural resistance to the disease, the significance of a positive skin test, as well as the question of malnutrition and its part in the development of the disease.

(h) *Propaganda in the campaign in India*

One of the watchwords in the campaign in Europe has been education of the public with regard to tuberculosis, and the same is even more necessary in India.

There are two kinds of propaganda which should be kept separate and which should not be done at the same time. The first is propaganda where the sick are found to be and concerns the education of them and their contacts with regard to the nature of the disease and its spread among them. Such propaganda should, of course, stress the seriousness of the disease, but it should not be overdone so as to frighten people. A poster such as 'Do not go near a tuberculous patient' as has been seen in India, does great harm and creates unnecessary suffering, specially as the idea behind it is quite wrong; tuberculosis is an infectious disease, but is certainly not a contagious disease. In Cyprus (Bardswell, 1938) propaganda of this type led to such a panic that tuberculous patients were liable to be turned out of a village and left to die by the wayside for fear of the infections they might cause. Further, misguided propaganda is sometimes seen in the giving of short lectures on tuberculosis in various villages, without knowing beforehand whether there are any tuberculous people in these villages at all. This costs money which could be more profitably used in propaganda where patients are. Such wider propaganda should be done only after a careful tuberculin survey of the area.

The second kind of propaganda is just as important for the whole combating of the disease, but is of a totally different type. This is the education of the general public through schools and colleges, reading-rooms, and through the press and radio, about the necessity of a campaign against tuberculosis. This type of propaganda should be designed to reach all classes of people. One of the main things to be stressed is that it is wrong to say we cannot do anything until social and economic conditions of people improve. There is an idea current, as stated earlier, that tuberculosis mainly affects the poor classes. If such opinion is allowed to go unchecked, it may in the end do great harm to the campaign, as it is likely to result in the failure to interest the well-to-do classes who should be made to realize that the tuberculosis problem is as acute for them as for the poor. The fact is that some of the most well-to-do families in India are riddled with tuberculosis. It would, therefore, be a very short-sighted policy for the rich people of India to do nothing in the hope that one day, when general living conditions have improved, it will be found that tuberculosis has faded away by itself. This is contrary to experience all over the world in modern times at least, where no decline has taken place without there having been a campaign with anti-tuberculosis activities directly attacking the disease.

It will be decades before we can hope to begin to see the results of all our labours. There may

be much disappointment, and many discouraging results. In the earlier stages of the campaign it may even appear that the disease is rapidly increasing, in spite of all our efforts, because disease now hidden will come to light and the demand for treatment will be out of all proportion to the existing facilities. It is under just such a situation that well-led propaganda will be able to create the will to conquer at any cost. We have every expectation that India, like the countries in the west, can and will face this common enemy of all its people, and face it with success.

Everyone who can take any share in the fight against the enemy tuberculosis, whether he be rich or poor, will be a partaker and a welcome partaker in the campaign, for the way to success will be a long and uphill road.

Summary

(1) A review is made of the various anti-tuberculosis activities which have grown up in the west, chiefly during the last fifty years, and attention is drawn to the differing emphasis, in the beginning of the campaign in different countries, on ways of tackling the disease, and the relation between the various activities employed to the tuberculosis mortality in the various countries.

(2) Experience in the west has shown that these activities in isolation from each other have not had the influence on the decline that a correlated and co-ordinated scheme with the different activities closely linked has had; as a result nearly all countries have now come to employ a more or less uniform scheme.

(3) The new emphasis on the after-care of ex-patients through colonies, village settlements and after-care organizations is discussed.

(4) The widening of the work of the tuberculosis clinic in recent years to include the searching out of patients with pre-clinical disease by examination of contacts and by surveys of special occupations and groups is pointed out as giving the clinic an increased prominence in the prevention of tuberculosis.

(5) An outline is given of certain research work bearing on the campaign, such as the questions of acquired immunity, virgin soil, race susceptibility, inheritance, climate, poverty and malnutrition.

(6) The present situation in India is reviewed with regard to the prevalence of tuberculosis and the present anti-tuberculosis activities.

(7) The possibility or desirability of introducing all the links of the western campaign into India at the present time is discussed.

(8) The position which should be occupied by tuberculosis clinics in India is dealt with, as also their work, staff and equipment, with a warning against the isolation of their activities from other measures indispensable for bringing out the full value of the clinic.

(9) Suggestions are made for creating facilities for institutional treatment in connection with clinics.

(10) It is pointed out that the first step in the campaign is the proper training of tuberculosis doctors without whom the campaign cannot succeed.

(11) Suggestions for tuberculosis research work in India, essential for the campaign and the combating of the disease, are mentioned.

(12) The need for education of the public through the right types of propaganda is stressed, both with a view to reaching those among whom the sick are found, and with a view to securing the co-operation of the whole public of India, without whose co-operation and sacrifice no campaign to stamp out the plague of tuberculosis can succeed.

THE CAMPAIGN AGAINST TUBERCULOSIS IN ITALY

By T. J. JOSEPH, B.A., M.B., B.S. (Madras)
'Perfezionamento' (Rome).

Benito-Mussolini Scholar, 1933-34.

Medical Superintendent, Pendra Road Sanatorium,
C. P.

LONG before the discovery of the tubercle bacillus by Robert Koch in 1882, the infective nature of consumption was known and voluntary sporadic measures were adopted in different places in order to prevent the spread of infection.

Early developments

Thus in Italy, as early as 1621, the sanitary authorities at Padua forbade Jews from buying and selling without licence the blankets, beds, and other articles that had belonged to patients who had died of pulmonary tuberculosis, and early in the eighteenth century, the republic of Lucca gave orders that the houses and belongings of persons who had died of consumption should be disinfected.

The earliest institutions for the care of the tuberculous in Italy were isolation sheds attached to monasteries where patients were left to die in peace.

In 1782, two wards in the hospital for incurables at Naples were set apart for consumptives. In the same year, the earliest-known anti-tuberculosis fund in Italy, namely, 100,000 'ducats', was raised in Siracusa for helping poor consumptives.

In 1853, a number of institutions for scrofulous children were started along the Adriatic coast. These were supported entirely by voluntary contributions. Soon after, alpine colonies for children predisposed to tuberculosis were also started.

Preventive campaign intensified after the discovery of the tubercle bacillus

Under the stimulus of the discovery of the tubercle bacillus in 1882, more active and general measures for the prevention of tuberculosis were adopted. Local governments prohibited tuberculous patients from living in crowded areas of towns. The regular inspection of milk supplies and slaughter-houses was ordered. Spitting in public places was prohibited by notices and posters. Periodic examinations of school children and teachers were demanded.

In the first decade of the twentieth century, the 'General Sanitary Regulations' of Italy were passed. Special wards and institutions for the tuberculous increased in numbers. The military authorities took active steps to prevent tuberculosis among the troops. For the first time the state set apart a sum of 200,000 lire for anti-tuberculosis work in 1914. The military authorities together with the Red Cross Society

provided for 3,000 beds in all, for the tuberculous.

In Italy, as in other countries, the years of the Great War showed a great increase in the mortality rate of tuberculosis.

In 1919, a law was passed authorizing the formation of *consorzi* (anti-tuberculosis associations) in certain provinces for co-ordinating all the anti-tuberculosis activities in these provinces. The asylums or mere isolation centres were gradually abolished and treatment centres substituted in their places, proclaiming that tuberculosis was not only a preventable disease but also a curable one. The battle which Carlo Forlanini had been fighting during the preceding two decades for popularizing artificial pneumothorax as a therapeutic measure helped greatly in bringing about this new view of tuberculosis.

The Fascist regime

With the coming of the Fascists into power a new era opened in Italy. The new life infused into the nation found its reflection in the campaign against tuberculosis also.

A few leading phthisiologists and public health workers together formed a 'National Federation for the Campaign against Tuberculosis'. These men carried out a rough survey of tuberculosis mortality and morbidity in Italy and also of the means which were then available for combating the disease. As a result of their findings they declared that the fight against tuberculosis, to be effective, should be an organized national fight; that the state should take the initiative; and that, while voluntary organizations could be valuable auxiliary means, these can never be adequate to meet the needs of the great national problem.

In 1926, a delegation of the above-mentioned federation waited upon Signor Mussolini and impressed upon him the need for including anti-tuberculosis work in the Fascist programme of national reconstruction. A year later a comprehensive piece of anti-tuberculosis legislation was passed into law, whereby a special national insurance against tuberculosis was incorporated into the national '*Carta del lavoro*' (labour charter), and anti-tuberculosis associations (*consorzi*) were made compulsory in all provinces, and the governors of provinces were made responsible to see that these *consorzi* functioned efficiently.

The relation of the state and its public health department to the campaign against tuberculosis

The Fascist government recognizes the health of the nation as a direct responsibility of the state. Inaugurating the campaign against 'social diseases' in Italy, Signor Mussolini said: 'It is evident that a well-ordered state should consider the health of the nation as its first concern'. The vigorous campaign against

* Discorso dell'Ascensione, Roma, March 1927 (quoted in 'Lotta contro la tubercolosi', April 1935).

tuberculosis which attracts the attention of even non-medical casual visitors to Italy is only a part of the drive which the Fascist government is carrying on against all 'social diseases'; and this drive in its turn forms a part of the general, all-round popular campaign for raising the level of national health by all possible means.

Speaking about the campaign against tuberculosis in particular, Signor Mussolini said: 'While you scientists and medical men confront this problem in your laboratories and clinics, we statesmen of the Fascist regime shall meet it with ever-widening means which shall be adequate to the end'. 'In the law of insurance against tuberculosis, the Fascist government has provided you with an armament formidable in the fight. The unification of all your energies symbolized in the Roman sign of the Littorio is more necessary here than anywhere else†. Collecting all our energies, improving day by day the various methods of combating the disease, and bringing into the fight fervent enthusiasm and our spirit of decision, we are sure to win against tuberculosis‡.

The Italian campaign is directed, controlled and supported by the state. The Minister of the Interior is at the head of the organization which forms an integral part of the national public health department. In Italy the curative and preventive aspects of medical work are less and less being kept in separate compartments, but they are gradually being made to form part of one complete scheme for the promotion of national health. In fact curative medicine is being more and more looked upon as an aspect of preventive medicine. Not only doctors in government employ but also private practitioners are made to fit into the scheme of preventive work.

The state supports the movement by suitable legislation and by grants from the government treasury. The legislation of 1927, referred to above, has formed the backbone of the campaign ever since. During the five years 1929 to 1933, the Minister of the Interior has advanced 214 million lire§, for anti-tuberculosis work in Italy.

The consorzi

These are the provincial anti-tuberculosis associations. Each province is compelled by laws to have its own *consorzio*. The prefect (governor) is usually the president of the association. The *consorzi* are specially concerned with the preventive aspect of tuberculosis, the dispensaries being directly under them. They co-ordinate all the anti-tuberculosis activities, both preventive and curative, in the province.

* Message from 'Il Capo del Governo' to the second national congress against tuberculosis, Milan, 1927.

† Message from 'Il Duce' to the national congress against tuberculosis, Bologna, 1931.

‡ Quoted by 'Giornata della due Croci', April 1934.

§ One lira may roughly be taken as equal to 3½ annas.

Each province is divided into communes and each commune has to pay to the provincial association a subscription in proportion to its population and wealth, the rate per head being one lira or less per month. On the *consorzi* are represented: The province and the communes (compulsorily), charitable organizations, approved trade unions, and provident and insurance organizations. Medicine is represented by the medical director of the *consorzio* who receives instructions from the centre, and the chief provincial doctor (surgeon-general) who collaborates directly with the governor. The *consorzi* work in co-operation with the sanatoria and other treatment centres which are financed by the national insurance.

National insurance against tuberculosis

The aim of the Fascist government is ultimately to insure the nation against all diseases. As a first step towards this ideal, the 'social diseases' are being brought under insurance. It is significant that among the social diseases pre-eminence has been given to tuberculosis. Italy is the only country where there is a special insurance against tuberculosis.

Roughly, the outline of the scheme is as follows: The insured person contributes one lira per month for a daily wage of 8 lire or less, and 2 lire per month for a daily wage of more than 8 lire. The employer pays the same amount. In return the insured, if he falls a victim to tuberculosis, gets free consultation and treatment in the institutions conducted by the insurance associations. Moreover, during the period of illness of a bread-winner, his family immediately dependent upon him gets a monthly allowance.

More than half the population of Italy has been insured. Not only labourers, but also agricultural workers, small-holders, share farmers, teachers in primary schools, etc., are gradually being brought under this scheme. Insurance against tuberculosis is compulsory for persons of both sexes, who are insured against invalidity and old age.

Out of 150 million lire expended in 1930 by insurance, 95 millions were devoted to the treatment of tuberculosis.

The following are the approximate figures:—

Treatment at home : 20 million lire.

Treatment at sanatoria : 70 million lire.

Out-patient treatment : 860,000 lire.

Allowances to families of patients placed in institutions : 5 million lire.

For construction : 60 million lire.

The national medical organization

The direction of the medical and scientific aspect of the campaign against tuberculosis in Italy is vested in the 'Italian National Federation against Tuberculosis'. This body is mostly constituted of doctors, especially phthisiologists, and is concerned with the study of the medical

and social problems connected with tuberculosis, such as tuberculosis survey, collecting and tabulating tuberculosis statistics, training doctors and nurses in tuberculosis, supervision of sanatorium and dispensary construction and technique, etc. The members of this body prepare films, charts and posters for propaganda and education, promote and co-ordinate research in tuberculosis, collect world news and literature connected with tuberculosis, and edit or contribute to tuberculosis journals in and outside Italy. This body regularly holds conferences on tuberculosis problems in the different provinces in rotation. It also represents Italy on international conferences and organizations.

During the last two years an organized attempt is being made to extend the activities of the federation to the Italian possessions in Africa. The 1937 annual meeting of the federation was held at Tripoli in the presence of a strong force of Italian and foreign representatives presided over by Signor Balbo, Governor-General of Libya.

Training of doctors

The Italian National Federation against Tuberculosis recognized the need for training a sufficient number of doctors in the modern methods of diagnosing and treating tuberculosis, as one of the first steps in a campaign against the disease. Therefore a number of training centres were formed in different provinces, most of them in relation to universities. At present the chief of these centres is the Carlo Forlanini Institute opened in 1934 in a suburb of Rome. This is a large institution affording accommodation for 1,300 patients. To this hospital-sanatorium is attached a clinic for the post-graduate training of doctors, a school for the training of nurses and a model tuberculosis out-door dispensary.

The library has all the clinical records of patients ready for reference, and receives scores of periodicals in all the chief languages of the world, mostly dealing with tuberculosis work in different countries. The laboratory is equipped for all kinds of research. The modern radiological department forms an important unit.

There are two courses open to doctors, one of six months for the general practitioner and another of two years for those who aspire to become heads of tuberculosis institutions. In this institution about a hundred doctors are trained every year.

The institution takes full advantage of the proximity of the metropolis and the university of Rome. The professors of the university, government health officials, such as the director of public health, the inspector of tuberculosis dispensaries, the director of social insurance and others, take part in the teaching programmes. During the course, the students visit all kinds of tuberculosis institutions.

Crores of rupees spent

The Carlo Forlanini Institute has cost 45 million lire for construction and equipment. From 1927 to 1934, three hundred million lire have been spent in sanatorium construction alone.

During the five years 1929 to 1933, the anti-tuberculosis associations in Italy have spent a sum of over 412 million lire for their work. During the same period the Fascist institution for social insurance has spent 850 million lire in anti-tuberculosis work, while the Minister of the Interior has directly advanced 214 million lire for the same purpose. Including the amounts spent by the national association for the protection of women and children, war invalids and Orphans Aid Society, the Red Cross Society, etc., the total amount spent in anti-tuberculosis work in Italy during the five years 1929 to 1933, is 1,645,309,330 lire. Taking the rupee as equivalent to 4½ lire on an average rate of exchange, this amount is over 36 crores of rupees.

Results achieved

The work of the National Federation against Tuberculosis and the expenditure of large sums of money (nearly 2,000 million lire during the six years 1929 to 1934) have resulted in a large increase in the number of dispensaries and sanatoria, and in a remarkable fall in the death rate due to tuberculosis in Italy, as shown by the following figures :—

Number of anti-tuberculosis dispensaries.

1924 ..	108	} An increase of 197 in three years.
1927 ..	305	
1934 ..	425	

Number of beds for tuberculous patients.

1924 ..	5,395	} An addition of over 30,000 beds within ten years.
1929 ..	26,680	
1934 ..	39,600	

Number of deaths due to tuberculosis of all forms.

1924 ..	60,548	} The death rate nearly halved within a period of ten years.
1929 ..	50,169	
1933 ..	35,420	

Certain special features

The campaign against tuberculosis in Italy in its present form is one of the youngest and most vigorous in Europe. In Italy the state is more to the forefront of the movement than in most other countries. The rapidity with which the movement gained strength during the Fascist regime, and the quickness of results achieved, are unprecedented.

The Italian campaign is marked by the special national insurance against tuberculosis. This has been the means by which large sums of money (850 million lire in five years) became available for the campaign. Tuberculosis insurance and invalidity insurance both form part of the national social insurance fund. It is in the interests of the fund that as few people as possible should become permanent invalids on

ANTI-TUBERCULOSIS WORK IN BENGAL

By A. C. UKIL, M.A., M.S.P.E. (Paris),
F.S.M.F. (L.C.), F.N.I.

(Honorary Officer in charge, Tuberculosis Research, Indian Research Fund Association, and Honorary Senior Visiting Physician, Department of Chest Diseases, Medical College Hospitals, Calcutta; Chairman, Medical Sub-committee, Tuberculosis Association of Bengal)

Early history

BETWEEN 1882, the year of the discovery of the tubercle bacillus by Robert Koch, and 1900, Indian workers have very occasionally published papers on the subject. But the problem of prevention of tuberculosis in Bengal does not seem to have been discussed until the early years of the twentieth century. It was thought that tuberculosis was rampant among all classes of people in Calcutta, that approximately 10 per cent of the total deaths were due to tuberculosis, and that the prevalence of this disease was far more than that of any of the purely tropical diseases. The names of Waters, Mulvany, Jennings, Harris, Rogers, Pilgrim, Pearce,

(Continued from previous page)

account of tuberculosis. Therefore this fund takes care to see that the disease is diagnosed as early as possible, that beds are provided in adequate numbers, and that the treatment is as prompt and efficient as possible.

It is remarkable that the Italians in their legislation against tuberculosis have not provided for compulsory notification of the disease. They made a study of the working of notification in different countries and came to the conclusion that compulsory notification often fails to serve its purpose, and sometimes is worse than useless. They claim that the system of insurance, apart from the assistance rendered, has the great advantage that anybody who has any suspicion of tuberculous disease will at once go voluntarily to the nearest tuberculosis dispensary or hospital, knowing that he is entitled to free consultation and treatment by virtue of his insurance. Thus nearly all tuberculous cases come under the notice of the dispensaries and clinics. For this reason the Italians claim that statistics about tuberculosis incidence in a country under insurance are much more reliable than those in a country where tuberculosis is by law merely a notifiable disease, but not insured against.

A division of labour or duality of function is present in the Italian organization. The *consorzi* under the Minister of the Interior (Director of Public Health) are in charge of the dispensaries and the preventive aspect of the work. They exercise jurisdiction over the treatment centres in so far as they form part of the preventive scheme. The insurance organization under the minister of corporations looks after the sanatoria and other treatment centres. In practice, these two units are found to collaborate in harmony with each other and with other organizations like the Red Cross Society.

Chatterjee, Craike and Calvert stand out prominently as having contributed to the knowledge of its prevalence and its prevention at the time. From the *post-mortem* records of latent and healed tuberculosis supplied by Rogers and Pilgrim (1909), it was considered that 'under proper conditions of treatment in the sanatorium in the early stages, the prevailing rate of mortality could be largely prevented'. It was further thought that 'such institutions, outside their function as a means of treatment, would serve the even more important one of acting as centres for the spread of knowledge amongst the people of the necessary precautions that should be taken in order to prevent the spread of tuberculosis to those who are healthy'.

Towards the early part of 1909, the Medical Section of the Asiatic Society of Bengal took a prominent part in discussing the tuberculosis problem from various viewpoints. The unanimous adoption of the following resolution, proposed by Lieut.-Col. Pilgrim, Superintendent of the Presidency General Hospital, and seconded by Dr. Pearce, the City Health Officer, shows the concern of the medical profession of the time for some sort of preventive work:—

'The Medical Section of the Asiatic Society of Bengal having discussed the subject of tuberculous disease in Bengal, and its wide prevalence, are of the opinion that it is an extremely common cause of great suffering and mortality, both among the European and Indian communities; and therefore venture to call the attention of the Government of India and the local Government, to the urgent necessity for providing a properly equipped sanatorium for the treatment of early phthisis, such as has now been provided with most satisfactory results in nearly all civilized countries'.

Some of the medical men present at this symposium, notably Chatterjee and Pilgrim, advocated the enactment of legislative measures against indiscriminate spitting and the introduction of compulsory health insurance for housing, treatment and after-care.

We also find a reference, in the old records, that the Maharajadhiraj Bahadur of Burdwan suggested to the Government in 1908 that a sanatorium should be established for the benefit of the members of the poor middle classes suffering from tuberculosis and other diseases and himself offered a contribution of Rs. 1 lakh towards its cost. Sir Andrew Fraser, the then Lieutenant-Governor of Bengal, sympathized with the scheme and appointed a committee to consider it. The committee tentatively selected Simultala as the most suitable site for the proposed sanatorium, and had a plan and an estimate of cost prepared. Excluding the land, the cost of the building and equipment was estimated at Rs. 1,85,000 and maintenance charges at Rs. 14,000 per annum. In 1909, however, it was decided by the Government that the financial position did not permit of the project being

given effect to, and it was accordingly dropped. Major Deare and the Rev. Mr. Hearn suggested Hazaribagh and Major Calvert suggested Kalimpong as likely places for the sanatorium treatment of pulmonary tuberculosis.

No records are available, however, about any well-considered anti-tuberculosis schemes for the province as a whole. In 1913, the Corporation of Calcutta proposed to establish a dispensary for the tuberculin treatment of consumption and suggested that 'a comprehensive scheme should be framed for the establishment of a tuberculosis hospital and sanatoria in Calcutta'. The introduction of tuberculin treatment at the dispensary was probably suggested by Cochrane and Sprawson at an earlier session of the All-India Sanitary Conference held at Lucknow. The Corporation thought that the question was a very large one which could not be dealt with effectively unaided and asked the Government of Bengal for the statement of their views and policy. While supporting the proposal to establish a dispensary for the tuberculin treatment of consumption, the Government expressed their inability to make any grant towards the establishment of a special hospital and sanatorium. They advocated, however, the initiation of a preventive campaign against tuberculosis along the following lines :—

(a) the establishment of an anti-tuberculosis dispensary in a rented building in the central part of Calcutta;

(b) the formation by the officer in charge of the dispensary of a Bureau of Information to collect statistics and to investigate important points in connection with the disease.

It was proposed to appoint a whole-time non-practising junior I.M.S. Officer on Rs. 1,000 a month plus staff allowance of Rs. 300 per month, to be assisted by a resident whole-time Assistant Medical Officer on Rs. 250 per mensem. His duties were fixed as follows: (1) to attend to the treatment of out-patients visiting the dispensary; (2) to consult with the medical practitioners in the town as to the advisability of treating some of their private patients with tuberculin; (3) to recommend a system of home prophylaxis in the case of out-patients; and (4) to keep a careful list of all cases notified, whether he ever had an opportunity of seeing the patients or not. The advisability of issuing leaflets, home instructions and all measures of that kind was left largely to his discretion.

This envisaged the introduction of compulsory notification of the disease but it was pointed out that the compulsory disinfection of premises was not to be insisted upon to begin with. A notification fee of Rs. 2-8-0 was proposed to be given to private practitioners notifying a case. It was estimated that the probable annual expenditure in notification fees would amount to Rs. 25,000 a year; and

(c) the appointment of a small staff of health visitors (preferably highly trained English ladies) to assist this officer at a salary of Rs. 200

a month with free quarters and a conveyance allowance of Rs. 50 per month. The menial and laboratory staff were also included in the estimate.

The Corporation generally approved of the scheme but were not willing to bear the whole of the cost, which for the first and second year of working was estimated at Rs. 2,500 a month, and accordingly requested that Government might bear half the cost. In reply the Government informed the Corporation that they would prefer to wait the result of Dr. Lankester's inquiries on tuberculosis which was being financed by the Indian Research Fund Association at the time (July 1914 to June 1916).

This inquiry by the Indian Research Fund Association was the direct outcome of a resolution passed at the Madras Session of the All-India Sanitary Conference in 1912 and at the Lucknow Sanitary Conference in 1914.

Dr. Lankester visited 85 cities, including 29 with a population of over 100,000 inhabitants, interviewed doctors, missionaries, educational officers and various institutions in the course of his tour covering 35,000 miles, and he submitted a report which was forwarded by the Government of India, Department of Education, to the various provincial Governments for their opinion early in 1916. The opinions of the local administrations were collected together in a 'blue book' and published by the Government of India in 1918.

On reference to the reports from Bengal, it is seen that it was admitted that tuberculosis was then widely distributed in different parts of the province and that the mortality due to it was considerable. Local surveys were carried out, from time to time, by Rogers (1904), Stewart and Proctor (1906 to 1907), Bentley (1911 to 1912) and others. Figures on tuberculosis were specially collected between 1911 and 1915. This led to the establishment of *small separate phthisis wards in the district hospitals and dispensaries in the province.*

The various other measures proposed were held in abeyance, apparently on account of financial stringency. The Hygiene Committee appointed by the Government advocated regular medical inspection of school children and emphasized the teaching of hygiene in the senior, middle and lower classes of schools. The Governor-in-Council at this time thought that it was desirable that arrangements should be made, as soon as possible, for medical inspection in the schools in Calcutta where the tuberculosis mortality was high. Then came the Great War and all these ideas seem to have vanished from the minds of sanitarians and administrators alike.

The birth of the Jadavpur tuberculosis hospital 1918 to 1923

In 1918, a young medical student from Bengal fell a victim to pulmonary tuberculosis in London and was sent home for treatment. Unfortunately he did not survive; but it was at his

instance and at the suggestion of his physician, Dr. B. C. Roy, that he made a bequest of his property for the establishment of a tuberculosis sanatorium in Bengal, or failing such an institution, the investment of the property by the Calcutta University for the purpose of founding a scholarship for research in tuberculosis. This benefactor was the late S. J. Provash C. Ghosh. The executors of his will were Sir P. C. Roy, Dr. B. C. Roy and Mr. B. K. Ghosh who, in order to effect the purpose of the testator, made the property over to the Calcutta Medical Aid and Research Society, founded with the object of establishing sanatoria and homes for consumptives. The property bequeathed amounted to Rs. 1,75,000.

The Calcutta Medical Aid and Research Society opened the first tuberculosis hospital in Bengal at Jadavpur, seven miles from Calcutta, with four patients, in the year 1923. This institution has now developed into a fine hospital of 139 beds, with the aid of Corporation and Government grants and public donations. The province of Bengal is grateful to this society and particularly to Dr. B. C. Roy, the late Mr. P. C. Kar and to Dr. K. S. Roy, its indefatigable secretary, for organizing the first tuberculosis hospital within the province.

1924 to 1928

The present writer, who had the privilege of working with the late Professor Calmette at the Pasteur Institute, Paris, and of studying tuberculosis work in various European countries, took up the problem on his return to India in 1923. The result of his first studies on the epidemiology and pathology of the disease in Bengal was placed before the Lahore session of the Indian Science Congress in 1926 and before the Tuberculosis Section of 7th Congress of the Far Eastern Association of Tropical Medicine held in Calcutta in 1927. Since then he has been in charge of the Tuberculosis Inquiry, as an honorary worker, under the Indian Research Fund Association. He took up the thread where it was left by Dr. Lankester and has tried to explain some of the unexplained epidemiological factors, by surveys and laboratory investigation. His public utterances and writings exposed before the profession and in the press helped to focus attention on the seriousness of the problem.

He has tried to point out how the problem differs in urban and rural communities, in tubercularized and untubercularized communities, in contact and non-contact families, in industrial and non-industrial areas, in congested and sparsely populated areas, in conditions of good living and sound community hygiene, and also according to nutrition and environment and other factors. The facts already in our possession at the time helped us to evaluate and diagnose the local problem, to some extent.

He made a further tour in Europe in 1929-30 exclusively studying tuberculosis and anti-tuberculosis work in various countries. He also

visited various tuberculosis institutions in India in order to gain a knowledge of local conditions. The full benefit of these visits was given to the study and prevention of tuberculosis in the province. It must be said to the credit of the medical profession in this province that they responded splendidly whenever a call was made for their services in the cause of prevention of tuberculosis.

The Jadavpur Tuberculosis Hospital did not seem to make any further progress during this period but its expansion quickly progressed from the year 1931 onwards. Its present bed capacity is 139, plus 6 beds under construction. Up to date it has received, besides the bequeathed property, a total capital grant of Rs. 1,45,000 from the Calcutta Corporation and Rs. 2,48,500 from the Government of Bengal. The recurrent grants from the Calcutta Corporation from 1931 to 1938 total Rs. 2,81,292. The public donations amounted to Rs. 5,90,334. This progress is no doubt encouraging, but one institution cannot solve the needs of the whole province.

Origin and growth of the Tuberculosis Association of Bengal (1929-38)

In almost every country, it is a private organization sponsored by private funds which, by conscientious and patient work, first demonstrates the need for public health protection in tuberculosis and points the road for further constructive work. The state comes in for legislative action and financial aid at a later stage to help in the realization of an unified control of the disease. It was chiefly through the educative effort and initiative of the National Tuberculosis Association in England that a departmental committee was appointed in 1911 and that Parliament voted a million and a half sterling in the same year besides agreeing to contribute 50 per cent of the net cost of treating the disease. The county and borough councils promptly came forward, with the result that tuberculosis mortality has decreased there by 50 per cent within the last 30 years. Knowing that tuberculosis is chiefly spread by intimate personal and family contact and that a multiplicity of interacting causes, such as ignorance, poverty, low hygienic standards of living, inadequate and bad housing, adverse industrial conditions and unfavourable social environments, operates in determining the incidence of disease in a community, the task of checking the spread of such an ubiquitous disease seemed to be stupendous without state aid, but the matter of starting the Tuberculosis Association of Bengal for the study and prevention of tuberculosis was rather an accident than the outcome of a long-thought-out plan.

Early in November 1928, two American ladies took the writer to see another American lady who was suffering from advanced lung tuberculosis and who died within a few days, under very tragic circumstances. All of us attended the funeral. The pathos and tragedy

of her life made such an indelible impression on one of the ladies (Mrs. Campbell Forrester), who had previous anti-tuberculosis training, that she made up her mind to work for the cause. On the afternoon of 28th November, 1928, she invited half-a-dozen men and women to confer on the problem of tuberculosis prevention in this province. A committee was soon formed, chiefly through her efforts, with H. E. the Governor of Bengal as President and Dr. C. A. Bentley, the then Director of Public Health, as its first Chairman. This American lady became its first Hony. Secretary and organizer and soon mobilized a band of earnest workers to help in furthering the scheme.

It was decided that a tuberculosis dispensary should be opened 'as a means of demonstrating to the public the practicability of the scheme of anti-tuberculosis work', which embodied:—

(1) The establishment of tuberculosis dispensaries for the finding by tuberculosis health visitors of suspected cases, the diagnosis of these cases by trained physicians, and, where possible, the segregation of "open" tuberculosis cases.

(2) Systematic visiting of tuberculosis cases and "contacts" in their homes by trained tuberculosis health visitors who teach the special hygiene and prophylaxis of tuberculosis.

(3) Intensive tuberculosis educational propaganda, including general hygiene, preventive and curative measures.

(4) Arrange courses for the training of tuberculosis health visitors, tuberculosis nurses and doctors as tuberculosis specialists.

(5) To encourage the medical inspection of school children, teachers and other employees with a view to safeguarding the young from tuberculosis and educating them in the hygiene of prevention.

(6) To encourage the establishment of hospitals, sanatoria, preventoria and health colonies necessary for dealing properly with the problem of tuberculosis.

The Association was founded in January 1929, and was registered on 15th June of the same year. The first tuberculosis dispensary was opened in two rent-free rooms offered by the authorities of the Chittaranjan Hospital, Calcutta. The honorary services of some eminent physicians were secured and a special training course was organized to train tuberculosis health visitors. Six months of honest work impressed a neighbouring municipality (Howrah) so much that they financed the opening of a second dispensary at the Howrah General Hospital in October of the same year. A little over 2,000 patients were examined and 2,600 home visits were paid by trained tuberculosis health visitors in the course of the year. A third dispensary was opened at the Medical College Hospitals on the 1st July, 1931. In August 1932, a grant of Rs. 5,000 a year by the Calcutta Corporation enabled the Association to open another dispensary early in January of the next year. An annual grant of Rs. 10,000 by the Government of Bengal for propaganda work, in 1933, enabled the Association to appoint two tuberculosis medical officers and two assistant publicity officers for publicity, education and expansion in the districts and to employ a clerk at the central offices of the Association. The

fifth Calcutta dispensary was opened in May 1935, at the Carmichael Medical College Hospital. It was decided to open the sixth dispensary at the Calcutta Medical School Hospital and the seventh one at Sambhunath Pandit Hospital, but lack of funds has stood in the way.

The first *mofussil* dispensary was started at Krishnagar, within the precincts of the Sadar Hospital, in the year 1932. The second *mofussil* dispensary was opened at Dacca in November 1935, and the third one at Kalimpong (Darjeeling) in October 1936. Since then two more dispensaries have been started, one at Darjeeling and another at Barisal.

In most cases, the dispensaries are attached to one of the well-equipped hospitals having x-ray installation. The advantages of such an arrangement are obvious—(1) the patients of the locality are already accustomed to approach the existing hospitals in case of illness and hence a large attendance is ensured from the very beginning, (2) the laboratory examinations, as well as x-ray examinations, being available in these institutions, the Association is spared any expenditure under these heads, which can thus look after the preventive side of the organization—its legitimate sphere.

The president of the Association is the Governor of the province, who presides at the annual general meetings and gives it such guidance as he may think fit but the management of the Association is vested in an executive committee with a chairman, a vice-chairman, and a committee of 25 members elected from among the members, along with representatives of Government, local bodies, Red Cross and other social welfare organizations. Dr. C. A. Bentley, who was Director of Public Health, Bengal, in 1929, was the first chairman of the executive committee. He was succeeded, on his retirement, by the late Mr. B. K. Basu, an ex-mayor of the Calcutta Corporation, who has been succeeded by Dr. B. C. Roy, another ex-mayor of Calcutta. The executive committee has three sub-committees under it to help the Association in various spheres of work:—

(1) the medical sub-committee, which is responsible for the control and guidance of the academic and technical side of the work;

(2) the finance and publicity committee, which is responsible for raising funds and for guiding publicity campaigns, and

(3) the journal committee, which runs a quarterly journal, first started in 1935.

The volume of work with which the Association is now confronted will be appreciated when we state that, in the year 1937, nearly 70,000 patients were examined at the dispensaries, including about 11,000 new cases, among whom tuberculosis accounted for 4,000 cases. Thirty-one trained tuberculosis health visitors paid 33,765 visits to the homes of tuberculous patients. Many more homes could not be visited for want of an adequate staff. Four thousand

three hundred and twenty-eight 'contact' cases were traced, of whom 604 were examined; 28.9 per cent of these showed active pulmonary disease. On account of paucity of beds for tuberculous patients in the province, collapse therapy was given to 523 ambulatory cases in the various dispensaries. The manner in which the work is dealt with at a well-organized dispensary is shown in the following scheme in operation at one of our dispensaries (Medical College Hospitals):—

Different sections in the dispensary (No. III, Chest Department, Medical College Hospitals)

I. Male diagnostic section:—

1. New cases.
2. Old cases—
 - (a) Tuberculous.
 - (b) Non-tuberculous.

II. Female diagnostic section:—

1. New cases.
2. Old cases—
 - (a) Tuberculous.
 - (b) Non-tuberculous.

III. Children's section:—

Examination and study of 'contact' cases.

IV. Therapeutic section:—

- A. Injection of chemicals, vaccines, and tuberculin—
 - Male side.
 - Female side.

B. Surgical work:—

1. Artificial pneumothorax.
2. Cauterization of adhesions in A. P. cases.
3. Aspiration of pleural effusion.
4. Oleothorax.
5. Aspiration of cold abscesses.
6. Phrenic evulsion.
7. Thoracoplasty.

(Items 6 and 7—with the help of indoor surgeons.)

8. Lipiodol bronchography.

C. Assessment of progress and prognosis:—

- (a) Estimation of sedimentation rate of blood and von Bonsdorff blood counts.
- (b) Estimation of vital capacity.
- (c) Taking of weight, pulse and temperature.

V. X-ray diagnostic and radiation therapy section—to come into operation at an early date.

VI. Indoor tuberculosis wards—containing 24 beds.

VII. Teaching:—

Under-graduate—

Students of the 5th year class are deputed for training for a period of one month in this section.

Post-graduate—

- (a) Post-graduates who come here for training for a three months' course from Bengal and other provinces—throughout the year.
- (b) D.P.H. students who are sent for lectures and demonstrations by the All-India Institute of Hygiene and Public Health.
- (c) Post-graduate course of the King George Thanksgiving (Anti-tuberculosis) Fund for approximately 30 doctors from all over India for a period of one month in the year.
- (d) Post-graduate course for medical and public health officers in Bengal, under the auspices of the Public Health Department.

VIII. Statistical section:—

Helped by a statistical clerk supplied by the Tuberculosis Association of Bengal.

Staff and duties:—

Number	Designation of post	Duties allotted
1	Senior visiting physician in charge.	General supervision; correspondence; teaching of students; in charge of indoor and outdoor cases; consultation work in other groups of hospitals including the Carmichael Hospital for Tropical Diseases.
1	Junior visiting physician.	Helps on alternate days.
1	Clinical tutor	Demonstration of cases to students and post-graduates and in charge of surgical work and A. P. room.
1	Senior house physician.	Indoor work; including medical help and registrar's work; in charge of instruments and property in the department; deals with outdoor cases, if he finds time.
2	Junior house physicians.	1st Jr.—Male new cases—examination and disposal; roll call of students and filling of schedules. 2nd Jr.—Female new cases.
6	Clinical assistants.	Children's section, male and female old tuberculous and non-tuberculous cases.
2	Clinical pathologists.	Work in the laboratory (senior pathologist is in charge of apparatus and chemicals).

N.B.—All the above staff are honorary.

Nature and extent of work done in Dispensary III, during 1935, 1936 and 1937

	1935	1936	1937
1. Total number of cases (old and new).	26,485	30,872	33,205

6. Reading of x-ray films (twice a week).	2,380	2,257	2,071
7. Radioscopy and radiation therapy—to be introduced at an early date (now being done in the central x-ray department of the hospital).			

Work done by tuberculosis home visitors at Dispensary III

The services of nine or ten paid tuberculosis home visitors have been kindly lent by the Tuberculosis Association of Bengal. They help in writing up the cards of patients, take temperature and weight, write up the x-ray requisition forms and are in charge of the card-index system of case cards, x-ray and other records. They also prepare patients for examination and operation. In the evening, they carry out their home visits to registered patients.

* * * *

A large amount of work was done by the statistical section. The publicity department of the Association gave 300 lectures in schools,

apartments in central Calcutta wherefrom the publicity work of the Association, under two paid publicity assistant officers, is directed. All the health visitors of the Association, male and female, had to pass through a course of training and to pass an examination before they were employed on grades of pay varying from Rs. 35 to Rs. 100 per month. They are paid a small conveyance allowance for their health visiting work. The work of the health visitors is supervised by one of the tuberculosis medical officers and 2 per cent of the health visits are personally checked by him. One of the tuberculosis medical officers is specially meant for publicity, supervision and expansion work in the *mofussil*. The dispensaries, both in the town and in the *mofussil*, are inspected from time to time and a report

Fig. 1.

bustees, public places and health exhibitions and participated in 18 exhibitions in Calcutta and 8 exhibitions in the *mofussil*.

Figures 1 to 5 show at a glance the growth and activities of the Association during the last nine years.

Staff and organization

The secretary of the Association has always been an honorary worker, except for a short break in 1937. The administrative offices are located, for the present, in some rent-free rooms in the Writers' Buildings, Calcutta, where the only paid staff consists of two tuberculosis medical officers, a clerk and a peon. The Association also maintains a publicity office in rented

submitted to the Association. All the dispensaries recognized by the Association now employ standardized methods of diagnosis, classification, charting, follow-up and recording.

The honorary secretary is the main pivot round which every activity of an association like this revolves. He or she has not only to manage the work of the office, but to see that the important work of health-visiting is done properly and to visit the infected homes in slum areas from time to time, to arrange about the instruction and examination of tuberculosis health visitors, to organize the publicity work and the expansion of *mofussil* work, to activate and co-ordinate the work of the various committees, to devise means of implementing a deficit budget, to organize fund-raising campaigns,

to receive and answer the questions of various patients and members of the public, to look after the publication of the journal and to think out methods of improving the quality and quantity of work. It is a serious strain on the time of any volunteer worker to perform such multifarious work but we are glad to state that every one of them responded splendidly to the call. Dr. Mrs. C. O. Remfry, who succeeded the first Founder-Secretary (Mrs. Campbell Forrester), rendered the longest period of disinterested service (seven years). Efficiency and progress of work demand that there should be loyalty and discipline on the part of officers and perfect co-ordination between the office-bearers of various committees. This we had in abundant measure.

when first detected at the dispensary shows where the problem stands. To discover and isolate all infective cases in institutions may be an ideal plan but it will remain a pious wish in this country for many years to come.

It has been noted by us that roughly one third of all patients coming to the dispensary prove to be suffering from tuberculosis, a majority of whom are cases of pulmonary tuberculosis. Fifteen per cent of them are in stage I, 25 per cent in stage II and 60 per cent in stage III. The remainder consists of non-tuberculous lung diseases, like abscess and gangrene of the lungs, bronchiectasis, bronchitis, asthma, etc., and also diseases not referable to the lungs. It has also been noticed that approximately 15 to 20

Fig. 2.

Working methods of the Association

We realized from the very beginning that in a province where the annual mortality from tuberculosis was in the neighbourhood of 100,000 and the total bed capacity for tuberculosis patients was only 476 (up to May 1938), we could not possibly isolate any appreciable proportion of the infective cases in hospitals and sanatoria. Moreover, it is recognized that hospitals and sanatoria themselves cannot meet the needs of tuberculosis in the average community. Tuberculosis therapy, therefore, in most instances, must be provided through the medium of home treatment; and the dispensary is but an avenue through which such cases could be approached. The fact that a predominantly large proportion of cases (55 to 60 per cent) are already in advanced stages of the disease

per cent of the cases can be given ambulatory surgical treatment at the dispensary, 25 per cent will require hospitalization, 40 per cent will be found to be too advanced for dispensary or hospital treatment and are thus suitable for being placed in a hospital or infirmary for advanced cases and 20 per cent have been found to be suitable for care colonies or for convalescent homes. Twenty per cent of the 'contact' children who have been found to have active lung infiltration will be found suitable for institutional care either in a children's sanatorium or in a preventorium. About 10 to 15 per cent of the total number of the tuberculosis cases in the community will be found to be suffering from glandular and bone tuberculosis. For them, there are no special institutions in India to-day. The above facts are mentioned

in order to help us to evaluate the problem in some of its aspects.

In countries where the bed capacity is large, the dispensary serves as a clearing house for cases meant for admission into various types of institutions. But in India the situation is different. Hence, the experiment of giving collapse therapy in suitable ambulatory cases was first tried in one of our dispensaries (Chest Department, Medical College Hospitals, in 1931). The results were found to be very encouraging—about 70 to 75 per cent of the cases showed positive results (i.e., 'improved') at the end of the year and 65 per cent of the cases with 'positive sputum' became negative at the end of the year. Many cases, which could not otherwise have been controlled, were thus able to resume their work while still under the care of

ensuring a good quality of anti-tuberculosis work.

(a) Tuberculosis health visitors' course

Candidates were obtained from some of the matriculates and passed students of the medical schools but we found a great difficulty in obtaining a suitable type of female health visitor. A simple curriculum was drawn up and eminent scientific workers were requested to run the course, who most gladly took up the work as a labour of love. The course has been greatly improved with the passage of time and the present one covers a period of six months during which the students have to attend 80 theoretical lectures, besides demonstrations, practical classes, dispensary and hospital work, and home visiting. As there is no

Fig. 3.

the dispensaries. Under this arrangement, the dispensary served as a centre for diagnosis, treatment and education of the patient and his home became an extension of the dispensary, through the help of tuberculosis health visitors. The dispensaries in this country must, therefore, be supplied with a few beds for the observation and treatment of cases, in the initial as well as later stages of the development of anti-tuberculosis work.

A. SUPPLY OF TRAINED PERSONNEL

When the Association was first started we had no trained health visitors and very few doctors with special training in tuberculosis, although we knew that this was a very important item in

other centre where this training is available in India, the Association has been requested, from time to time, not only to train health visitors from other provinces but also to supply passed health visitors to different areas. Some people suggest the employment of sub-assistant surgeons as health visitors. Our experience with regard to them has been disappointing, for in several instances passed doctors who had this training and were employed as such engaged surreptitiously in practice as tuberculosis specialists. We have since stopped the training of qualified doctors as tuberculosis health visitors. The training of nurses as tuberculosis health visitors has been suggested. This has also been tried by us but their employment is more costly

and is very often beyond the resources of local bodies or tuberculosis organizations.

A difficulty seems to have cropped up, at least in this province, regarding the name 'tuberculosis health visitor', as hitherto the name 'health visitor' has been given to ladies who have taken maternity training. The present Act does not, therefore, permit the use of the term 'health visitor' to our health visitors. We have since commenced styling them 'tuberculosis home visitors'. When the All-India Association is inaugurated, we hope that this difficulty will be rectified.

(b) Post-graduate training in tuberculosis

A short post-graduate course on tuberculosis was organized by the writer in the year 1931 by inviting eminent physicians, pathologists and surgeons of the city to lecture in the class.

of 'refresher courses' rather than attempts to make the doctors competent to take charge of tuberculosis institutions like hospitals or sanatoria. If we are to attempt this, a longer and a more thorough course of training is needed.

We have always felt that the under-graduate training in tuberculosis in our medical institutions is extremely inadequate. There is no standardized curriculum and no uniformity in the quality and quantity of education imparted on this subject. In the interests of the future of the medical profession and of anti-tuberculosis work generally, we feel that this state of affairs should be remedied.

When the Association first began to open the dispensaries, we did not possess enough specially trained doctors for anti-tuberculosis work in the

Fig. 4.

Besides this, short intensive courses of training were also organized, but in these cases only doctors from Bengal attended. When the King George Thanksgiving (Anti-Tuberculosis) Fund started the first post-graduate course in 1935, the Bengal courses were suspended. The Government of Bengal have recently made arrangements to give a month's post-graduate training in tuberculosis to medical and health officers in the districts, in collaboration with the Tuberculosis Association of Bengal. Besides this, the Association also participates in training, on the preventive side of tuberculosis, for D.P.H. students at the All-India Institute of Hygiene and Public Health. The courses of post-graduate training hitherto pursued by us are in the nature

city and in the districts. We were compelled, therefore, to appoint many doctors who, though they were good clinicians, did not possess the requisite knowledge of anti-tuberculosis work. But we devised two procedures for supplementing this deficiency:—

(1) by organizing post-graduate lectures in tuberculosis which they were invited to attend and,

(2) by holding periodical meetings—clinical, scientific and administrative—of all doctors working under the Association. At these meetings not only scientific matters were discussed but also those connected with the improvement of technique of anti-tuberculosis work. This method was found very useful to ensure the

necessary co-ordination and uniformity of procedure. In order to appreciate the difficulties of health visiting work and to ensure better results, joint meetings of tuberculosis health visitors and the dispensary doctors are held from time to time.

(c) An attempt has also been made to give short courses of training to health visitors working under the ward health associations of the Calcutta Corporation. Sanitary inspectors in the Public Health Department may conveniently be included under this category.

B. DEVELOPMENT AND STANDARDIZATION OF TECHNIQUE

A continuous effort has been made to develop and standardize methods of diagnosis, treatment, classification, charting and recording of

(5) Standardization and recording of case cards. With the kind co-operation of the Department of Vital Statistics at the All-India Institute of Hygiene and Public Health, the Association has been able to evolve a comprehensive 'case card' which attempts modern statistical analysis. With the help of these case cards, we are now able to analyse many valuable data which were so long left untabulated.

The checking and supervision of the work of health visitors and of statistical analysis, and the procedure of after-care and follow-up, have been standardized by appropriate methods.

(6) Periodical 'refresher courses' are held from time to time for the benefit of tuberculosis health visitors working under the Association, in order to revise and bring their knowledge up to date.

Fig. 5.

cases and of surveys and supervision. The following are some of the items which have been standardized and followed at the various dispensaries under the Association :—

(1) Technique and interpretation of the Mantoux and von Pirquet tests.

(2) Minimum standards in the diagnosis of the childhood and adult types of tuberculosis.

(3) Classification and charting of cases.

(4) Laboratory and x-ray technique.

We have not yet been very successful about the standardization of the laboratory and x-ray technique, chiefly because the different hospitals where such work is done are not under the control of the Association but we hope gradually to achieve success in this direction also.

(7) Procedure and checking of home visits.

In addition to filling up the 'home-visiting cards' the tuberculosis health visitors have to explain the methods of prevention and effective isolation in the home, the adjustment of their family budgets, the balancing and supplementing of their diet, and to ask them to look on the dispensary service to patients with a friendly eye. The health visitors have to be extremely careful and tactful in visiting work, as the least amount of publicity may lead to the patient-tenants being compelled to leave the premises.

(8) Surveys.

(9) The minimum requirements regarding accommodation, equipment, working and

affiliation of dispensaries have now been standardized and no dispensary is affiliated to the Association which does not conform to the minimum requirements. When a dispensary is affiliated to the Association, the latter deputes one of its tuberculosis medical officers to initiate the work and lends the services of a tuberculosis health visitor for the first three months. It also supplies, at cost price, printed case cards, return forms, registers and propaganda material. Technical advice is also given free and a copy of the journal of the Association is supplied without obligation.

(10) Notification and registration.—Until recently, tuberculosis was not recognized under the category of 'communicable diseases'. At the persistent request of the Association, the Government of Bengal declared tuberculosis to be a 'notifiable disease' only in municipal areas, except Calcutta, in Bengal on the 3rd August, 1936. The Municipality of Calcutta has also recently declared it to be a notifiable disease. It is to be regretted that very few municipal agencies and members of the profession have complied with the provisions of this Government order. The Tuberculosis Association of Bengal notified 809 sputum-positive cases and 240 tuberculosis deaths to the Calcutta Corporation and 288 sputum-positive cases and 74 tuberculosis deaths to *mofussil* municipalities and district boards in the year 1937, but it is regretted that the response has so far been very discouraging and that proper preventive measures were seldom taken. It is felt that if the municipal and district board laboratories undertook to examine, free of charge, the sputum of all suspected cases sent to them by qualified medical practitioners, the notification of 'open' or infectious cases would be facilitated and a wider application of preventive measures rendered easier.

We are aware that notification involves some possible inconvenience to private practitioners and patients, unless provision is made for the institutionalization of patients. But even with these drawbacks, I believe that a beginning should be made with notification, in spite of its manifest disadvantages at the present moment.

(11) Legislation.—Efforts have been made to introduce a short *ad hoc* Tuberculosis Act, through the Government of Bengal, but the chief difficulty which confronts its introduction and application seems to be the lack of tuberculosis beds in the province and of the provision of an Act based on the health insurance system.

C. TUBERCULOSIS SURVEY

The scientific basis of a tuberculosis programme was recognized from the very beginning. As the crucial factor in the control of the disease is the prevention of 'large dose' infection, one of the first steps in the prevention of such infection must necessarily be the finding of the cases. The rôle of the survey in dispensary procedure

is therefore of very great importance. The Association has undertaken surveys of educational institutions, work houses, orphanages, tuberculous homes and of selected areas and towns and villages. The work of the present writer, under the auspices of the Indian Research Fund Association, on the epidemiology of the disease in urban and rural areas, in tuberculous homes and in industrial areas has been greatly aided by the staff of the Tuberculosis Association of Bengal. Fresh knowledge gained from these surveys has no doubt helped us to improve the working methods of the Association.

D. PUBLICITY AND EXTENSION

The value of a well-planned campaign of health education for the lay public was recognized by us from the very beginning. Until the Government grant in 1933 enabled us to appoint two medical officers and two publicity officers our volunteer workers took the task of education and publicity on their own shoulders. Our publicity department is now fairly well organized. We have to examine the old methods from time to time and introduce new ones every year. The following are some of the important methods of publicity which have been developed:—

(a) Newspaper publicity, which includes the publication of news items, short stories, reports of lectures and meetings and results of surveys and anti-tuberculosis campaigns.

(b) Use of printed work, which consists of leaflets, circulars, reports and posters. The Association has been running a quarterly journal for the purpose of lay health education since the year 1936. It contains information on the activities of the Association, articles on various aspects of tuberculosis, facts and figures, and other useful items.

(c) Use of spoken word; lectures and talks are given in schools, colleges, university classes, teachers' associations, in public places, parks, *bustees* and exhibitions and over the radio.

(d) Graphic methods. This includes exhibits, posters, special tuberculosis films, charts and graphs, slides, etc. Dramatic displays have been occasionally utilized. Special attention has been devoted to publicity in schools and colleges and efforts have been made to rouse interest in anti-tuberculosis measures by offering prizes for essays on tuberculosis.

Most of our dispensaries, which are attached to teaching hospitals, take part in undergraduate and post-graduate medical education. The dispensaries also take part in the education of the patients assembled there by asking the health visitors and publicity officers to lecture to them on early detection, prevention and vocational rehabilitation.

Well-organized publicity is very necessary for extension work either in the city or in the *mofussil*. Although our medical and publicity officers have been touring the *mofussil* for several years, the response has been rather poor. As a

result of the efforts for the last 10 years, only five *mofussil* dispensaries have hitherto been opened. The chief difficulties which have stood in the way of opening more *mofussil* clinics are that the municipalities and district boards do not come forward to contribute a substantial portion of the recurring expenditure. Public enthusiasm has also been found freakish and undependable in a large number of places. To my mind, a lack of civic consciousness, tenacity and the 'will to live' has been responsible for such a poor response in extension work. As the dispensary is the field unit from which anti-tuberculosis activities emanate, we are insisting not only on the opening of more clinics in the city and in the *mofussil* but are also trying to impose on them certain conditions for affiliation in order to ensure a uniformity of working methods throughout the province. Where *mofussil* centres are not affiliated, we have found it extremely difficult to exercise the necessary supervision and to introduce uniform procedures in diagnosis, treatment and follow-up work.

We are ashamed to note that in a province with a population of 4.6 crores we have got only one tuberculosis hospital of 139 beds, and that in the suburbs of Calcutta. A scheme for establishing a climatic sanatorium for this province was formulated in 1935. A Government committee was appointed to select a suitable site and the entire capital expenditure of the scheme amounting to about Rs. 3 lakhs was obtained from a Marwari philanthropist. The committee unanimously selected a site in the Kalimpong hills but, for some unexplained reason, the Government has not yet been able to start the sanatorium. But a small beginning has been made by the authorities of the Calcutta Medical Aid and Research Society in establishing a small sanatorium for non-pulmonary and convalescent pulmonary cases at Kurseong in the Darjeeling district (1937), which has provision for 24 patients.

We should like to refer to a very unreasonable objection on the part of the public in many parts of Bengal against the establishment of tuberculosis institutions in the neighbourhood of, but well removed from, towns. The funds for the establishment of a tuberculosis hospital 23 miles from Calcutta (Rs. 1,15,000) and of a sanatorium near Kalimpong (Rs. 3 lakhs), obtained by donation from two philanthropic citizens, have been lying idle for over three years, owing to uninformed criticism and objection from the residents of the neighbourhood. It is now accepted in all parts of the world that modern scientific hospitals and sanatoria are rather safeguards to the health of the locality, far from endangering it in any way. We feel that the State should intervene and override all such objections; otherwise, the establishment of tuberculosis institutions will be well-nigh impossible in any part of the province. It is realized that suitable educative propaganda should, at the same time, be carried on to transform the views of the public.

E. CO-OPERATION WITH OTHER PUBLIC HEALTH BODIES

We have had a very happy relationship as regards co-operation and co-ordination with the

Public Health Department of the Government of Bengal and with the Red Cross Society. We cannot say the same thing in the case of municipalities and district boards, most of which do not seem to have appreciated the seriousness of the problem and their duties in relation to it, or their inactivity must be due to the proverbial lethargy of our people. In any case, it seems to us that it is worth while educating the members of the self-governing bodies to help them to form a sympathetic opinion about the problem and the measures proposed to cope with it, so that they may take energetic action. We have also noticed a certain amount of duplication of effort regarding publicity methods employed by the Public Health Department of the Government and local bodies. It is a matter for consideration how far our respective efforts in these directions should be co-ordinated to avoid overlapping, to secure economy and to achieve better results.

We realized from the very beginning that the general practitioner was the backbone of the profession and that he was an important key to the application of anti-tuberculosis measures in the family. It is a matter of regret that the profession in general, in this province, has not yet responded by coming forward to consult the dispensaries for diagnosis, advice, follow-up and notification to the extent that we desire them to do. The private practitioner should be made to realize that the Association's activities are only complementary to his position as a family physician. This aspect of the work requires further consideration from all anti-tuberculosis workers.

We have tried to establish a close contact with the education department and with the maternity and child-welfare clinics. We have not been satisfied with the progress so far made in both cases. Two reasons may be ascribed to the poor progress in school medical inspection regarding tuberculosis :—

(i) The educational authorities have not yet fully realized the significance of the fact that a large number of students and teachers fall victims to tuberculosis in the prime of life, and that it is of the utmost importance to detect and take care of these persons in order to safeguard the health of the rest. I would even say that the educational authorities ought to make suitable arrangements, by establishing their own clinics and sanatoria, for the proper diagnosis and treatment of such cases, by introducing some sort of health insurance system, as prevails in German universities.

(ii) The inadequate medical staff of the department, who are not specially trained in tuberculosis, cannot render effective service and co-operation in this direction.

As regards maternity and child welfare clinics there ought to be more co-operation than we have at present. It seems to us that periodical joint meetings of the medical and health

visiting staffs of these two organizations might be useful in achieving the desired end.

The importance of the follow-up and after-care of cases treated at the dispensary or discharged from hospitals or sanatoria has been recognized from the very beginning. We cannot say that we are satisfied with the progress made in this direction. The Association printed 'after-care notification cards' and distributed them to different hospitals with a request to refer all discharged tuberculosis cases to the care of one or other of the recognized dispensaries. But we regret to note that in a very few cases is this done by the authorities of tuberculosis wards, hospitals, and sanatoria. Surely, the time has come for a better relation and co-ordination for a common purpose in this direction.

In spite of our best efforts we have not been able to develop 'care committees' in touch with the dispensaries. This has been partly due to the apathy of the population but chiefly to the absence of social insurance organizations in this country. An attempt has, however, been made to give additional nourishment to deserving cases from the funds of the Association but a central organization like the Tuberculosis Association of Bengal cannot set free adequate funds to supply the needs of a large number of deserving cases in this direction. One fact has, however, been observed which is worth recording—wherever additional nourishment (milk, fruits and cod-liver oil) has been given to indigent patients in their homes, an increase in weight and an improvement of the general condition have been generally noted, so that any money which can be spent in this direction will be well spent. In the absence of regular 'care committees', the Association has fought for the reinstatement of 'arrested' cases, who were wrongfully discharged by their employers without sufficient reason, and has succeeded in some cases.

As regards the re-instatement of arrested cases among the Government employees, the Association has been able to induce the provincial sanitary board to ratify certain standards for the re-employment of such persons. The Association is now trying to influence the opinion of big employers of labour, like the railway companies, to accept these recommendations. The criteria for temporarily or permanently invaliding employees have also been drafted and accepted by the sanitary board.

As a result of representations made to the Government of Bengal, a tuberculosis sub-committee of the Bengal sanitary board was formed early in 1935. The Association has three representatives on this committee—the honorary secretary, the chairman of the medical sub-committee and the health officer of the Calcutta Corporation. The Association is also represented on the Bengal provincial sanitary board. Our representatives on these committees have fought

for a proper notification and registration of cases, for post-graduate education and other cognate matters. Certain legislative measures are under the consideration of this committee at present.

The present position with regard to certain types of institutions and their co-operation with the dispensary organization is shown in the following diagram of a complete anti-tuberculosis scheme. The defects in the present Bengal organization are indicated by the sign plus (+).

Finance

During the first three years, the sources of income were membership subscriptions (life and ordinary) and donations, a grant by the Howrah municipality, contribution from the Bengal Health Welfare Committee (Red Cross) and the sale of two million 'health seals' presented by the National Tuberculosis Association of America. These seals used to fetch an income of Rs. 4,000 to Rs. 5,000 every year. Ladies used to take a prominent part in the sale of these seals, which was further facilitated by the co-operation of the various post-offices in the city. The Indian Red Cross Society showed their practical sympathy from the very beginning by advice and contributions. The King George Thanksgiving (Anti-tuberculosis) Fund, which was inaugurated in the same year as the Tuberculosis Association of Bengal, has regularly given a grant of Rs. 3,000 to Rs. 4,000 a year since 1932. In the year 1932, the sale of anti-tuberculosis matches, prepared and printed in England, was given a trial. But this did not seem so popular as the health seals. This method of raising money was subsequently replaced by the organization of an anti-tuberculosis flag day.

Our flag-day organization has now become a comprehensive and effective procedure in raising funds for anti-tuberculosis work, as will be judged from the fact that we collected Rs. 7,750 in 1937 and Rs. 9,600 in 1938. A complete list of the areas, workers and prospective donors and subscribers is kept in the office and is being constantly enlarged. It is hoped that the more comprehensively we reach the public the higher will be the collections in future. A thorough publicity organization is very necessary for the success of such collections.

It has been stated before that the Government of Bengal has been giving a contribution of Rs. 10,000 a year from 1934, and there is a grant of Rs. 4,750 by the Calcutta Corporation. The Bengal provincial branch of the Indian Red Cross Society has given Rs. 1,500 a year. Besides these supports, private agencies, such as the Royal Calcutta Turf Club, the Alexandra Rose Day Fund and various commercial firms, have given liberal support to the funds of the Association.

It may be mentioned here that the 'health seals' campaign has not been given a fair trial

in this country. From our three years' experience with it, we firmly believe that it is likely to prove to be a great source of income if properly organized. It may be of interest to know that the seal sale campaign which was first introduced in Denmark in 1907 and later in the U. S. A. in the same year has proved of great help in supplying funds for anti-tuberculosis work. The seal sales in U. S. A., which fetched 3,000 dollars in 1907, fetched 5,500,000 dollars in 1930. A method of collection by which the largest number of people can be reached serves more than one purpose—(i) it helps to raise funds and (ii) it changes the mental outlook of the general population towards the tuberculosis campaign. The student community in Bengal has proved to be one of our best supporters in our fund-raising campaigns. Women workers have also been our staunchest supporters. An idea of the different sources of revenue will be judged when it is stated that in the year 1937 the Tuberculosis Association received Rs. 21,500 from grants from various sources enumerated above, Rs. 450 from ordinary membership fees, Rs. 1,200 from life membership fees, Rs. 7,500 from the flag-day collections, besides smaller donations in cash and kind from various firms and associations. Thus, apart from the grants, the Association had to raise over Rs. 16,000 for its general expenditure.

Building fund

A fund was started in the year 1935 for building a permanent headquarters office and clinic fitted with x-ray apparatus. The fund stood at Rs. 17,000 at the close of 1937. The Association took part in the building of an annexe at the Jadavpur Tuberculosis Hospital for poor Anglo-Indian patients. Late in September 1931, the Presidency General Hospital, which has been caring for a certain number of advanced tuberculosis cases in the verandahs of the wards, found it necessary to evacuate these patients, eleven in number, owing to financial stringency. The Association arranged for housing and nursing them in a temporary shed at the Kidderpore parsonage, until sufficient funds were raised, through the kind co-operation of the Metropolitan's Committee, the Red Cross Society and the Rotary Club of Calcutta, to construct an annexe at Jadavpur for their accommodation and treatment. A part of the recurring expenditure is obtained from the Red Cross Society, the District Charitable Society and other sources.

X-ray fund

An x-ray fund, called the 'Kalyani x-ray fund', was started in 1936 for supplying free x-ray facilities to indigent tuberculous patients. The fund now stands at Rs. 1,500.

Nourishment fund

The Association made an attempt to start a 'nourishment fund' from the beginning but their

efforts in this direction have not been very successful. Only Rs. 320 were collected in 1937. We feel that this work should be legitimately delegated to 'care committees' in the dispensary areas. The invested funds of the Association now amount to Rs. 25,000.

Appreciation

A silver challenge shield, called the 'Hassan Masud Suhrawardy Memorial Shield', was

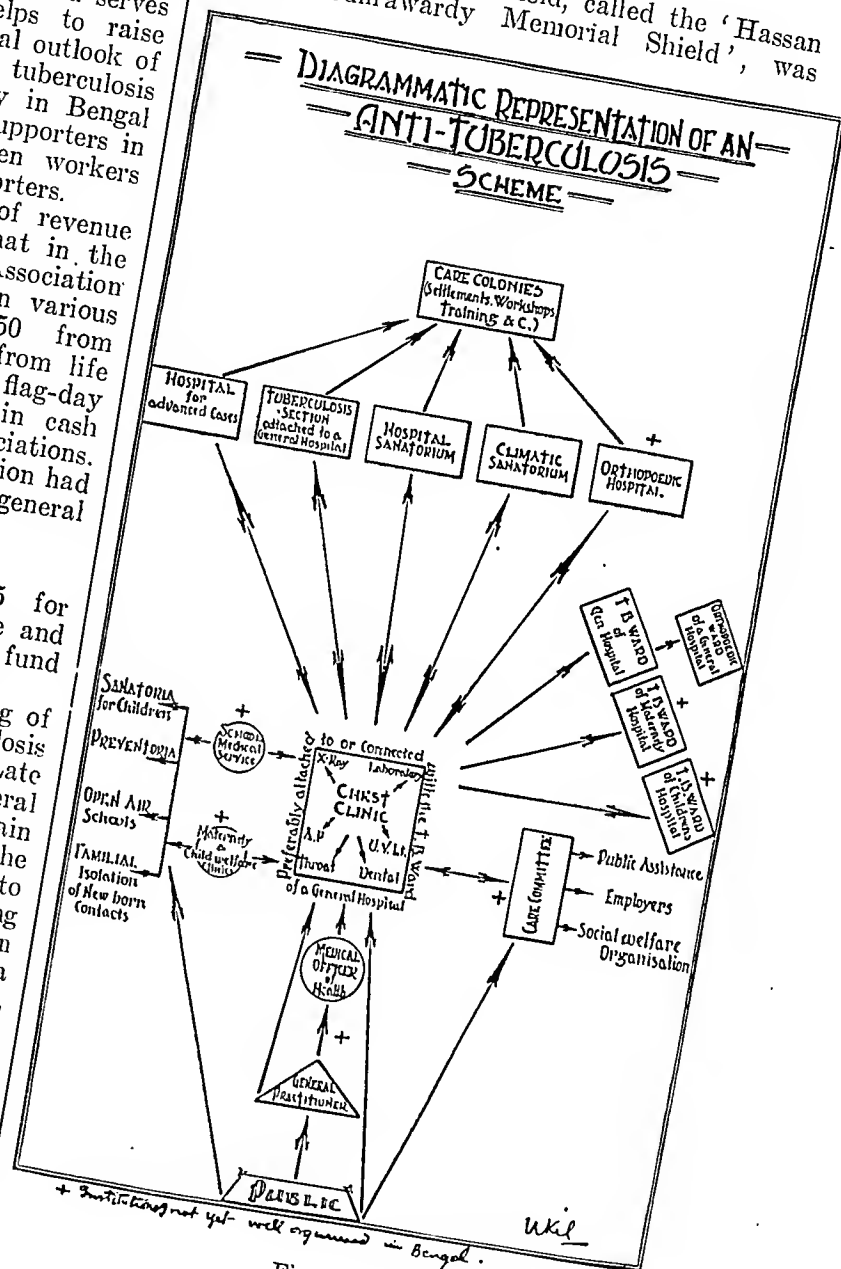

Fig. 6.

placed at the disposal of the King George Thanksgiving (Anti-tuberculosis) Fund by Sir Hassan Suhrawardy, an eminent medical man of Bengal; offering it annually to any corporation, municipal council, or municipal committee, or any other organization, association or committee doing anti-tuberculosis work in British India and the states, which showed the best anti-tuberculosis activities during the

year. The Tuberculosis Association of Bengal won the shield twice—in 1934 and 1937—in appreciation of its work.

An ever-increasing demand from the neighbouring provinces for facilities for anti-tuberculosis training under the auspices of the Tuberculosis Association of Bengal shows that its working methods are being appreciated far beyond its own territories. The different committees of the Association are keenly trying to perfect the working methods every year. Although a fair amount of progress has been made, much remains to be done yet; so there is need for a continuous study and progress.

The problem and the future

The problem of prevention of tuberculosis in this country is complicated by the fact that we have to deal with a country which is chiefly rural, where the population is largely uninfected or imperfectly immunized *vis-à-vis* the tubercle bacillus and where education is so backward. The home survey and public health education of such an enormous population is a matter of considerable complexity. The problem of the rural areas differs considerably from that of the endemic towns and cities containing a large number of people within a small area, where special problems like overcrowding and insanitary surroundings have to be fought by a better housing and town-planning campaign. The problem differs still further in industrial areas where, apart from the hazard of the trades, a large number of uninfected rural people are brought together and made to live under conditions which favour large-dose infection. Thus, measures for the amelioration of overcrowding, under-nourishment and trade hazards in industrial areas also come within the sphere of activities of a tuberculosis association.

It has been noticed that an increasing number of rural people who migrate to highly endemic cities or industrial areas as students, young females, clerks, menials, indentured labour, etc., fall victims to the disease more frequently than urban people. Their protection by the administration of a protective vaccine, like the B.C.G. vaccine of Calmette, should receive serious consideration from all public health authorities.

It has been noted that, if cases are detected early and are treated on modern scientific lines, the results of treatment are as good here as in European countries. The question of early diagnosis, therefore, is an important one in preventive work. But for an early diagnosis campaign three things are essential: (1) an alert medical profession trained in modern methods of diagnosis and treatment of tuberculosis, evenly distributed over the affected areas, (2) suitable public education, which would induce suspected cases to seek medical advice at the earliest opportunity, and (3) the placing of facilities for modern diagnosis and treatment

within the reach of people and in areas where the need is greatest.

When we remember that 30 per cent of the patients taken care of at the dispensaries are without employment, any provision that we make for institutional treatment must be largely free or subsidized; otherwise we shall not be able to isolate the infectious cases, which should be the principal aim of all anti-tuberculosis efforts. According to a modest estimate, we have in Bengal approximately 200,000 'open' or infectious cases. To think of isolating even a reasonable fraction of these cases in institutions would be building an Utopia at the present moment.

Where then shall we begin? The dispensary system must, therefore, form the foundation scheme of any anti-tuberculosis programme as being the most easily operative and the least costly of them. The Tuberculosis Association of Bengal has devoted its efforts to implement this part of the scheme. But we have been immediately confronted with other facts which cannot be ignored. We have found that the dispensaries, which can only take part in domiciliary treatment, case-finding, education and unsatisfactory isolation of cases in the home, find it extremely difficult to take care of cases which should better be placed in preventoria, sanatoria, hospitals or care-colonies. If Bengal possesses 400 dispensaries, according to accepted Western standards, she can arrange for the ambulatory surgical treatment of only 15,000 to 20,000 cases. According to our calculation, Bengal should have 400 dispensaries, sanatorium or hospital accommodation for 30,000 early and moderately advanced cases, isolation hospitals for 40,000 advanced cases, 20,000 seats in care-colonies, 5,000 seats in preventoria and 10,000 beds for glandular and osteo-articular cases. A modest scheme prepared by us some time ago (*vide Calcutta Municipal Gazette*, 9th April, 1938, pp. 29-39) placed the immediate financial requirements of this province at Rs. 22 lakhs for capital and Rs. 2 lakhs for recurring expenditure. How and when can it be made available?

Happily for us a noble Vicereine of India has taken up the problem and has made a timely appeal on behalf of the suffering population of this country. We shall not probably get the whole of the money that we require, but it will undoubtedly help us to make good progress. Money alone will not solve the problem, unless the Government machinery, the local bodies and the public in general whole-heartedly co-operate with the eradication of the 'white plague'. Though there is a long way ahead and though we have not yet been able to touch even the fringe of the problem, there is no reason to despair. We must remember that 'honest work diligently made never goes unrewarded'. Let us live in this faith and go along cheerfully ministering service to the distressed, until we attain ultimate victory.

THE SERIOUSNESS OF TUBERCULOSIS IN INDIA AS SHOWN BY A STUDY OF INCIDENCE AND TYPE

By P. V. BENJAMIN, M.B., B.S. (Madras),
T.D.D. (Wales)

*Assistant Medical Superintendent, Union Mission
Tuberculosis Sanatorium, Arogyavaram, near
Madanapalle, South India*

Our knowledge at present as regards the incidence of tuberculosis in India is very meagre, as there have been few scientific investigations and these very limited in extent. Apart from these few investigations, our main knowledge rests on general observations deduced from dispensary and hospital records and mortality statistics. As regards health in the larger cities, because of the better facilities for collecting statistics there, it is known for certain that tuberculosis is exceedingly prevalent, but what the conditions are in the villages is largely a matter of conjecture. Many detailed surveys will have to be done over large and varied areas before we can get any real idea as to what is the actual state of affairs.

Tuberculin surveys

One of the ways of getting knowledge as to the extent and distribution of tuberculous infection is by tuberculin surveys of many thousands of people in different parts of India and in different communities, under differing conditions, urban and rural.

Ukil (1930) gives figures for a tuberculin survey of 6,500 individuals very predominantly urban, and a jail population, and a positive reaction was found varying from 11 per cent in those of five years and under to 75 per cent in those of 60 years and over. He also shows that the figures for rural areas are much less than for urban and that the positives increase as the conditions approach the urban.

Tuberculin survey of 6,665 individuals in South India

A tuberculin survey was carried out by the U. M. T. Sanatorium in parts of the Chittoor District and its environs, 3,015 in 1937 (Benjamin, 1937) and 3,650 in the present year. In these two surveys were included three *taluk* headquarters towns with a population varying from 4,000 to 10,000, two large villages with a population each about 1,000, and a number of small villages with populations varying from 50 to 300. In some of the villages, the whole population was tested. In addition, the survey included four schools in Madanapalle, one in Vayalpad, two in Chittoor, two in Kolar Town in the Mysore State, and an industrial school in Kâtpadi in North Arcot District.

The test was done without any selection in the towns and villages, for all ages and both sexes. All communities, Hindus, Christians and Muslims, were included. The majority tested

were of the poor and middle classes, as these formed the bulk of the population of the areas tested. But a number of well-to-do families was also tested.

In this tuberculin survey, the total number tested was 6,665, composed of Hindus 4,201, Indian Christians 1,668 and Muslims 796.

From these, 163 persons are omitted—Hindus 43, Christians 101 and Muslims 19—as they were coming into personal contact with tuberculous patients in the wards of the sanatorium during their daily work and, as such, were specially exposed to infection and could not be considered as a sample of the normal population.

There is no question of tuberculinization of the villages proceeding from the sanatorium, as most of the villages and all the small towns tested were miles away from the sanatorium. It is interesting in this connection to note that 227 persons living in the sanatorium compound, but not attending on patients, showed a percentage of tuberculin positives similar to that seen in the village group.

Technique

The method used for the tuberculin test was that of von Pirquet, according to the modern technique, with a scarification of the skin about half an inch long through tuberculin already applied to the skin, using, of course, the usual aseptic precautions. Readings were generally taken after 48 hours, a few only being after 72 hours, and the intensity of the reaction was noted under different heads. A positive was recorded when there was palpable oedema and redness of a width of more than 2 mm. When the width was from 3–5 mm., it was noted as +; from 6–10 mm. as ++; over 10 mm. as +++. The tuberculin employed was Burroughs, Wellcome & Co., Old Tuberculin, Human (T).

We realize that the Mantoux intra-dermal test is the more sensitive, and has the advantage over the von Pirquet test, that in a particular individual successive tests can be done with graded doses and the results compared. This should be the test used when the group tested is under control, and is amenable to such a test.

In the communities such as those with which we had to deal, it was impossible to use the Mantoux test involving an injection, except in a few educated individuals.

In this connection it is interesting to note that such an eminent tuberculosis worker as Bardswell (1938), in a recent tuberculosis survey in the island of Cyprus, had to abandon even the von Pirquet test, and do Morro's inoculation test, because of the difficulty of getting the co-operation of the population. Heimbeck (1938) is of the opinion that the accuracy of the von Pirquet reaction, according to modern technique, is very good, and that the margin of error, when compared to the Mantoux test, is only 1.8 per cent in persons below the age of 15, and only 3 per cent between the ages of 16 and

30. The von Pirquet test has been variously estimated to be equivalent to 1 in 10,000 dilution used for Mantoux (Dow and Lloyd, 1931), and 1 in 2,000 (Matthews, 1931), and in the African survey reviewed by Cummins (1935) as roughly comparable to the intradermal test with 1 in 5,000 dilution of tuberculin.

Analysis of findings

As a result of this tuberculin survey, we find that the average percentage of positives for the whole group is 37.8 for adults and 10.8 for children under 15 years of age. In small towns, children under 15 years of age showed 11.6 per cent positive and in the villages 8.2 per cent. Adults showed 40.1 per cent in the towns and 30.8 per cent in the villages. This is shown in table I.

too small a number on which to form any opinion; but it would be interesting to see in further investigations whether this higher percentage in the villages persists, and, if so, what are the special factors contributing to this.

It is of some importance to note the intensity of reaction. In Europe the intensity of reaction is not of such great importance among adults, but among small children an intense reaction is usually associated with active disease. Among Africans, the significance of a tuberculin reaction has been found to be similar to that among children in the European races. Hypersensitivity to tuberculin is considered a serious matter in Africans and other primitive races, as this hypersensitivity is not associated with an immunity, but just the opposite, and, therefore, is a danger signal. What the significance of

TABLE I
Results of a tuberculin survey

Community	TOTAL						TOWNS						VILLAGES					
	Adults			Children			Adults			Children			Adults			Children		
	Number	Positives	Per cent	Number	Positives	Per cent	Number	Positives	Per cent	Number	Positives	Per cent	Number	Positives	Per cent	Number	Positives	Per cent
Hindus	1,995	730	36.6	2,163	214	9.9	1,401	562	40.1	1,664	183	10.9	594	168	28.3	499	31	6.2
Indian Christians.	701	227	32.4	866	92	10.6	574	192	36.9	647	72	11.1	127	35	27.6	219	20	9.1
Muslims	393	210	53.4	384	64	16.7	332	172	51.8	317	51	16.1	61	38	62.3	67	13	19.4
TOTAL	3,089	1,167	37.8	3,413	370	10.8	2,307	926	40.1	2,628	306	11.6	782	241	30.8	785	64	8.2

When we analyse the total number investigated according to different communities, we find that there is very little difference between the Hindu and Indian Christian groups, but a marked difference is found in the Muslim group, the percentage of positives being much higher in this group than in the two other groups, both in towns and villages, and also among adults and children. Compared with 36.6 per cent and 32.4 per cent positives for Hindus and Christians respectively, Muslims show 53.4 per cent positives for adults, and 16.7 per cent for children, as compared with 9.9 and 10.6 per cent for Hindu and Christian children. While among Hindus and Christians the percentage of tuberculin positives is higher in the towns than in villages, among the Muslims the opposite is found. The *purdah* system and special social habits among the Muslims may increase the chances for tuberculous infection and consequent higher percentage of positives in this community, but why the villages show a higher percentage than towns cannot be explained. As this group comprises only 777 individuals, it is

sensitivity to tuberculin means in India, we do not as yet know.

In table II are given the reactions found in the investigation.

It will be seen from this table that 56.4 per cent of the positives were reactors with a reaction between 3 and 5 mm. wide; 31.5 per cent with a reaction of 6 and 10 mm. wide; and 12.1 per cent with a reaction of above 10 mm. wide. If we group the two stronger reactions together, we find that as regards community, Muslims have as many as 61.3 per cent of the strong reactions, whereas Hindus have 40.5 per cent, and Christians 37.6 per cent.

The higher percentage of strongly positive reactions among the Muslims coincides with a higher percentage of infection rate among the same community as shown by tuberculin tests.

It was possible to persuade 69 of those showing strong reactions, and a few with suspicious symptoms, to come to the sanatorium for x-ray and other examinations. Of these, seven were found to be suffering from active tuberculosis, five of them with cavities and positive sputum.

TOTAL ..	6,665	1,660	

clerks, and those with in-door occupations. The group with the lowest percentage among adults is those engaged in agriculture. Those whose occupation could not be definitely ascertained and also those where the numbers were less than ten in any single group are all grouped together in the miscellaneous group.

It is evident from the figures given by the above survey that the villages in the area surveyed are no longer free from infection, and are not 'virgin soil' in the formerly accepted sense of the word, and yet this area is comparatively isolated with some of the villages about 25 miles away from rail and main roads, is sparsely populated, and has one of the best climates in South India.

comparatively large proportion of these show a tendency to chronic disease with localization, and marked fibrosis round tuberculous foci and cavities, but this state of affairs does not hold good for other races. Investigations done in America among the negroes and in Africa among the native population show an entirely different type of disease. A recent investigation done in Tanganyika (Wilcocks, 1938) shows a preponderance of cases of acute 'galloping consumption' and bilateral disease. Fibrosis is not common, and, when it occurs, does so chiefly in middle-aged people. The lung bases are frequently attacked. Cavitation is frequently seen, but it is rare to see a zone of fibrous tissue round these cavities. Massive consolidation is

occasionally found, and military spread often occurs.

Type of disease found in patients in India

A detailed study has been made of the type of tuberculosis found in 2,158 Indian, Anglo-Indian and European patients admitted to this sanatorium since 1930, all of whom were diagnosed as suffering from pulmonary tuberculosis. With a view to the determination of type, the following points were studied: the amount of fibrosis, evidence of previously healed lesions, tendency to dissemination, the question whether one or both lungs were involved, the amount of cavitation, all as shown in x-ray films; the evidence of resistance to the disease as shown by the length of time between onset of symptoms and admission to the sanatorium, the activity of the disease as shown by blood examinations (Schilling count and sedimentation test).

The results are shown in table IV.

cent showed a tendency to localization, while as many as 41.6 per cent showed marked dissemination. In 71.3 per cent of the patients, both lungs were involved. As regards cavities, 73.3 per cent of the patients showed cavitation, 52.5 per cent of these showing more than one cavity; the walls of the cavities in 94.1 per cent appeared soft, and only 5.9 per cent showed evidence of even moderately hard fibrous walls. As regards resistance to the disease, judged by the duration of symptoms before the patients came to the sanatorium, 77.2 per cent of the patients belonged to the 'acute-initial' group, according to Cummins' classification, that is, with continuous symptoms of less than two years' duration, and only 22.8 per cent to the 'chronic-recrudescent' group, that is, with symptoms lasting more than two years, or with symptoms followed by intervals of good health. As many as 72.0 per cent showed high activity of disease, as judged by the blood.

TABLE IV

Analysis in percentage of findings in 2,158 Indian, Anglo-Indian and European patients

	INDIANS		ANGLO-INDIANS		EUROPEANS	
	Number 2,021	Percentage	Number 94	Percentage	Number 43	Percentage
Fibrotic	108	5.3	12	12.7	17	39.5
Exudative	1,879	93.0	81	86.2	26	60.5
Pleurisy	34	1.7	1	1.1
Previously healed lesions ..	321	15.9	30	31.9	19	44.2
Acute-initial, 1 to 24 months ..	1,560	77.2	67	71.3	27	62.8
Chronic-recrudescent	461	22.8	27	28.7	16	37.2
Localized	397	19.6	21	22.3	24	55.8
Moderately disseminated ..	783	38.7	45	47.9	16	37.2
Markedly disseminated ..	841	41.6	28	29.8	3	7.0
Unilateral	581	28.7	20	21.3	18	41.9
Bilateral	1,440	71.3	74	78.7	25	58.1
With cavities	1,482	73.3	61	64.9	21	48.8
Cavities with soft walls ..	1,395	94.1	50	82.0	13	61.9
Cavities with moderately hard walls	87	5.9	11	18.0	8	38.1
With single cavity	704	47.5	32	52.5	14	66.7
With two or three cavities ..	385	26.0	14	23.0	4	19.0
With multiple cavities ..	393	26.5	15	24.5	3	14.3
Activity of disease shown by Schilling count and sedimentation rate—						
Low	157	9.3	13	16.9	5	17.9
Moderately high	315	18.7	13	16.9	12	42.9
High	1,215	72.0	51	66.2	11	39.2

From this table it will be seen that among the 2,021 Indian patients, only 5.3 per cent showed any evidence of marked fibrosis, while 93 per cent showed a predominantly exudative type of disease. Previously healed lesions, as denoted by calcified spots either in the lung or hilus, were seen in only 15.9 per cent. Only 19.6 per

The Europeans are very few in number, being only 43, but among them the type of disease approximates to what is found among Europeans in the west. In the group 39.5 per cent showed evidence of considerable fibrosis and 44.2 per cent of previously healed lesions; 55.8 per cent showed a tendency to localization of the disease.

The figures for the 94 Anglo-Indian patients indicate a type of tuberculous disease in the lung between that of the Indians and Europeans.

Another investigation into the distribution of lesions in the lung (table V) shows that as high as between 71.2 and 73.1 per cent. of the patients have lesions in the middle zone of one or both lungs, and 32.6 to 33.6 per cent have lesions in one or both bases. It is recognized that the more chronic type of the disease is found in the apical and sub-apical zones of the lungs, and that lesions in the middle and basal zones are usually of the more acute type.

The results of these investigations show that for Indian patients the disease is of a very serious type; it is acute, rapidly developing with little tendency to show a natural resistance and healing. The allergic condition is such that there is a severe exudative reaction followed by a rapid breaking down of tuberculous tissue with a resultant cavity formation.

chronic forms of the disease with some severe cases. But when once the conditions of life are changed, by, for instance, migration to the mines, the situation becomes quite different, and a great many succumb to a very acute type of the disease.

In India we seem to have a similar situation. There is a widespread incidence of tuberculous infection, as far as can be judged; at the same time the immunity response is very low. Conditions of life in India are rapidly changing. The villages are being rapidly brought into contact with towns and industrial centres through improved means of communication. A liking for the amenities of civilization attracts people from the villages. There are more opportunities for infection in the increased concentration of people for education as well as for industry. The poverty of the villager makes him easily lured to the town in the hope of quickly getting rich there. Life in the city is usually associated

TABLE V
Distribution of Lesions in the lungs

	RIGHT LUNG LESIONS				LEFT LUNG LESIONS

Percentage	56.5	67.7	71.2	32.6	48.1	60.3	73.1	33.6

Conclusions

In the earlier part of this paper a review has been made of a tuberculosis survey in a limited area and of a study of the type of disease found in Indian patients. The survey, of course, is too small and limited to be able to form from it any general conclusions for the whole of India or even for districts or areas outside that surveyed. It does, however, support the general impression that tuberculous infection is wide-spread even in the villages.

The study of the type of the disease found in Indian patients can perhaps be used for a general conclusion, as the patients included in the study have come from all parts of India, and little difference has been noticed in the type of the disease in patients coming from different parts of the country. It may be concluded that for Indians as a whole tuberculosis is a very serious disease, because of its tendency to show itself in an acute, rapidly developing form. This reveals a general lack of immunity among Indians as a race.

The African investigations, already referred to, show that, as long as the Africans remain undisturbed in their own natural surroundings, tuberculosis does not appear as an epidemic disease, but it spreads comparatively slowly, and there are a large number of relatively mild and

with much increased strain both mental and physical. Not only is this true in the city, but it is equally true wherever civilization is making headway, even in the villages.

The changing conditions of life in India to-day, taken in conjunction with wide-spread infection and a low immunity, make tuberculosis an increasingly grave problem.

DEDUCTIONS FROM EXPERIENCE IN A TUBERCULOSIS EX-PATIENTS' COLONY IN INDIA

By P. V. BENJAMIN, M.B., B.S. (Madras),

Colony*

DEVELOPMENT OF AFTER-CARE SCHEMES FOR EX-PATIENTS

IN the earlier stages of the campaign against tuberculosis in the West, emphasis was laid on the treatment of the tuberculous patient, generally in a hospital or sanatorium, and then, when the hospital or sanatorium had done all that it possibly could, the patient was discharged to return to the conditions of living from which he came. Fortunately for many of these patients, the conditions of living and work to which they returned did not upset the favourable results gained during treatment, and these patients were able to remain well, even when they resumed their old or similar ways of life. But there were always a number who could not stand the strain of their old conditions and who broke down and sometimes returned for institutional treatment; others died at home. In addition to those who returned to their ordinary life with either probability or possibility of remaining well, there were discharged year by year a number of patients with a positive sputum in spite of treatment, who were not only a potential source of danger to those among whom they lived, but who had often little hope of being able to maintain the condition of equilibrium obtained by their treatment. The poor ex-patient was more likely to break down than the more well-to-do.

Macnalty (1932) writes 'The patient in a good economic position can, upon his discharge from a sanatorium, live the carefully regulated life prescribed under satisfactory conditions with a good prospect of the benefit he has received from sanatorium treatment being consolidated. The patient less favourably circumstanced, on the other hand, returns only too frequently to the full stress of life, to unsatisfactory conditions of living, and finds it impossible unaided to carry out the directions he has received. It is the common experience that patients so situated not infrequently relapse'.

It is now more and more being recognized that the ultimate results of treatment to a great extent depend on the after-care of patients, and without this after-care much of the expenditure of skill, time, and money in treatment is wasted.

Many patients can, however, return to their normal lives with every prospect of keeping well. Sandiland (1937), although it is not known in what stage of the disease were the

patients to whom he refers, considers that 50 per cent of patients could return to their former employment or some modified form of it, while 15 per cent will remain chronic invalids and the remaining 35 per cent need some form of after-care schemes, as they will be unable to compete with healthy men in their former employment.

In India, follow-up figures for ex-patients are not very numerous. But Frimodt-Møller (1937) finds that of 1,695 patients whom he has been able to trace out of 2,604 patients treated in the U. M. T. Sanatorium at Arogyavaram, Madanapalle, 898 or 53.0 per cent were alive five years after leaving the sanatorium and 819 or 48.3 per cent were doing full work. If we omit those who were discharged with no improvement as a result of treatment, namely 434, we find that of the remainder, 1,261 (*i.e.*, those who have gained improvement) or 64.4 per cent were doing full work five years after leaving the sanatorium. The three stages were approximately equal in number, namely, 430, 429 and 402 for stages I, II and III, with 88.4, 73.9, 45.2 per cent respectively alive and working five years after discharge. These figures prove at any rate that a large proportion of patients who leave the sanatorium, having gained improvement, on returning home can remain well and do full work under the ordinary conditions to which they have been accustomed. On the other hand, 35.6 per cent were unable to keep up the improvement that they obtained while under treatment in the sanatorium and died of their tuberculosis within five years.

It is in the effort to help this class of patient that various after-care schemes, such as colonies, village settlements and workshops have been brought into being. But as Brieger (1937) says in summarizing a survey of various schemes 'This historical retrospect intensifies the impression that "the road of after-care is strewn with combatants and dreamers, with the disillusioned and shipwrecked". The problems were recognized, but the underlying principles were not stated and the methods by which a solution was attempted were inadequate'. Again, speaking of the establishment of separate after-care institutions, he writes:—'The organization of treatment and after-care in distinct units, each of which was intended for the fulfilment of one object only, is a system which has not shown itself capable of development and has not been equal to the problems set by the rehabilitation of the tuberculous persons. . . . An attempt to create independent establishments for separate problems of after-care broke the continuity of treatment. . . . On principle, an after-care establishment is justified only if it grows of necessity out of a sanatorium'.

AFTER-CARE FOR EX-PATIENTS AT U. M. T. SANATORIUM

(a) *Ex-patients on staff of the sanatorium*

Early in the history of the U. M. T. Sanatorium, Arogyavaram, a request came from some

of the patients themselves for some kind of work in or about the sanatorium by which they could become economically independent in the security given by those who knew their medical condition. This was mainly from those who were discharged as 'much improved' and whose disease was not completely 'arrested'. As has been done in many parts of the world, the sanatorium has attempted to provide for a number of such ex-patients by finding them employment on the staff of the institution. Since the beginning of the sanatorium in 1915, but mainly since 1920, work, either temporary or permanent, has been found in this way for 20 men and 19 women, as nurses or nursing orderlies, clerks, store-keepers, x-ray and laboratory orderlies, teachers, motor driver, doctor, pathologist, peons; a few have taken a special six months' course of training in laboratory work and have afterwards gone to other hospitals. But the number of ex-patients which a sanatorium can take on its staff is limited, partly by the number needed on the staff, partly by the number it can afford to take, partly by the technical nature of much of the work and partly by the need of having a fair proportion of its staff who are physically strong. In this last connection it must be stated, however, that a number of the ex-patients taken on the staff have after a few months' work proved that they are quite capable of doing full-time work, without any fear of a break-down.

(b) *The ex-patients' colony*

There were soon found to be a large number of patients who needed some kind of after-care but who could not be taken on the staff of the sanatorium either for the reasons stated above or because they could not, for physical reasons, undertake the kind of work required in the sanatorium, or else they were not educationally or culturally equipped for such work. Yet these kinds of patients also begged to be provided with any kind of work by which they could live and be close to medical help. The result was that in 1920 a small ex-patients' colony section was begun privately, which included at first silkworm rearing, silk spinning and weaving, and cotton weaving. Later, the need was felt for further kinds of work, specially as the output of hand-woven products that could be sold was limited. In 1930 the colony became a separate entity and was registered under Act XXI of 1860. A site of about 9½ acres adjoining the sanatorium was purchased by money raised among and through the staff of the sanatorium. The site purchased included some village houses, wells, and a fruit garden. The weaving section was removed to this new site.

The colony was registered as a separate body mainly for financial reasons peculiar to the sanatorium, but such a separate registration may not be necessary for all such institutions. Although the colony is an independent unit, it is organically bound to the sanatorium through the

governing body of the colony; the majority of the governing body are by constitution leading members of the staff of the sanatorium and the other three of the governing body have also been members of the staff of the sanatorium, including two ex-patients. The result is that the whole policy of the colony is directed by those who have an intimate knowledge of the problems of tuberculosis and of the needs and abilities of ex-patients.

The colony has been slow in its growth, largely because of the difficulty of getting money for its expansion. It has been impossible to take in a great many who applied for admission and who really needed colony treatment. At present there is accommodation for eleven ex-patients and two of them are married men with their wives living with them, and one of them has three children, two born in the colony. The activities of the colony have gradually expanded, and besides silkworm rearing, and silk and cotton weaving, there have been carried on vegetable and fruit gardening, poultry and cow-keeping, printing with a very small hand-press, tailoring, various small crafts, such as palm-leaf weaving, papier-mâché work, and experiments in fruit-syrup and soap making; in addition, a general store has been developed which began with an ex-patient with one coolie carrying about merchandisc in a basket, and which has now developed into a proper shop with a turnover of about Rs. 2,000 a month and employing 5 ex-patients.

Altogether 37 ex-patients have been taken into the colony for shorter or longer periods.

TYPE OF EX-PATIENTS ADMITTED TO COLONY OR EMPLOYED BY THE SANATORIUM

It is of interest to see what kind of ex-patients have been admitted to the colony or have been employed on the sanatorium staff. The following table shows the stages (Turban Gerhardt) in which the patients originally were admitted to the sanatorium and the results of treatment on discharge, and also whether their sputum was tubercle-positive or negative on admission and discharge. The figures include 57 men and 19 women, in all 76. They include 68 Indians, 7 Anglo-Indians and 1 European; 2 patients treated in other sanatoria, about whom records are incomplete, were also employed.

It will be seen that the majority of the ex-patients were in stage III, 43 out of 76, and of the whole number only 14 or 18.7 per cent were discharged as 'arrested'. As regards sputum, 57 or 75 per cent were positive for tubercle bacilli on admission, and 19 or 25 per cent were still positive on discharge.

The majority of patients afterwards admitted either to the colony or taken on to the sanatorium staff had had to have a long period of treatment and did not show a quick response. The average length of treatment for the 76 patients was 497 days, being 192 for those in

TABLE I

Stage	Number of ex-patients	DISCHARGE RESULTS			SPTUM ON ADMISSION AND DISCHARGE		
		Arrested	Much improved	Improved	+ and +	+ and —	— and —
I	8	6	2	..	1	1	6

				+	+				
				(2)	(1)				

+ (1), + (2) = Deaths from other causes.

stage I, 378 for those in stage II and 625 for those in stage III.

No women have been admitted to the ex-patients' colony as conditions in India make it more difficult for a colony for women than for men. Of the stage I patients only 2 were admitted to the colony, the rest being connected with the sanatorium staff.

At the present time there are 22 ex-patients in the colony and on the sanatorium staff. Some of the ex-patients have stayed on a few months, others have been as long as 23 years.

The after-history, *i.e.*, the history after discharge from treatment in the sanatorium, is known for all except 5 of the ex-patients, and it covers those who have been away from treatment from six months to twenty-three years.

It will be seen that 54 or 71.1 per cent are known to be alive and working; 14 or 18.7 per cent have died of pulmonary tuberculosis, and 3 are known to have died of non-tuberculous disease—typhoid, pneumococcal pneumonia and heart disease. Of the 19 discharged with a positive sputum, 9 have since died.

The period for which those who died were alive after their original discharge from the

sanatorium varied from one year and eight months to nine years, except for an orphan boy admitted temporarily to the colony who lived only nine months; the average length of life after original discharge of those who died was nearly five years. Of those who died from pulmonary tuberculosis, 7 were in the colony and 7 on the sanatorium staff, and 5 of them died some considerable time after they had ceased to be connected with either colony or sanatorium. It is most improbable that the majority of these ex-patients could have lived so long had they not been in the colony or on the sanatorium staff.

DEDUCTIONS FROM EXPERIENCE WITH THE COLONY

(a) Finance

The financing of an ex-patients' colony depends, of course, on the size of the scheme. But there are certain points which we may quote from our own experience, and a few figures are given to show that a beginning of a colony may be made at a very low cost. A sum of Rs. 2,250 was spent on the site purchased, which included several village houses, a garden, and three wells. The village houses already there were utilized, but made fit for ex-patients to live in by

removing parts of the walls and substituting wire frames, and by putting in stone or cement floors. Other simple, partly open, thatched houses with good floors were built, each costing about Rs. 130. This type of house has been found quite suitable for the purpose, and, in addition to the advantage of cheapness, has the advantage that those who come from villages, if they go back to their villages later, learn that they can live under village conditions and keep well. This is of special importance, as our experience shows that those who value a colony life are mainly those who come from such or similar conditions.

Up to now the capital expenditure on industries has not been very large. The printing was begun with a small Adana press costing, with some accessories, Rs. 60 to Rs. 70. The building used was a small village house with a flat stone and clay roof. This small press has been working for eight years with little additional expenditure, except on more types, and has been able to do a great deal of the small printing required by the sanatorium, in addition to some outside orders.

The weaving shed is a semi-open building with a good roof and a good floor, and houses several looms. The looms were purchased second-hand; these and the building cost about Rs. 800, and since then there has been practically no capital expense. The weaving has supported between 2 and 5 ex-patients.

For a very little expenditure, such as the above, a means of earning a livelihood may be provided for one or more ex-patients. On the other hand, while industries have up to now been on a very small scale, partly for financial reasons, partly because the whole scheme was in the nature of an experiment, there is no reason why in the future we may not look forward to the development of larger industries involving larger capital expenditure. In fact, it will only be possible to develop the colony by having larger industries.

All capital expenditure has had to come from donations. It is not possible to raise money for capital expenditure from the earnings of the ex-patients. This has been found to be the handicap in Europe, and we believe it to be true for India too. To a large extent the labour of ex-patients is sub-standard labour, and in general they need a higher standard of living, as regards food, than the ordinary healthy villager, and hours of labour have to be shorter. This means in most cases a higher rate of salary than would be paid under similar conditions and for similar work in a village. But we have found that it is possible to make the colony self-supporting as regards ordinary maintenance. This, besides being desirable, seems to be necessary to achieve in India, as it is unlikely that for a great many years to come there will be public schemes for support of the tuberculous and their families. Only a few of the western

projects for helping ex-patients are self-supporting, and the deficit is made up in many by subsidies to individuals from sources such as municipalities, district boards, county councils, health insurance. But such sources are absent in India, and therefore, colony schemes or similar schemes will largely have to depend on their own resources.

Another point to bear in mind is that any capital raised for the starting of a colony or industries connected with tuberculous ex-patients will have to be a gift to the cause of helping such people. If the industries started can be made to pay their way, it will be good, but it will be asking what is impossible to require any kind of interest or dividends to be paid on capital invested.

(b) *Relation to sanatorium*

There has been considerable discussion as to whether a colony should be located away from a sanatorium or attached to a sanatorium. We are convinced that to be a success a colony must be in close relation to a sanatorium; whether technically part of the one institution or not, is not of great importance. There are two great principles behind a colony, namely, medical security and work which gives financial security for the colonists.

Medical security is obtained partly by medical control of the whole colony, partly by the presence of skilled medical aid when such is necessary. The work of the ex-patients, specially in the earlier part of their lives in the colony, has to be carefully controlled from a medical point of view. The beginning of life in the colony is a test of the stability which it is thought has been gained in treatment in the sanatorium. There should, therefore, be a possibility of easily transferring a patient temporarily back to the sanatorium, if the stability required has not been obtained.

Moreover, the selection of patients to go on to the colony must be made by those who have been looking after the patients and will continue to look after them. Others cannot make this selection. For example, we admitted one to the colony from outside who had a medical certificate from a tuberculosis officer that he was quite fit for a colony and he arrived with an intestinal tuberculosis for which he needed hospital or sanatorium treatment.

Temporary transfer back to the sanatorium has been necessary in a number of our patients; for example, two of the ex-patients had severe hæmoptysis and temporarily returned to the sanatorium; one had a small hæmoptysis, but after careful examination it was decided to be unnecessary to transfer him back to the sanatorium, and after some days of rest he returned to work and has remained well. Two of the ex-patients had to return to the sanatorium, because of a relapse, and had a phrenico-exairesis operation, after which they were able to return to the colony and have since remained well. Six

ex-patients returned to the sanatorium after being from a few months to several years in the colony, and did not return to it, four of them dying in the sanatorium and two not being suitable for return to the colony. The confidence of the ex-patient in the nearness of medical help, which is one of the reasons why he wants to live in a colony, is only obtained if those who have treated him in the past are there to help, if need arise in the future.

On the other hand, while there is medical control of the colony and skilled medical aid is available if required, there should be as little institutional atmosphere about the colony as possible, and as much freedom as possible should be allowed.

(c) *Selection of the ex-patient for the colony*

An important part of the success of a colony lies in the selection of the right type of patient. Not all ex-patients need a colony life; at the same time not all those who need it are suited for it. Various estimates have been made in England as to the number of ex-patients suited, varying between 10 and 30 per cent.

Very few stage I patients need a colony life after treatment. Only two of those admitted to the colony were in stage I. One had positive sputum on admission and negative on discharge; he tried to live at home several times, but each time went down in health; he has remained well in the colony for several years. The other was a weaver who temporarily went into the weaving section, but could not settle down and returned home after a few months.

Those who most need a colony life are those whose disease has not been 'arrested', especially those in stage III and those who are discharged with a positive sputum. These form the majority of those admitted to our colony. Several have had artificial pneumothorax treatment; one had had spontaneous pneumothorax with empyema.

Only patients who have gained a prospect of stability through treatment should be admitted to the colony. For example, those who cannot stand graduated exercise of more than two furlongs are not suitable for the colony. They still need sanatorium treatment.

Another point is that only those who have had a considerable period of treatment in hospital or sanatorium should be admitted to a colony, because only such persons have learnt their limitations and the necessity of a regulated life to be able to take advantage of the conditions of a colony and remain well. Papworth, the most successful of all colony schemes, requires that a patient must have had at least six months' treatment in hospital or sanatorium, before he can be admitted to the village section. The average length of treatment of those admitted to our colony was 463 days. Three out of the four who were under treatment less than four months could not settle in the colony; the other

was asked to leave as it was not necessary for him to stay.

Certain people who really need a colony life are temperamentally not suited for it. This we have found to be true of several of our ex-patients who stayed for a time in the colony. One who had sufficient private means to be able to live without work and so did not need the income from his work in the colony, could not settle down. Three Anglo-Indians were unable to settle, possibly because the kind of life and society available in the colony was not what they had been accustomed to.

All ex-patients who are admitted to the colony need not stay on for life. A period of some months or years may prove that they have become quite stabilized, and, if conditions at home are suitable, they may then be able to return home and keep quite well. Of 20 ex-patients who have left the colony to go home, after being in the colony for a period varying from some months to several years, 14 are known to be keeping quite well; 3 have died and 3 are unknown.

This sending of patients home from a colony, if there is a possibility of their remaining well outside, will become increasingly possible if and when more tuberculosis clinics are established with good after-care committees. But a nucleus of skilled workers must be retained in the colony even if they are fit to leave, as they are needed for maintaining the industries and training the unskilled.

(d) *The industries in the colony*

One of the fundamental principles of a colony is that those who live there should work, the aim being that through their work they should become economically independent and have the mental satisfaction of being again able to earn their own living.

The choice of industries is limited by certain factors. They must be those that ex-patients are physically able to do; they should be those for the output of which a market can be found; they should preferably be industries which employ a fair proportion of unskilled labour; they should be those which can hope to be self-supporting; they should be those which give mental satisfaction to the workers and encourage self-respect.

Although gardening is one of our sections, we have found that in the climate of South India, the heavier work of gardening, such as digging, is too difficult for ex-patients. But there are many things in a garden of some size which can be done by ex-patients, even if the heavy work is done by coolie labour; seed-sowing, planting out of seedlings, collecting of fruit and vegetables and preparing them for the market, can all be done by ex-patients.

Papworth has found a solution for the heavier type of work by the introduction of machinery wherever possible. This has involved a heavy outlay of capital amounting to lakhs of rupees.

It will be a considerable time before it will be possible to invest a capital of this size in an industry for ex-patients in India, where there is no hope for a dividend. But, in the meantime, much could be done by a judicious use of coolie labour for the heavy part of the work, with ex-patients doing all the direction and the lighter parts of the work.

A beginning can be made with industries for which there is a local demand. A sanatorium of any size has a demand for fruit and vegetables, eggs and milk, printed matter, cotton goods, etc., and it is possible for the colony to undertake the supply of some of these. We began with weaving, especially as there were required by the sanatorium certain kinds of weaving which were done on hand-loom. A certain amount of small printing is required by a sanatorium and can easily be done in a colony. We started with a small hand-press, but, if capital becomes available, a larger press will be bought so that eventually all types of printing may be done. As very little pasturage is available locally, it is not possible for us to do much dairy farming, but in some places this would be very suitable for ex-patients.

Of course, wherever possible, wider markets should be sought and canvassed so that the industries may expand.

Unless the colony has a wide range of industries, it is not often possible to employ an ex-patient in his own trade. Our experience, when we ask what our ex-patients can do, is that they say 'I can do anything'. This amounts to unskilled labour and, therefore, the industries should be chosen which need a fair amount of unskilled or comparatively unskilled labour. One of the difficulties which we have felt is that up till now we have not had enough outlet for unskilled labour.

It should go without saying that the industries chosen should have the hope of being self-supporting. We have had our failures in this respect as we have been feeling our way towards development. We found that under the local conditions we could not make a silk industry pay. We also found that we could not make poultry farming pay; feeding materials are comparatively dear here, disease was common, thefts were common, and the local egg price was 5 annas or less a dozen, and local people did not see why they should pay more for colony eggs, even if they were a little larger and from 'scientifically' fed hens.

Other industries or crafts which we have had in mind as suitable have had to be given up, as materials were not available locally, and the cost of importing them would make production costs too high.

To be mentally and emotionally satisfying and to induce self-respect, industries should be chosen which can compete in the open market and for which there is a demand. Ultimately a colony will fail if it depends on an output which is bought for sentimental and charitable reasons.

This applies to some of the handicrafts. We have tried several, but have given them up. Of course, there are handicrafts which can be carried out, and if the work is of the right standard, its appeal will be on its artistic or practical merits, and not on the fact that it was made by ex-patients and is bought 'to help the poor ex-patients'.

In India, in all our industries, we are up against the problem of keen competition, amounting to the competition of sweated labour. In England, ex-patients' colonies were attacked by the trade unions, but those in charge of colonies paid trade-union wages and on this the ex-patients were able to live. In India, we suffer from the lack of trade unions and a general low standard of living. An ex-patient requires a higher standard of living if he is to remain well.

In the things which do not require much capital, there is the difficulty of competition. We started certain types of cultivation; after a year or two the villager saw it was a good thing and he began and undercut us. Some of our weaving was undercut by schools which included no labour costs in their sale prices, as their work was done by schoolboys. In our shop we are up against competition also and our ex-patients cannot work the long hours of the outside shopkeepers; in spite of this, however, we are able to hold our own. In these ways we find difficulties in our industries; some of our experiments have had to be abandoned, and some have stood the test of time and have developed, and we hope to develop them further.

CONCLUSION

A review has been made of an experiment with an ex-patients' colony for the last eighteen years. Even now it is only small, but we are not sorry in many ways that it has not had a very rapid growth, because we have been learning, specially since its reorganization in 1930, and we believe in the principle of slow growth on the right foundations. Some of the greatest failures in schemes for ex-patients have been those which have begun in the grandest way. One of these is Clairvivre in France for which a capital of 52,000,000 francs was voted by the state. A wonderful town was built for ex-patients and after very few years there were left only a few living in it. The causes for its failure were said to be several, but Brieger (1937) says that 'ultimately it resolves itself into a gigantic housing scheme . . . with the medical side in an entirely rudimentary condition', and it was based on the principle that those who should go to live there should depend on their disability pensions.

'Tuberculous families will take advantage of the amenities of a settlement, if by so doing they are materially and psychologically better provided for (i.e., than they would be outside the colony). Thus, these settlers, in such a community, must build up industries to enable

(Continued at foot of opposite page)

TUBERCULOSIS IN THE ZENANA

By ROSE A. RISTIE, B.S., M.D.

*Director, Tuberculosis and X-Ray Departments,
Women's Christian Medical College, Ludhiana, Punjab*

We in India are not yet living in a world of known facts, so far as tuberculosis is concerned, so we need to collect and pool all our findings, so that we can the better appreciate our problem and organize our forces to combat it. In Ludhiana for the past seven years we have been studying this disease, and working on an efficient anti-tuberculosis programme.

More and more the zenana looms as the gravest source of infection and the most tuberculosis ridden. We are persuaded that the key to the whole fight lies in the zenana, for without the intelligent co-operation of the women in the home, we can accomplish but little. This becomes very apparent from the fact that over 590,000 of the 600,000 annual deaths from tuberculosis in India occur in the home, for there are less than 3,000 beds for the tuberculous in all sanatoria and general hospitals combined. Until we can take this citadel in which the 'Captain of the Men of Death' holds sway, then and then only will we begin to gain the victory.

The advice has been well given that 'He who has no facts based upon figures should not speak until they are available'. It is true that without figures, man is lost in this world. This article is a study of the statistics and social aspects which we have found in Ludhiana; and which may account largely for the very grave tuberculosis situation that exists among India's womanhood. For comparison and help in evaluating various factors, certain figures and findings are given from an exhaustive study of

(Continued from previous page)

them to make a living, and these industries can only be built up if a natural selection among the settlers takes place, and this is possible only on the principles which have been put into practice at Papworth'. It is on similar principles that partly from our own experience, partly from the experience of others, we are trying to work. At the root of it all is the ex-patient, unfitted for competition in the outside world, craving for security in life for himself and his family, security in work and security in medical attention.

mortality among young women, by Edna E. Nicholson, in Detroit, Michigan, U. S. A., the home of the Ford motor car.

GENERAL FACTORS

Population

The total population of Ludhiana, according to the last census (1931), was 68,586. This is distributed among the various community and sex groups as shown in table I.

The particular thing of note in connection with tuberculosis in the zenana is that 58.33 per cent of the total population are male, while only 41.6 per cent are female, an excess of male over female of 16.7 per cent. This proportion is about twice as high as for the Punjab as a whole, which is 8 per cent; Detroit's is 4.8 per cent.

Tuberculosis mortality statistics

During the past eight years, excluding 1935, 1,224 deaths due to pulmonary tuberculosis have been reported to the Municipal Health Officer, an annual average of 175 deaths. Table II gives these statistics, according to age, sex and community. This table is not given as a complete statement of the tuberculosis mortality in Ludhiana, for accurate figures for this are not available, but for the sake of comparing the various age and sex groups in the different communities, we believe it to be a reliable source of information.

The actual death rate can only be estimated by various factors. During 1936, the municipality employed a doctor to verify all deaths. He certified that, in his opinion, 28 additional deaths were due to tuberculosis. This added 21 per cent to the deaths reported as such in that particular year, which percentage, if added to table II, would give the more accurate yearly average of 212 instead of 175, or a death rate of 308.4 instead of 254.9 per 100,000.

This table shows that, of the total number of tuberculosis deaths, 65.6 per cent were female and only 34.4 per cent were male. This contrasts strangely with the general population percentages of only 41.6 per cent female and 58.3 per cent male. This is shown graphically below.

Thirty-four per cent of all tuberculosis deaths occurred between the ages of 15 and 24: of these, 73.5 were women and only 26.5 were men. In Detroit 23 per cent of all tuberculosis deaths occur in this age period: of which 64.8 per cent were women and 35.2 per cent were men. These figures are higher than for any other age period. This shows that there are one or more common causative factors for the high mortality of young women among the Hindus and Mohammedans in Ludhiana and in Detroit. This also indicates that the tuberculosis problem is centred in this age and sex group and that special effort should be given for its prevention and treatment among young women.

TABLE I
Population of the town of Ludhiana, 1931

Age, sex and community distribution

For the evaluation of the influence of age, sex and community upon the tuberculosis mortality, only the Mohammedan and Hindu statistics are used. A greater percentage of the Sikh industrial workers leave their families in the village, and the presence of over 250 young women in the Women's Christian Medical College and hospital vitiates the Christian

tuberculosis statistics. We do not have available the population according to age, so a true death rate (deaths per 100,000 of the specific age group) cannot be calculated. The death ratios given here are figured per 100,000 of the general sex and community population. The actual death rates would be many times higher than these ratios as the death rates are calculated on but a fraction of the total population of each

sex and community group. These ratios are graphically illustrated in the charts. The corresponding table is also given below.

between 50 and 60 years. However, the Mohammedan women ratio rises more rapidly, being 44.46 as against the Hindu of 18.81 for the

General population.

Tuberculosis deaths.

An examination of specific ratios shows that the peak of total tuberculosis mortality falls among young people between the ages of 20 and 25. When sex is taken into consideration, it is evident that the greatest mortality among females, 84.09 per 100,000 of the sex and community group, occurs in this same age group, but that the peak of male mortality, 28.27, is not reached until the age period 30 to 40. The female mortality ratio exceeds the male for all age groups with the single exception of Mohammedan men over 50 years of age. The female mortality ratio is 403.8, that of the male is 148.7—a difference of 255.1—over 2.7 times greater among the women than among the men for all ages and both communities.

According to community, there is a great similarity between the Mohammedan and Hindu. The highest ratio is for Hindu young women aged 20 to 25 years, the lowest for Hindu men

10-14 age group, and the total ratio for Mohammedan women exceeds that for Hindu women by 13.2.

Home environment

Since environment has a great influence upon the individual's susceptibility and especially upon the development of active disease, the home is to be regarded as a centre of great importance in any study of this kind. In Ludhiana the home of each tuberculosis death is visited by one of our three public health visitors who notes the conditions, gives advice regarding disinfection, diet, etc., and she also gets as many contacts as possible examined in our tuberculosis clinic or by one of our assistant doctors, on her weekly home visits with the public health visitor. The home is also revisited periodically, in order to find early cases that may develop. Tabulation of the findings of our senior public

health visitor for 100 tuberculosis-infected families taken consecutively from the list of such families is as follows:—

room is the upper limit of satisfactory conditions); (2) poor ventilation indicating improperly constructed houses; and (3) poor state

TABLE IV
Home environment in 100 families

Poor	..	35	38	73 "
Fair	..	3	4	7 "
Good	..	12	8	20 "
Homes disinfected after death of patients	..	8	11	19 "

The point of greatest significance in this table, and in fact in this whole article, is that 54 per cent of all these tuberculous homes had suffered the loss of one or more members from

of cleanliness showing ignorance or carelessness regarding the primary laws of health. Although disinfection is done free, not one in five of the houses was disinfected.

Tuberculosis death ratios per million by sex and communities in Ludhiana (seven-year average).

the same disease, before the death of the present members; 22 per cent had suffered multiple losses: one family had lost 6, another 5, another patient was the last of his family, all having died of tuberculosis. Poor hygienic conditions existed in over two-thirds of all homes, as indicated by (1) over-crowding (1.5 persons per

Tuberculosis death ratios for all ages per million of the community and sex population in Ludhiana (seven-year average).

The Detroit conclusions regarding housing conditions are as follows: 'Wherever there are open cases of tuberculosis, it is reasonable to expect that crowded living quarters will increase the amount of disease by intensifying and

multiplying the contact. However, in the absence of an open source of infection there is little indication that housing, in itself, exerts any direct influence upon mortality, bad as it may be from moral and aesthetic viewpoints'. This emphasizes the importance of segregation of the tuberculous member, especially from the crowded, dirty, dark houses of the majority of the poor.

Personal factors

There are not much data on the social status of the victims. Among our tuberculosis clinic patients are included high officials' sons and daughters, college students, and those with much of this world's goods, as well as the poorest of the poor.

Diet

In her recent article on 'Nutrition and Diet in Northern India', Dr. Dagmar Curjel Wilson concludes that 'the diets studied and the condition of those consuming them are by no means unsatisfactory'. However, one-fourth of the Mohammedan and one-sixth of the Hindu school children she examined were below the normal standard of nutrition, though this was not great. Four annas per day per head was given as adequate for food. The great majority of our clinic patients must live on Rs. 15 or less per month for the whole family, averaging 5.9 in these statistics before the death of the patient. Rs. 15 per month gives each member of a family of 5 only 1.6 annas per day for all expenses, rent, clothing, food, medicines, etc. The Punjab diet is considered one of the best in India, and hence its quality is not responsible for the greater prevalence of tuberculosis here. But it is deficient in quantity in too many homes, especially in the tuberculosis-infected homes. The women again probably suffer more of this deficiency than the men of the household. It is said that the Hindu family is apt to spend a smaller proportion of its income on food than the Mohammedan family with the same income. When it is possible, 4 annas per head per day should be spent on food, to economize on this is truly false economy.

Pardah

The evil effects of the *pardah* system are very much accentuated by tuberculosis invasion of the home. If the infection is present, either known or unrecognized, in these dirty, ill-ventilated, over-crowded homes (65 per cent of our study were so classified), the wonder is that all girls do not succumb soon after being thus imprisoned with this terrible foe. Practically 100 per cent of guinea-pigs succumb when confined with a tuberculous member of their community. It is amply proved that it is the massive and repeated dosages of bacilli which are responsible for most cases of disease. The earlier seclusion, including the *burqa*, of the Mohammedan girl

shows its effect in the earlier rise of her tuberculosis death ratio, to 44.46 in the 10 to 14 age group as against her Hindu sister's to 18.81. Their brothers' rises were slight: to only 6.88 for the Mohammedan youth and to 12.70 for the Hindu. A few years later, during the universally critical period of child-bearing, practically all members of these *pardah* families get the full effect of their seclusion, and their death ratio soars.

We long for the time when our Mohammedan sisters can throw away their *burgas* and, with the abolishment of *pardah*, they and their Hindu *pardah* sisters can enjoy fully their natural inheritance of sunshine and fresh air and exercise. Especially we plead that these young human flowers be not confined and restricted just as they are blossoming out into womanhood and need more of these life-giving elements.

Marriage

Positive statements of those who are not married are not given in the records. The inference is made, and table IV is based on it (except for the ages 14, 15, and 16), that those who are recorded as 'daughters of' are not married. This would not be true in all cases, though it probably does indicate that all were living in their father's homes.

There were six deaths of married girls before the age of 16. We are thankful for the Sarda Act, but it is apparent that the people need more education as to its necessity, and the officials need to be more vigilant in its enforcement. Detroit's conclusion concerning early marriage and child-bearing at an early age, i.e., before 20, is as follows: 'Undoubtedly this constituted the most important single causative factor in the mortality of this group'. If this is true in Detroit, with a total of only 48 per cent of married girls, how much greater influence it must have on our Indian young women, with a total of 80 per cent married, and about 96 per cent of the 20 to 24 age group married.

Duration of the disease

The average number of months of illness as given in the medical officer's statistics was 11.14 for all: 9.9 for women and 12.3 for men. This is but a rough estimate, and too much emphasis cannot be put upon it. It gives an inadequate picture of the great burden of illness that is put upon only those tuberculous patients who die. Women die quicker than men; as child-bearing immediately precedes the onset of symptoms, this would account for much of their earlier death. However, women very frequently give as their excuse for not being admitted, or for going home from the sanatorium too soon, that their husbands need them to cook their *chapatis* and to care for the babies. These women would surely die sooner than those who receive better care. It also greatly increases the dangers of infection for the rest of the

household, especially the children. Public health propaganda should stress this danger.

Summary and conclusions

The municipality vital statistics show a death rate for pulmonary tuberculosis of 254.8 per 100,000. This does not include corrections of data, nor the non-pulmonary forms of tuberculosis. Clinic statistics show 68 per cent pulmonary and 32 per cent non-pulmonary. Of the deaths recorded, 65.6 per cent were women, although they represent but 41 per cent of the total population. Considering the Hindu and Mohammedan communities only, the death rate for women is 403.8; for men, 148.7; women's being 2.7 times that of men's. There is not much difference between the Mohammedan and Hindu statistics. The female mortality of both communities shows a very high maximum peak of over 83 per 100,000 of the total female population for the 20 to 24 age group.

We believe that these statistics support our opinion that the high female mortality, especially of the 20 to 24 age group, is due in large measure to two factors: early marriage including early child-bearing, and the *pardah* system—always remembering that there can be no tuberculosis without a source of infection. Infection was proved in over half of the homes studied by the previous death of one or more members of the family. Infection is by no means universal in Ludhiana, for less than 60 per cent of the girls over 12 years of age in the Government Girls' High School had a positive tuberculin (Mantoux) skin test.

If this is true, then the problem of tuberculosis in the zenana, in fact the whole tuberculosis problem, centres in the protection of the developing young women and especially of the

expectant and nursing mothers. The adverse effect of *pardah* is suggested by the contrast between the death ratios of boys and girls, that of the girl rising sharply soon after she leaves the more free life that her brother continues to enjoy, and by the female ratio continuing above that of the male with the single exception of Mohammedan men over 50 years of age. The deleterious effects of *pardah* lie in the lowering of the resistance of the women and especially in the more intimate contact (practically 24 hours every day) with any infection which may be present in the home.

The effect of pregnancy is proved many times in the clinic by the history of the onset of symptoms immediately following child-birth. The death ratio among young women 20 to 24 years of age in Ludhiana is 83, while in Detroit for this same 'dangerous period', it is but 16.8. This great difference is due to these same two factors: Detroit has no *pardah* and only 45 per cent of the group were married before 25 years of age. The added strain of pregnancy accentuates the evil effects of *pardah* and of all the insanitary conditions of the home and of any deficiency of diet. We believe many of the tuberculous families in Ludhiana, and in India as a whole, are living in 'primary poverty'.

In addition to general propaganda and clinic work, pre-natal clinics with good tuberculosis diagnostic and instruction facilities would be most valuable for this special propaganda and preventive work. The obstetrician should ever keep tuberculosis in mind and know how best to deal with it. Public Health and General Nursing Schools and *dais'* courses should emphasize this grave danger to their clientele so that their graduates may be efficient

ROLE OF SOLARIA IN ANTI-TUBERCULOSIS WORK*

By B. JAYARAM, M.B., B.S., T.D.D., L.R.C.P. & S.
Medical Officer, Krishnajaumanni Tuberculosis
Sanatorium, Mysore

and

A. K. SHERIFF, M.B., B.S., T.D.D.

No infectious disease, much less tuberculosis, can be eradicated by therapeutic measures only. In tuberculosis the infection is universal and morbidity, disability and mortality high. Prevention is cheaper, easier and obviates the suffering and loss of human lives that this disease entails.

Choice of preventive methods

For tuberculous infection to be transmitted, prolonged and intimate contact with an open case is necessary. Infection is not always followed by disease, and if disease does appear there is usually a long latent period. During this interval the body forces, as represented by the word 'immunity', come into play and decide the issue between silent infection and manifest disease. The prevention of tuberculosis, therefore, falls essentially under two heads:—

- (a) Prevent infection from taking place.
- (b) After infection has taken place, prevent it from becoming manifest disease.

In view of the fact that 75 to 100 per cent of adults are infected, the latter consideration becomes the more immediate and practical issue, while the former remains the ideal.

Value of home visiting in prevention of tuberculosis

Through the systematic home visiting of all known tuberculosis cases, by a qualified nurse,

* Summary of a paper, condensed for want of space.

(Continued from previous page)

tuberculosis 'officers' in a big or small way, for the homes they visit.

We find that with instruction in the clinic and by the public health visitor in the home, many women are doing good work in the nursing care of the patient and in prevention of further infection. The majority of women are capable of doing likewise—though they cannot read!—and will do so, especially when they learn the good news that tuberculosis is not a hopeless disease and that there is no need for still others of their relatives to contract it.

It is the zenana woman who suffers most. It is also her privilege as well as her duty when instructed and the necessary help is given, to give the death blow to this terrible foe which holds sway in her home.

all contacts are persuaded to be examined by a qualified doctor. Work in Mysore shows that 14 per cent of contacts have signs of manifest tuberculosis in various stages; 15 per cent of these are children under 10 years of age, with enlarged cervical or tracheal bronchial glands, and of these many have lung infection and some have tuberculous peritonitis. There are many more who give a positive intradermal tuberculin reaction only.

Frank cases of tuberculosis are either segregated in their homes and educated in the hygiene of prevention or admitted to some suitable institution. Those that only show signs of infection by a positive tuberculin test and weakness, probably with palpable cervical glands, are picked out and x-rayed in order to decide whether active tuberculous disease is present. From the point of view of prevention it is this the largest group that really matters. If the resistance can be increased, there is a good chance of arresting the disease.

Sunlight as preventive of tuberculosis

This can be done by the judicious use of sun, air and physical exercise, which are the most efficient preventive factors. We are all familiar with the health-giving powers of the sun, and the remarks of a well-known authority in respect to its use as a preventive factor in tuberculosis are of interest.

Graph showing the ultra-violet-ray content of the sunlight in units during the months of September and October 1937, as observed in the P. K. Sanatorium, Mysore.

A. P. Cawadias says: 'Instead of endeavouring to prevent disease by acting on the external factors of disease, a work done by the public health authorities and a matter of hygiene in general, we try to prevent disease by strengthening the constitution of the individual. Sunlight has undeniably proved of the greatest value in strengthening of the constitution, and this should be applied preventively to children, especially to weak children.'

The Mysore solarium

The Indian Red Cross Society, Mysore City, has set up a 'solarium' which could aptly be termed a 'day-preventorium', to give practical application to the above knowledge. The solarium is an inexpensive building with a wedge-shaped tiled roof, running north and south, supported on wooden pillars, with a cement floor and open on all sides except for bamboo chieks which can be rolled up or let down to any height to control the admission of the sun's rays. Pre-tuberculous children from infected homes are brought every morning and are given a graduated dose of sun-exposure under strict medical supervision. The smaller children take the sun bath lying down and others who can walk and play are given a loin cloth and a washable hat, and are encouraged to play in the open. The point, however, must be stressed

sun in India. Experiments carried out in Mysore over a short period (September and October 1937) show that there is a fair amount of these rays available.

In explaining the good results that follow from the work in Mysore, we should not ignore the influence of rays other than ultra-violet and the effect of fresh air (ærotherapy) which has been proved to have a stimulating effect on general metabolism. It is the sunlight as a whole and the air bath which are more important.

Sunlight is a mixture of three groups of electro-magnetic radiations, viz, infra-red, the luminous or coloured rays, and ultra-violet rays. The infra-red have a hyperæmic and thermic effect, the luminous a psychological effect and the ultra-violet a biological effect in that they stimulate metabolic, endocrine, nervous and

Patients under treatment at the solarium.

that just as exhibition of a drug is regulated by the pharmacological dose and individual idiosyncrasy, so heliotherapy has to be carried out in accordance with a strict technique and dosage, not only to derive the maximum benefit, but to ward off undesirable incidents, which must follow if tuberculous individuals are indiscriminately exposed to the sun's rays. Strict individualization and careful graduation are the fundamental principles of this treatment.

The morning sun is most potent therapeutically, particularly in our country, as later on in the day the heat is very exhausting. The insolation is begun on the legs and more and more of the body is exposed, increasing gradually the duration of exposure provided no untoward result, either local or general, follows.

On completion of treatment, each child is given a bath and half a pint of milk, some tomato juice and cod-liver oil. The clinical results so far achieved are very encouraging.

Action of sun's rays

There is a certain amount of controversy as to the exact amount of ultra-violet rays in the

vegetative functions. The effect of sunlight on the human organism may be described as :

1. Direct or local.

This action is analgesic, germicidal, and sclerosing, it helps to bring about a rapid healing of any surgical tuberculous condition and is valuable in various other non-tuberculous conditions as well.

2. Indirect or remote.

This causes bronzing of the skin, and has a general powerful stimulating effect on both the mind and body.

Conclusion

The Mysore plan of work is simple and cheap. The structure costs Rs. 300 and is large enough for 12 children to be treated simultaneously. If this plan is adopted all over India, we will come to possess a very effective weapon against tuberculosis. However, in this important prophylactic effort, all depends on the indispensable co-operation of medical men, health authorities and charitable organizations, and it is with the object of interesting such persons and organizations that these few lines have been written.

METHODS OF DESTRUCTION OF TUBERCLE BACILLI IN THE SPUTUM FOR USE IN INDIAN HOMES, WITH SOME EXPERIMENTS

By R. M. BARTON, M.A. (Oxon.)

Pathologist, Union Mission Tuberculosis Sanatorium,
Arogyavaram, near Madanapalle, South India

It is now generally accepted that most infections with the tubercle bacillus, at least those from which pulmonary tuberculosis results, are produced by inhalation of material containing tubercle bacilli. This material may be either moist or dry. In the moist form it is usually inhaled from droplets produced by a patient coughing, sneezing or speaking loudly. These droplets have a very limited range, various writers placing the distance between eight inches and two feet under normal conditions. The second form of inhalation is of dry material which may be from dried droplets or from dried sputum. This has a far greater range and therefore prevention of infection from this source is of the greatest importance. This paper will deal with the destruction of tubercle bacilli in the sputum.

Present methods of disposal of sputum in Indian homes

A number of patients from different parts of India were asked what they did with their sputum before coming to the sanatorium; some were from villages and some from towns. Very few had used any kind of disinfectant. The most common practice appeared to be that the patient spat outside the door of the house. A few used some kind of vessel, often without any cover, and then threw the contents outside, a little distance from the house. One, a medical student, had the sputum buried. In towns one spat in the bathroom, and another poured out the contents of the vessel into the open drains of the town. Several said they had no sputum, which may mean they swallowed it, as they had sputum after coming to the sanatorium. Although it was not admitted by any of the patients asked, it is known that among the poor classes, sick patients spit on the floor of the hut or room in which they are lying. All this means that the majority of patients with a positive sputum are producing vast numbers of bacilli, which no attempt is made to destroy. What is the fate of these bacilli under normal conditions?

Viability of the tubercle bacillus

Sunlight has a fairly rapid effect on tubercle bacilli in sputum, causing them to die in a period varying from minutes to hours, according to the condition of exposure, such as the intensity of light, thickness of film, and so on.

Calmette (1923) says that the tubercle bacilli in the films of sputum spread on glass slides are killed by 10 minutes' exposure to direct sunlight. Soparkar (1917) found that tubercle bacilli in sputum exposed to direct sunlight are killed in

between six and eight hours. Caldwell (1925) found that he obtained positive results with sputum mixed with sterile dust exposed to direct sunlight under typical spring conditions in Arizona for 72 hours. Blanco and Ondovilla (1936) found that in different years they obtained different results from exposing thin films of sputum, 1 to 4 mm. thick, to direct sunlight; sterilization was effected in two hours in August 1929 with temperatures of 39°C. and 45°C.; in 1930-32 sterilization was not effected in six hours in July or eight hours in August with maximum and minimum temperatures of 35°C. and 29°C. in July, and 32°C. and 24°C. in August. In July 1935 with maximum and minimum temperatures of 35°C. and 18°C., sterilization was effected in 11 hours. They conclude that the bactericidal action of sunlight varies with the intensity of the radiations and with the greater or lesser degrees of protection afforded by the composition of the sputum.

Decomposition or putrefaction of material containing tubercle bacilli does not have any rapid effect on the bacilli. Calmette found tubercle bacilli virulent in wet mud after four months and in garden soil after seven months. Soparkar isolated tubercle bacilli from decomposed sputum up to 20 days, but not after 26 days. Tubercle bacilli are destroyed in sewage, whether in septic tanks or spread as manure, only with extreme slowness (Calmette). Soparkar also states that it takes three to four hours in direct sunlight and three to four days in diffuse daylight for a pellet of sputum to become sufficiently dried to be capable of being reduced to dust.

When sputum was exposed to *diffuse daylight*, Soparkar found the tubercle bacilli alive after six days and dead after eight days. Blanco and Ondovilla found that sputum exposed to diffuse daylight in a room facing south at Lago Sanatorium in Spain, ceased to be infectious after 28 days.

In *dim light* and in the *dark* tubercle bacilli in sputum live very much longer, in dark corridors and hallways 'for two or three months and probably longer', say Baldwin, Petroff and Gardner (1927); in the dark living virulent bacilli were found after 309 days by Soparkar.

As regards *heat* at temperatures considerably below boiling point, tubercle bacilli in a moist environment are killed by an exposure of 12 hours at 50°C. or four hours at 55°C. (Calmette). Cornet says tubercle bacilli in sputum are killed at 55°C. in six hours. Such temperatures are reached and maintained in some places in India on the ground in open sunlight.

Tubercle bacilli can stand *desiccation* for periods of two to eight months, according to Gloyne (1930), and as long as 10 months, according to Soparkar.

As regards infectivity of dust from rooms of patients, several workers have experimented and obtained living tubercle bacilli from

the dust. Calmette found tubercle bacilli in dust, but experimenting with guinea-pigs and rabbits, considered that 'practically speaking . . . dusts contaminated with dry bacilli offer but little harm to healthy respiratory passages'. All workers do not, however, agree with this. Wileocks (1938) was able to obtain positive results from two out of six specimens of dust collected from the floor of African huts.

The practical conclusions to be drawn from the above outline of work on the viability of the tubercle bacillus under certain conditions seem to be :—

- (1) That sputum poured out or spat out in the open in sunny weather in India soon ceases to be infectious and, therefore, infection from this source cannot be great.
- (2) That sputum spat on the floor inside houses or in places not exposed to sunlight is potentially a source of danger.

Some methods used for collection and destruction of tubercle bacilli in sputum

One of the most usual methods of collecting sputum is not one of the most satisfactory, namely, the common type of spittoon with a wide flanged top and a comparatively narrow opening. This provides a large space on which sputum can collect and dry, and many types are difficult to clean out. Flies also collect on the edge and, as Brown and Petroff (1919) have shown, are capable of carrying away virulent bacilli in their bodies, although they were unable to infect guinea-pigs by food contaminated by such flies. Where there is careless spitting, it does, however, save sputum falling on the ground.

Cheap aluminium sputum cups with removable hinged lids and rounded inside at the bottom are available at about Rs. 9 a dozen. Failing such a proper sputum cup, an ordinary tin with a wide mouth and something to cover it may be used. But such vessels should contain something to keep the sputum moist. Water may be used and then the whole may be boiled from two to three minutes and the contents may be then safely thrown out. But there is the objection that on sentimental grounds people may not like to boil the contents in the place where they usually have a fire for cooking and will be unwilling to make another fire.

For use in the country it has been suggested that earthen pots may be used containing earth or sand. A cover should be used to prevent flies gaining access to the sputum, and the whole should be thoroughly heated over a fire each day. There is the same objection with this method as with boiling.

A method of dealing with sputum, advocated for general use, should have the following advantages :—

- (1) Simplicity of use by even uneducated people.

- (2) Efficiency and speed of disinfecting power.
- (3) Cheapness.
- (4) Safety.

One of the commonest agents used is lysol, and this is now available fairly widely in India, at least in the small towns. But it is not very cheap, and when obtained in the usual form is definitely dangerous, when, as is usual in villages and even town homes, there is no special place to put it away from children. Its disinfecting power is, however, good when it is used in about a 2 per cent solution. Adams (1938), for example, found that no growth of tubercle bacilli could be obtained after sputum had been mixed with lysol in $2\frac{1}{2}$ per cent dilution for half an hour.

Some experiments with disinfection of sputum

In order to test the efficiency of certain other methods of destroying tubercle bacilli, a few experiments have been carried out, using the Löwenstein-Jensen medium for control purposes.

(1) Kerosene oil

There is a popular belief among some classes that kerosene oil has a strong disinfecting power based, no doubt, on its lethal effects on insects. Sputum from several patients was mixed and then kerosene oil was poured on the top, and the whole was mixed and left for periods of one hour and two hours. The floating kerosene oil was pipetted off and then part of the sputum was cultured direct on to the medium; the cultures showed a heavy contamination as the kerosene oil had no effect at least on some of the bacteria other than the tubercle bacilli. The other part of the sputum was treated with 6 per cent sulphuric acid for 20 minutes, then centrifuged at high speed for 20 minutes, the supernatant fluid pipetted off and the sediment washed with distilled water and centrifuged again for 20 minutes. The sediment, when cultured, showed a vigorous growth of tubercle bacilli for the sputum treated for both one hour and two hours, as heavy as on controls made from part of the sputum not treated with kerosene oil.

(2) Cow-dung

There is also a popular belief in the efficacy of cow-dung as a disinfectant, and floors on which a patient has spat are treated with cow-dung, sometimes with the definite idea of disinfection. An attempt was made to see whether cow-dung had any effect on the viability of tubercle bacilli, but unfortunately a method was not found which was capable of destroying all the mass of contaminating bacteria, without destroying the tubercle bacilli also. Therefore, no conclusion could be arrived at up to now as to whether cow-dung had any effect, but the fact that, as mentioned earlier, tubercle bacilli are destroyed in sewage, either in septic tanks or spread as manure, with extreme slowness, makes it seem unlikely that cow-dung will have

any other effect than preventing the spread of dust to some extent.

(3) Certain chlorine compounds

Some of the chlorine compounds are fairly readily available, being used in connection with the chlorination of water supplies, and, therefore, two were tried—perchlaron and calx chlorinata.

The technique employed was that sputum from several patients with positive sputum was mixed together and then portions were treated with equal amounts of various strengths of perchlaron and calx chlorinata in distilled water and left for 40 minutes at room temperature (about 90° to 95°F.). The mixture was then centrifuged at high speed for 20 minutes, the sediment was washed with sterile distilled water and again centrifuged for 20 minutes, and then was cultured on to several tubes of Löwenstein-Jensen medium. Controls of sputum treated with 6 per cent sulphuric acid only were also made. In some earlier experiments sputum was treated for five hours, but this was found unnecessary. The strengths of the chlorine used were 1 per cent, 2 per cent, 3 per cent and 4 per cent. In earlier experiments stronger solutions were also used, but were found unnecessary.

The immediate effect of the chlorine solution on the sputum was striking. Above 2 per cent strength the sputum was very speedily homogenized with effervescence and became watery with a little shrivelled-up material floating on the surface. With 1 per cent and 2 per cent the action was slower, but by the end of 1 hour the sputum was homogenized by the 2 per cent solution. Smears from all the sediments showed tubercle bacilli.

The cultures were examined weekly up to six weeks. The controls showed heavy growth, but only the sputum treated with 1 per cent perchlaron and calx chlorinata showed any growth, and in these tubes some showed no colonies and others showed only two or three colonies. There was no growth from the sputum treated with 2, 3, or 4 per cent solution.

One objection to the use of chlorine solution is that the solution is not stable and, therefore, an experiment was made using solutions which had been mixed five weeks earlier and kept in screw-capped bottles in a cupboard. Of three tubes cultured from sputum treated with 1 per cent perchlaron and 1 per cent calx chlorinata only one tube of each showed three colonies; the others were negative. The 2, 3 and 4 per cent solutions showed no growth.

Conclusion

The above experiments have shown that at a room temperature of 90° to 95°F., which is a temperature found widely at least in South India and in the hot weather in North India, a 2 per cent solution perchlaron and calx chlorinata when mixed in equal quantities with sputum for one hour will kill the tubercle bacilli. Both

these chlorine compounds are fairly readily available and are cheap, costing about eleven annas a pound. When kept in a screw-capped bottle the disinfecting power of these solutions is fairly constant, at least up to five weeks. The chlorine solution should be mixed with the sputum for an hour before the sputum cup is cleaned, and the contents of the cup may then be thrown out. The chlorine solution should not be poured into the cup before, as the chlorine may be unpleasant to the patient and produce coughing. A heaped teaspoon (such as is bought in the bazaar for $\frac{1}{4}$ anna) to one pint gives about a 2 per cent solution.

Summary

(1) Enquiry among patients showed that very few made any effort to disinfect the sputum in their own homes.

(2) A short review is made of our knowledge of the viability of the tubercle bacillus outside the body and leads to the conclusion that spitting in the open in sunny weather in India is not likely to lead to much spread of infection. Sputum spat in places not exposed to sunlight is potentially dangerous.

(3) The collection of sputum in the common type of spittoon, in tins and earthen pots is discussed.

(4) Lysol, while efficient in disinfecting power, is not cheap, and in unskilled hands has its dangers.

(5) Some experiments are described dealing with destruction of tubercle bacilli in sputum:

(a) The popular belief of the disinfecting power of kerosene oil is proved to be without foundation.

(b) Certain chlorine compounds, perchlaron and calx chlorinata, such as is used for water chlorination, etc., are found efficient when used in a 2 per cent solution for one hour at room temperature.

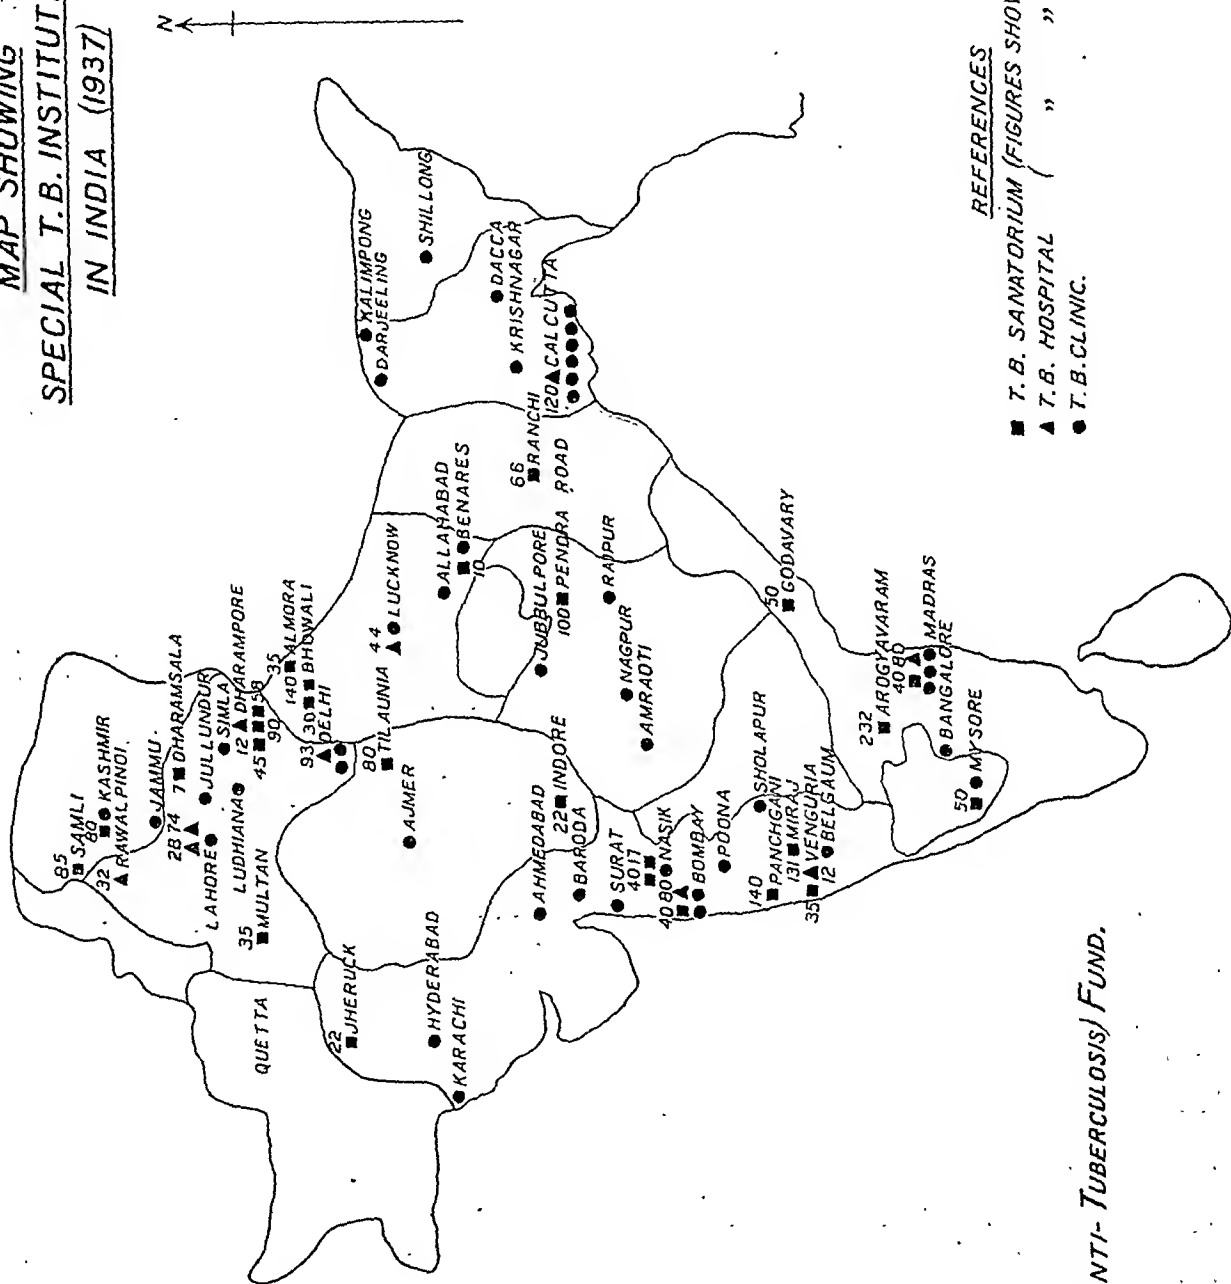

(c) If kept in a screw-capped bottle, these solutions were proved to be still efficient five weeks later.

(d) The chlorine compounds are easy to use and are efficient and cheap.

Indian Medical Gazette

SEPTEMBER

THE SPECIAL TUBERCULOSIS NUMBER

THE success of the special tuberculosis number we published last year encouraged the chairman and committee of the King George Thanksgiving (Anti-Tuberculosis) Fund to suggest the publication of another special number this year. The suggestion was a very welcome one, as at the moment tuberculosis is a subject of vital interest to all concerned with India's welfare, and should be especially so to our readers and members of the medical and allied professions generally; further, we ourselves very much appreciate the expert help and advice that we receive from the secretary and the editorial committee of the fund in arranging this special number.

The last special tuberculosis number was devoted almost entirely to treatment and it was agreed that this number should be devoted to the prevention of tuberculosis in India.

In the case of tuberculosis, as in other chronic infectious diseases, the problems of prevention and cure are intimately associated and it is hard to imagine any preventive campaign that did not entail the treatment of those already affected, or conversely any treatment campaign that would not, by limiting the source of infection, prevent the disease from spreading. However, the committee have chosen for publication in this number, as far as possible, articles in which the subject is considered primarily from the point of view of prevention.

As far as tuberculosis in India is concerned, the outstanding event of importance during the last year has been the conception and launching of the King-Emperor's Anti-Tuberculosis Fund by Her Excellency The Vicereine. The value of this public-spirited action of Her Excellency is represented not only by the number of rupees that have been and will be subscribed, but by the widespread attention that has thereby been focussed on this disease. The Rajah who gives a lakh of rupees does so because he understands the gravity of the tuberculosis problem in India and wishes to contribute his share, but the peasant who is persuaded to part with an anna in exchange for a token wants to know more about it, and the loss of his anna as much as the acquisition of the tuberculosis token will tend to make him tuberculosis minded. More good will be done by directing the healthy minds of India's three hundred million peasants than by curing the diseased bodies of relatively few.

The good that the fund has achieved in this direction can never be measured; it may not be very apparent to-day but it is very real, and if the effort is sustained the maximum effect will

be felt some years hence when the next generation is reaching manhood. We can, however, add up the sums that have been collected, and these have reached a very impressive total.

The problem that we are now facing is not how the money can be spent to the advantage of tuberculous patients in India—this can be done in a thousand ways—but how it can be spent to the greatest advantage of the maximum number of patients and at the same time directed towards stamping out this scourge. For inspiration and guidance we can look to other countries, but we shall have to work out our own problem in our own way. In the first place expenditure on the same scale, proportionately (either to the population or to the number of tuberculous patients), as has been incurred in certain other countries during the last two decades, would absorb the whole of India's resources, but even if the cost could be left out of consideration no foreign scheme could be adopted successfully in this country. The disease in India is different from the disease that is seen in Europe, and there is no doubt that with her many racial types and her many different climates, its clinical manifestations and epidemiological behaviour will show marked variations within the country itself. In this connection there are many questions to be answered, and local research must form an important part of the scheme.

Most tuberculosis workers seem to be agreed that the pivotal point of any anti-tuberculosis scheme must be the tuberculosis clinic or dispensary. The funds that have been subscribed will allow of the establishment of a few such dispensaries in each province. It will be far better to establish well-equipped and well-run clinics in a few selected areas than to dissipate the resources of the fund by establishing a large number of ill-equipped and inefficient ones. An ill-run clinic will not only achieve nothing but it will do actual harm by giving the tuberculosis clinic a bad name and thereby eventually bringing the whole scheme into disrepute. On the other hand, the success of a well-run clinic will encourage others to establish them in their areas, and, if the demand is insistent enough, the money will be forthcoming from some source or another.

A certain amount of unselfishness will have to be displayed, as in many areas where funds have been subscribed it will not be possible, at first at any rate, to carry out any relief measures, and here the inhabitants will have to comfort themselves with the knowledge that the scheme as a whole is progressing satisfactorily towards its final goal, the eradication of tuberculosis from India. A selfish, parochial outlook will be disastrous to the scheme and already the establishment of sanatoria in Bengal has been hampered by unreasonable local opposition; we say 'unreasonable' because the presence of a well-run sanatorium would be beneficial rather than detrimental to the health of the local community. Perhaps the greatest enemy to the

scheme may be the apathy and a fatalistic attitude of the people themselves, but the prosecutors of the scheme will also find that they have prejudice and active opposition to overcome, and it is the duty of every practitioner of scientific medicine to attempt to establish himself as a leader of thought in his own locality and to counteract this prejudice and opposition with all his will; if he does this he will be doing far more for the cause than he would by subscribing a few rupees.

Though no concrete scheme has been formulated in this number, we feel that the opinions expressed by some of India's leading tuberculosis workers as to the various measures that should be adopted to control tuberculosis in this country will be of very great value to our readers and to those whose duty it will be in the various provinces to organize the campaigns in our war against tuberculosis.

KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND

A REVIEW OF ACTIVITIES FOR THE YEAR, 1937-38, PREPARED
BY THE SECRETARY, DR. B. K. SIKAND, M.B., B.S., D.P.H.

SINCE the publication of the last 'Tuberculosis Number' of the *Indian Medical Gazette* in April 1937, the Fund, which at the moment represents India's national effort in the preventive campaign against tuberculosis, has continued its activities.

Tuberculosis has been described as a 'social disease' because its prevalence and intensity vary according to different social and economic conditions. In this country the problem of prevention is intimately bound up with many aspects of life, such as education, *purdah*, early marriage, improvident reproduction, wasteful customs, nutrition, housing and insanitary habits. The solution to most of these predisposing factors is education.

The anti-tuberculosis campaign in India, therefore, resolves itself into the following:—

- (1) Correction of the general ignorance in respect of the causes and prevention of tuberculosis;
- (2) Abolition of harmful social customs and habits;
- (3) Improvement of housing conditions, *e.g.*, town planning, sanitary improvements, etc.;
- (4) Provision of tuberculosis dispensaries for early diagnosis of cases and contacts and for home visiting;
- (5) Establishment of hospitals, sanatoria and preventoria.

A campaign against tuberculosis which does not include treatment of the disease is inconceivable just as is an antimalarial scheme without suitable treatment of malaria. No hygienist would, therefore, underestimate the importance of treatment; at the same time a successful campaign in western countries is concerned more and more with preventive methods and the development of social hygiene, although treatment of infected persons must also hold an important place as a preventive measure.

Training of tuberculosis workers

Early diagnosis is essential for cure and prevention; it follows that one of the important activities of the fund is to help medical practitioners to improve their knowledge of the diagnosis, treatment and prevention of tuberculosis. It has been made clear that a great demand exists for such training and in 1937-38 three post-graduate courses were organized by the Fund with the help and co-operation of the respective heads of the medical departments, and medical and anti-tuberculosis institutions. These courses were held in Madras (September 1937), in Bombay (November 1937) and in Calcutta (January 1938). The number of applications from those who desired to attend far

exceeded the available accommodation, as many as 571 applications being received for 75 seats. Seventy-four doctors in all were admitted to these three courses and the Fund paid actual travelling expenses to all out-station candidates up to a maximum of Rs. 100 per head whilst no tuition or admission fees were charged.

Educational activities

Propaganda work has been carried on during the year both through provincial and district committees and during the tours of the organizing secretary, 4,165 pamphlets and leaflets and 14,014 posters and charts were supplied free of charge on request to educational institutions and public health workers, and 5,123 pamphlets and 1,662 posters were sold to different organized bodies. A large stock of posters, leaflets, handbills, and charts suitable for popular education is always maintained in the Fund's office. A pamphlet entitled 'Knowledge of tuberculosis in pictures' and a leaflet 'The tuberculosis clinic' were added during the year.

Co-operation with other agencies

The Maternity and Child Welfare Organizations both at headquarters and in the provinces have helped to create a liaison with their centres, where expectant and nursing mothers receive instruction and by this means the Fund has been able to approach large and appreciative audiences.

Through the help of the President of the All-India Women's Conference, it has been possible to obtain the co-operation of women social workers; it is hoped that through this medium the Fund will enlist an increasing number of workers.

Exhibitions

Anti-tuberculosis propaganda is inseparable from general health propaganda and the Fund has co-operated in a number of health exhibitions by sending suitable material.

Co-ordination

The central office collected information regarding tuberculosis institutions throughout India and attempted to guide and co-ordinate anti-tuberculosis activities in different areas. A map showing the numbers and sites of tuberculosis institutions is included in this special number.

Provincial committees

The 16 provincial and state committees in existence, all continued to do useful work in spite of financial difficulties. They have continued to carry on an intensive anti-tuberculosis campaign all over India by means of lectures, radio talks, magic lantern demonstrations and by the distribution of popular literature. In addition, committees in Ajmer-Merwara, Assam, Bangalore, Baroda, Bengal, Bombay and Central Provinces opened new clinics. Ten new tuberculosis clinics were opened during the year, which, besides being centres of prevention and education, have, by providing ambulatory treatment, done much useful work.

Mysore has begun to develop a method of dealing with the tuberculosis problem by means of a number of solaria which are in some ways comparable to the day preventoria and sanatoria of Poland. In the latter country tuberculosis patients for whom hospital accommodation is not available attend during the daytime, and are accommodated in large open sheds or special buildings where they have the advantage of open air treatment and of being removed for some hours each day from their unhealthy home surroundings. In Mysore, where close co-operation exists with the Maternity and Child Welfare organizations, children from tuberculosis-infected homes, discovered as a result of health visitors' work, are encouraged to attend the solaria for a definite period each day. There, in addition to graduated sun exposure, they are given extra milk, cod-liver oil and other necessary medicines. In a country like India, where the great need for hospital or sanatorium accommodation for tuberculosis patients can never be

fully met, this is a method which seems to have great possibilities both in respect of prevention and cure, particularly for those living in urban areas.

International relationship

The Fund continued to be a member of the International Union against Tuberculosis and in this way has kept in touch with the development of anti-tuberculosis work in other countries. We have also been able to establish relationship with the Imperial Tuberculosis Bureau of the Empire Conference on the care and after-care of the tuberculous. Several representatives from the provincial committees have recently had the opportunity of studying at first hand the work of different tuberculosis institutions in England.

King-Emperor's Anti-Tuberculosis Fund

The year 1937 has been an auspicious one for the tuberculosis movement in this country as Her Excellency the Marchioness of Linlithgow has launched a vigorous campaign against this disease in India. Her Excellency's appeal on behalf of the King-Emperor's Anti-Tuberculosis Fund has received a wide response and the list of subscriptions steadily mounts. There can be no doubt that this call for funds deserves the fullest support from every citizen of the Indian Empire because tuberculosis is not only a common and formidable enemy, but can only be conquered if every individual takes part in the campaign and gives of his best to the common cause.

Her Excellency in issuing the appeal for the King-Emperor's Anti-Tuberculosis Fund added that if she was successful, as she hoped to be, it was intended to found an Anti-Tuberculosis Association for India, consisting of a central body supported by provincial and state organizations which would be expected to affiliate to the central body and to apply a uniform policy to the circumstances of the different areas in which tuberculosis prevailed.

A NOTE FOR THE GUIDANCE OF PROVINCIAL ORGANIZATIONS

1. Tuberculosis dispensary clinic

This institution occupies a front position in the organization for combating tuberculosis in a given area and is the centre for preventive work.

In urban areas tuberculosis dispensaries should be established, having their own staff under a medical officer, either full-time or part-time. Except in cities sufficiently large to warrant the establishment of a separate building fully equipped and staffed, it is advisable to locate the tuberculosis dispensary within the boundaries of a well-established hospital in order to utilize the facilities for x-ray diagnosis and surgical work that should be obtainable there.

In rural areas, on the other hand, with scattered and less developed communities, the organization of separate dispensaries devoted solely to tuberculosis work is impracticable and here tuberculosis clinics should be opened in existing dispensaries on one or more fixed days each week. This will necessitate the doctors in charge of these particular dispensaries having some specialized knowledge of tuberculosis work.

Emergency beds, attached to a tuberculosis dispensary clinic, are useful for patients requiring observation for a day or two or for minor surgical treatment, but patients should not ordinarily be retained in such beds for more than a week.

2. Domiciliary treatment

Owing to the small number of beds available for tuberculosis cases in general hospitals and special tuberculosis institutions, domiciliary treatment must perforce be resorted to in a majority of cases for many years to come. In home treatment and care of patients and their families, the health visitor and the care committee play an important part. These are discussed below. The organization of open-air centres where

patients can be kept by day may be helpful especially when patients come from congested areas.

3. Health visitor

Formerly known as the tuberculosis nurse this worker is preferably a woman and a trained nurse. Owing, however, to the great shortage of women nurses in India it will be necessary in many areas to employ others to perform the duties of tuberculosis health visitor. In some provinces and states educated girls who have passed the matriculation examination may be given a short specialized course of training at a central well-organized dispensary and when considered qualified may be posted as health visitors. In other places it may be found necessary to utilize men for this work and sub-assistant surgeons, sanitary inspectors or even exceptionally efficient dispensers or dressers may be employed. In any case it seems desirable to observe the principle of having a uniform rate of pay in each provincial or state area for any person performing the duties of a tuberculosis health visitor.

4. Care and after-care committees

These should be organized on a voluntary basis in connection with all tuberculosis dispensaries and should consist of non-officials and officials. The committee meets at the dispensary where the circumstances and difficulties of patients requiring aid are explained. Each case is considered on its merits, given financial assistance if required, and, where desirable, helped to find suitable employment. Without such committees, composed of members who are familiar with the life and difficulties of patients and their families the work of a tuberculosis dispensary is seriously hampered and its scope restricted. Even after patients have ceased to be under treatment, the committee should endeavour to keep in touch with them where possible.

5. Training of tuberculosis staff

The success of all efforts to deal with the problem will depend on the provision of an efficient and sympathetic body of workers. The establishment of suitable training centres for doctors, health visitors, and members of care committees should therefore be accepted as an important function both for the central and for the provincial organizations. The school teachers in village schools are capable of rendering valuable assistance in anti-tuberculosis work and for them a suitable course of training would seem to be desirable.

The training should be undertaken at provincial and state centres in major provinces and states, while smaller units should look to their adjoining large neighbours or to the central organization for help in this respect.

6. Hospitals and sanatoria

The removal of the infective case from close contact with his family and associates is one of the most effective measures for preventing the spread of the disease. Unfortunately it is expensive. For cases requiring prolonged treatment in bed accommodation arranged on a district basis is advisable, tuberculosis wards in existing hospitals being constructed for the purpose.

A large city may maintain its own tuberculosis sanatorium or combined institution comprising hospital and sanatorium with an after-care organization, but generally sanatoria should be organized on state or provincial or even on a divisional basis. It is desirable that all these institutions should be of a simple type of construction.

In some areas, the establishment of tuberculosis colonies adapted to Indian conditions may be possible.

7. Preventorium methods

The value of open-air schools in combating tuberculosis is proved and any steps in this direction are of value. Similarly the establishment of play-grounds and open-air shelters are of help in the campaign.

8. Co-operation

The central, provincial and state associations will require to co-operate closely with all organizations, official and non-official, interested in the tuberculosis problem. Government departments, such as the medical and public health, are most closely concerned and a great deal of the actual work will be carried out by and through them. The Education Department and official agencies for development and rural reconstruction should also be consulted. Among voluntary agencies the Red Cross Society, St. John Ambulance Association and Maternity and Child Welfare organizations are interested and have been carrying out active tuberculosis work in a number of areas. Charitable and social organizations which are concerned in any way with the problem should be approached to help. The best way to link up all these bodies is to appoint representatives from them on the council of the association.

It should be remembered that the success of all tuberculosis measures will depend on obtaining the co-operation of the entire medical profession, especially the general practitioner.

9. Funds

The various activities mentioned in this note are all legitimate objects upon which the funds of the association may be spent. In allocating funds in the first instance an endeavour should be made to spend not less than 75 per cent on institutions and organizations primarily of a preventive character (the chief of which

is the tuberculosis clinic) and in this way districts will derive immediate benefit from the sums contributed by them.

10. Housing

In view of the wide-spread existence of slum conditions which contribute so largely to tuberculosis in urban areas and of the tendency that unfortunately persists towards the creation of more overcrowded areas, tuberculosis associations should take a leading part in stimulating measures directed towards the removal of existing slum conditions and their prevention in future.

11. Education work

All kinds of educative work on the control and prevention of tuberculosis fall within the scope of a tuberculosis association and should form an important part of its activities.

NOTICE

THE editorial committee of the King George Thanksgiving (Anti-Tuberculosis) Fund wishes it to be made quite clear that approval of the above papers, as suitable for publication, does not necessarily carry with it approval of the principles enunciated therein. They do not wish the number to represent only their own points of view, but rather those of all workers in India, who, by their position and achievements, can be considered competent to express an authoritative opinion.

Special Article

B. C. G. VACCINATION IN PRACTICE*

By L. NÈGRE,

Chef de Service à l'Institut Pasteur, Paris,
and

R. K. GOYAL, D.Sc., Ph.D., M.R.C.P., F.R.S.E.

From the School of Tropical Medicine, Calcutta

WE have already described the experiments showing the immunizing powers of B. C. G. in the case of small laboratory animals, cattle and anthropoid apes.

Calmette and Guérin tried to determine the behaviour to natural tuberculous infection of vaccinated monkeys and cattle. The experiments of Wilbert at the Pasteur Institute, Kindia, had shown that monkeys vaccinated by subcutaneous injections of 50 mgm. of B. C. G. or 5 oral administrations of 50 mgm. were resistant to infection when placed in contact with tuberculous monkeys, whilst the controls contracted the infection.

Cattle were vaccinated by intravenous injections of 20 mgm. of B. C. G. or preferably by 50 to 100 mgm. by the subcutaneous route. The resistance thus conferred lasted at least a year; it could be maintained by similar subcutaneous revaccinations.

For successful vaccination, it is indispensable to separate the heifers from the tuberculous surroundings immediately after birth, otherwise there is danger of natural infection before the immunity by B. C. G. can be established.

Calmette and Guérin wanted to determine if B. C. G. vaccination alone could stamp out

tuberculosis in 5 years in a heavily infected farm, where all measures of isolation and disinfection were suspended. The vaccination was to be performed within the first 15 days of life and the cattle were to be revaccinated each year by the subcutaneous route with 100 mgm. of B. C. G. Guérin, Richart and Boissière vaccinated 88 cattle in a heavily infected farm at Gruville. Vaccination was repeated each year and all the new-born calves were also subjected to the same treatment. A large number of cattle had to be destroyed for economic reasons. Amongst the grown-up animals 10 out of 53 showed tuberculous lesions; 30 heifers were born and brought up in these surroundings, they were simply vaccinated as detailed above, but no other precautions were taken. They were sacrificed and found to be free from lesions ascribable to tuberculosis. Twenty out of these 30 were born of mothers who were either definitely suffering from tuberculosis or were suspects. The young ones were brought up on the unboiled mother's milk in the first month of life.

Thousands of vaccinations effected in cattle in different countries fully bore out the efficacy and safety of B. C. G.

The Veterinary Commission of the B. C. G. conference recognized the immunizing properties of the vaccine and encouraged its use in the prophylaxis of bovine tuberculosis.

One rigidly controlled experiment was undertaken in 1926 by the Commission of Alberta, Canada. The report of Professor A. C. Rankin published by the National Research Council of Ottawa established the harmless nature of B. C. G. in the case of healthy calves.

*Submitted direct to the *Indian Medical Gazette*.

Fifty calves (25 vaccinated and 25 controls) isolated from all tuberculous contacts were tested one year after vaccination by an intravenous injection of virulent bacilli. All the controls had tuberculous lesions. Only one vaccinated calf, dead at 3 months, was found to be tuberculous. Three presented calcified and healed lesions, 1 showed 5 small calcified tubercles and 20 were free from both macroscopic and microscopic lesions.

In another experiment, 50 calves (25 vaccinated and 25 controls) were kept for 8 months in an infected herd. Amongst the controls, 5 died before the date fixed for destruction, 7 presented extensive caseous lesions, 72 per cent had microscopic lesions.

In the vaccinated, 8 had small non-extensive lesions, while 68 per cent were free even from microscopic lesions.

Ascoli vaccinated more than 5,000 cattle since 1925 and Gerlach in Austria more than 4,000 calves; none of the vaccinated beasts slaughtered after a year presented any lesions, although they came from a herd containing 50 per cent infected animals. Sanz in Chili vaccinated 2,554 calves and 993 pigs from 1925 to 1929. During these 4 years, none of the vaccinated animals presented tuberculous lesions.

At Berkeley, California, a Commission consisting of Haring, Traum, Hayes and Henri vaccinated 282 calves less than 10 days old and 15 older ones. One hundred and eighty-two belonged to a heavily infected herd, while 90 taken from tubercle-free farms were observed with an equal number of controls. These authors concluded in favour of the efficacy of the vaccination.

Assis and Dupont in Brazil, the Ukrainian Commission of Karkoff, Buxton and Stanley Griffith in England also concluded in favour of the efficacy and safety of B. C. G. in the case of cattle.

The results obtained with cattle constituted a solid basis for the application of anti-tuberculous vaccination of human beings.

The method of administration to infants

The bacillary infection is much graver for the infant in the first few months of its life than for older children or adults. At this early age, it is absolutely dependant on people who look after it. If a very young baby were to be brought up in tuberculous surroundings, it would almost never escape the contagion. The preventive vaccination should therefore be practised as early as possible after the birth of the baby, in order to protect it from threatened infection and to raise its resistance in case of future illness.

The vaccination of infants after the first few days of birth can be effected by the subcutaneous route, as in young cattle. But the subcutaneous administration in the newly-born is not popular with the relatives, hence Calmette had recourse to the oral route. A large number

of authors have shown that microbes and toxins easily penetrate the intestinal mucosa of animals and of newly-born babies; only incompletely differentiated cells form the intestinal lining in the first fortnight of life.

B. C. G. vaccine, being constituted by living, avirulent and non-tuberculeogenic bacilli, must be freshly prepared. It cannot be conserved for more than 10 days. It is therefore impossible to stock it and to despatch it in advance. The Pasteur Institute, Paris, sends it out only when the birth of the child is notified. It should be administered in the first 10 days of life of infants on the breast.

The Paris Institute delivers the vaccine in ampoules, each one represents a single dose for oral administration. Each dose is mixed with a little milk in a teaspoon, and is administered half-an-hour before suckling. Three doses are given on alternate days as early as possible after the birth, i.e., third, fifth, and sixth or seventh, eighth and tenth days.

The ingestion is absolutely inoffensive, no digestive disturbance or malaise being produced. There is no inconvenience or danger in vaccinating the newborns of healthy parents. The vaccination protects against an accidental infection, which is always a possibility.

It is desirable not to give B. C. G. to premature, jaundiced, malformed or obviously debilitated infants, as the accidents occurring naturally would be attributed to B. C. G. by the relatives. Professor A. Convelaire has shown that approximately 12 per cent of non-vaccinated babies born of tuberculous mothers die of congenital debility, which manifests itself in the first month of life.

It is always necessary to isolate the newly-born from the tuberculous parents from the very day of birth. This isolation should be strictly enforced for a few months after vaccination as the immunity develops gradually. If complete segregation be impossible, the usual precautionary measures to combat the disease should be taken for an indefinite period.

The duration of immunity conferred by B. C. G. is not definitely known, it is therefore necessary to vaccinate by the oral route at the end of the first and third years and later at seventh and fifteenth years of life.

The same procedure of 3 doses given at 48 hour intervals should be followed, the vaccine should be given on an empty stomach in the morning, half an hour before the first meal.

The first human experiments

The animal experiments having demonstrated the safety of B. C. G., Calmette and Weill-Halle tried it on an infant. It was tried in July 1921 on a suckling, who was in constant contact with his tuberculous grandmother and was thus almost sure to be infected; 6 mgm. in 3 doses were given shortly after birth, the infant grew up normally and remained free from tuberculosis.

After this favourable attempt, Weill-Halle and Turpin vaccinated 317 infants from July 1921 to July 1924. These cases were kept under strict observation, as 67 of them were born and brought up in bacilliferous surroundings. The total quantity of B. C. G. for ingestion was later on increased to 3 centigrammes.

Up to January 1927, only 1 out of 317 cases died of tuberculosis. The fatality occurred at 4 months of age, the baby being suckled from his birth by his tuberculous mother; 14 others died of diseases other than tuberculosis. No functional trouble nor any arrest of development was noted in any of these cases.

The harmlessness of B. C. G. for babies appeared thus to be established. The Paris Institute decided from July 1924 to distribute B. C. G. to private practitioners for vaccination purposes. In order to prepare reliable statistics, a circular letter was issued during 4 years to all the practitioners who employed B. C. G. A register was specially kept for all the babies who were either born of tuberculous mothers or were brought up in bacilliferous environments. The Institute Pasteur thus followed 3,607 special cases from July 1924 to July 1928. The total number of vaccinations during this period was 114,000.

The mortality from tuberculosis of babies 1 month to 1 year old brought up in tuberculous families was 1.5 per cent. All the cases which were reported to have died of meningitis were counted as having died of tuberculosis even though death occurred during the first 3 months of life. In the case of vaccinated infants aged 1 to 4 years, the mortality from tuberculosis, calculated on the same basis, was 0.3 per cent. Mortality from all diseases of babies 1 to 12 months old (vaccinated and in contact with tuberculous patients) was 7.3 per cent and those of 1 to 4 years old, 1.7 per cent.

There being no official statistics of mortality from tuberculosis, Calmette sent a questionnaire to 204 dispensaries or offices. The replies showed that 4,854 non-vaccinated babies born from 1925 to 1927 showed a mortality rate of 15.9 per cent, whilst the 2,368 vaccinated, of the same age, presented a 3.4 per cent mortality rate.

It is evident that for children of the same age, born and brought up in exactly similar conditions and examined by the same institutions, the preventive vaccination reduced the tuberculous mortality by nearly three-quarters.

In another investigation, 814 babies were vaccinated but were brought up in contact with their tuberculous mothers for at least a year after birth. They showed a 2.4 per cent mortality rate from tuberculosis, whilst the death-rate from all causes was 10.6 per cent.

The value of vaccination is clearly demonstrable by these figures for the category of children whose mortality is admitted on all hands to be very high.

More recent statistics

At present, more than 1,200,000 vaccinations have been carried out in France and nearly the same number in other countries.

The last investigation conducted by Calmette was definitely in favour of vaccination. Eight thousand and seventy-five babies in tuberculous contact were observed by 114 dispensaries; the mortality from all causes from birth to 1 year was 4.6 per cent in the vaccinated and 16 to 25 per cent in the non-vaccinated.

Five hundred and fourteen infants of doctors' families were vaccinated at birth during 8 years, i.e., 1925 to 1932, 60 of them undoubtedly lived with tuberculous people, 43 were in contact with suspects, 140 were revaccinated once or twice at 1 and 3 years of age. From 1924 to 1932 inclusive, 7, i.e., 1.3 per cent, died, and only 1 succumbed to a malady suspected to be tuberculosis.

At Brest, J. Querangal of Essarts and Madam de Carbonnieres of Saint-Brieux followed up the babies in 823 families for 8 years. The general mortality was 7.3 per cent in 1,193 vaccinated babies and 17.7 per cent in 1,084 non-vaccinated controls. In 262 families in which babies were exposed to tuberculosis with certainty, the mortality from all causes in 366 vaccinated cases was 11.2 per cent between 1 month and 7 years, but 23 per cent in non-vaccinated controls. Deaths, probably due to tuberculosis, were 6.2 per cent in vaccinated and 13.2 per cent in the controls. In 561 families apparently free from tuberculosis, the general infantile mortality between 1 month and 7 years was 5.5 per cent in 827 vaccinated and 13.6 per cent in 616 non-vaccinated.

The above-mentioned authors could establish by comparison that in the families of Brest, the general infantile death-rate was 7.6 per cent between 0 to 1 year and 11 per cent between 0 and 3 years. In tuberculous families of the same region, the vaccinated babies had a general death-rate of 5.7 per cent from 0 to 1 year and 7.6 per cent from 0 to 3 years, but the controls had 14.7 per cent and 20.8 per cent mortality respectively.

In 463 families, the general mortality in 640 infants born before the era of vaccination (1927) was 20.1 per cent. In exactly the same families, babies born after 1927 showed 9.7 per cent mortality for vaccinated and 17.7 per cent for non-vaccinated. These statistics clearly establish the beneficial effects of B. C. G. The results obtained in other countries confirm the conclusions drawn from the French figures.

Professor Badouin vaccinated 8,452 newly-born babies from 1926 to 1936. There was a decrease of 55.4 per cent in the general death-rate of the vaccinated. The mortality from tuberculosis was 70 per cent less in the vaccinated, although the non-vaccinated were also cared for by the nurses of Bruchesi Institute. As a matter of fact, the vaccinated had 43 per cent visits and the non-vaccinated 64 per cent.

In the families where babies died of tuberculosis, 94 per cent of the vaccinated survived and only 78 per cent of the non-vaccinated.

The tuberculous mortality of infants living in tuberculous families was less by 51.5 per cent in the vaccinated.

The experiments of William H. Park at New York were particularly suggestive, as these were conducted since December 1926 on babies born of tuberculous mothers in the hospital, who were regularly examined; 208 of these babies were vaccinated and 350 were kept as controls up to 1st January, 1930. After 3 years of observation, deaths from tuberculosis in the non-vaccinated of 0 to 1 year were 8 per cent, and only 0.9 per cent in the vaccinated. In 1 to 2 year-old infants, the non-vaccinated had a tuberculous mortality of 3.8 per cent and in the vaccinated it was nil.

From 1927 to 1934, Aronson and Dannenberg in Philadelphia vaccinated *per os* 70 newly-born babies and kept 163 as controls. Out of this number 41 vaccinated and 84 non-vaccinated were born and brought up in tuberculous families. From amongst the 84 non-vaccinated, 10, or 11.9 per cent, died of tuberculosis between the ages of 4 to 30 months, on the other hand, only one or 2.4 per cent of the vaccinated died. Fifteen other vaccinated babies and 41 controls were reared in families containing members with either healed or supposedly-healed lesions. Two out of the 41 non-vaccinated died of tuberculosis between 7 to 11 months of age, but none of the vaccinated contracted the disease. Out of the 14 vaccinated and 38 controls brought up in tubercle-free families, none developed the disease.

More than 100,000 babies were vaccinated in Roumania since 1927. The general mortality rate was reduced by more than half.

Tuberculin skin reactions after B. C. G.

We have previously pointed out the difference between allergy and immunity. But a marked allergic reaction is a sign of absorption of B. C. G. It is therefore interesting to determine the tuberculin reaction in vaccinated subjects.

Unfortunately in the case of babies who have been vaccinated and brought up in contact with open cases of tuberculosis, it is impossible to determine whether the positive tuberculin reaction is due to B. C. G. or to the superimposed infection.

This difficulty has been overcome by Leon Bernard, R. Debre and M. Lelong. The babies born of tuberculous parents were removed to healthy families and vaccinated. There was thus no question of being brought up in baneful surroundings.

The non-vaccinated babies segregated from birth always remained tuberculin-negative, whilst out of 105 vaccinated cases, 50 showed, at least once, a positive cutireaction (von Pirquet's reaction).

Debre and Cofino extended this study by increasing the dose of tuberculin in negative reactors, the amounts used being 0.1, 0.5 and 1 mgm. of tuberculin. All the 141 controls gave a negative reaction, whilst 88.6 per cent of the cases vaccinated *per os* gave a positive reaction (out of the 117 positives, 42 von Pirquet's and 75 Mantoux's tests were positive).

In a more recent study, Debre, Lelong and Pictet demonstrated 97 per cent positives in vaccinated babies, who had been kept away from tuberculous people. The allergy appeared generally within 3 months and persisted up to 5 years.

The intradermal reaction with graduated doses was found to be much more valuable than cuti-reaction, the percentage of positives being much higher.

The positive allergic reactions establish without a shadow of doubt that B. C. G. is absorbed by the intestinal route. It appears that allergy following oral vaccination appears slowly, is often transitory and is not easy to detect, as in 50 per cent of cases it can be revealed only by giving increasing doses by the intradermal route.

One can conclude from the work of Debre that allergy conferred by B. C. G. can persist up to 5 years. It is therefore possible that the immunity also lasts for a fairly long time. In the case of cattle and monkeys, it endures for 15 to 18 months, and can be prolonged by annual revaccination.

The revaccinations *per os* in infants are practised at 1, 3, 5, 7 and 15 years. The ingestion by allergic subjects is without any danger, therefore tuberculin reactions are not elicited before the revaccination. In cases of positive allergic reactions, it is useless to revaccinate, as the positive reaction indicates either the persistence of B. C. G. or the presence of a virulent infection.

B. C. G. in older children

The oral route of administration had been exclusively used for the newborn, Calmette and Guérin wanted to know if older children or adults could also be vaccinated by the same method. Their suggestion was followed by Vaucel and Saleun who administered *per os* 3 doses of 1 centigramme of B. C. G. to non-allergic black people of all ages. These authors showed that 55 per cent became tuberculin-positive 3 months later. After a second test, 25 per cent more reacted positively. Boisseau and Nodenot made non-allergic subjects of 2 to 50 years of age ingest a single dose of 3, 5 or 10 centigrammes of B. C. G. The tuberculin reactions were positive in the following proportion:—

40	per cent for 3 centigrammes.
80.25	" " 5
89.74	" " 10

Debre, Lelong and Pictet, however, had less favourable results in the case of the segregated children. They administered 3 fresh doses of 1 centigramme to 101 non-allergic infants 10

months to 4 years of age, who had already received B. C. G. *per os* at birth. Six months later only 50 per cent gave positive tuberculin reactions.

As B. C. G. is absorbed by the intestinal mucosa in an appreciable number of infants other than the newly-born, so it is very easy to administer it to subjects of all ages. It would be essential in such cases to exclude tuberculosis by clinical, radiological and allergic tests. The fact, however, must not be lost sight of that the best age for vaccination is the first 10 days of life.

If for some reason the vaccination is not done at birth, one should wait till the age of 6 months, because an accidental infection very early in life cannot be excluded by skin tests before this age. The intradermal or cutireactions are obtainable after a long period, if the infection be very mild (*'paucibacillare'* as the French call it). From 6 months to 2 years of age, the vaccination can be performed if the subject be in good health and were to give 2 negative cutireactions performed at 7 days interval. The baby should be isolated from all suspected cases and 3 doses should be administered as described before.

Revaccinations at 3, 7, and 15 years are to be performed in the same way. The Pasteur Institute, Paris, has prepared a special B. C. G.-NR for the use of subjects more than two years of age.

Subcutaneous vaccination

The guinea-pigs and cattle having given favourable results in the subcutaneous anti-tuberculous vaccination, the problem of the use of the same method was broached in the case of tubercle-free adults.

The first vaccinations were tried on a few hundred young soldiers in Senegal and Madagascar.

It is well known that black people coming from regions containing very few or no Europeans are extremely susceptible to tuberculosis. When such people are brought to Europe, they readily succumb to infection and the disease resembles the form observed in European babies.

It was therefore necessary to find out if the subcutaneous route could be utilized for the vaccination, as the intestinal route is not very favourable for adults. The amount selected was 1/10 to 1/20 mgm. as this dose did not cause the production of a cold abscess at the point of inoculation. Four hundred Senagalese and Malgaches were vaccinated, and none of them developed tuberculosis.

At the same time Weill-Halle and Turpin in Paris and J. Parisot at Nancy and Wallgren in Sweden undertook the experiment of vaccination by the hypodermic route.

Weill-Halle worked with sucklings of a few weeks to a few months old; he started with 1 mgm., then reduced it to 1/4 mgm., then 1/20, 1/50 and finally 1/100 mgm. in order to decrease the local reaction. The injection of

1 mgm. always caused the appearance of a local subcutaneous nodule (granuloma), which ultimately healed without having any ill-effect on the general health. The dose of 1/100 mgm. produced a slight subcutaneous infiltration which persisted for some weeks and was gradually absorbed. Later, Weill-Halle selected the axillary border of the scapular region as the site of injection and injected 1/50 mgm. at two points, i.e., 1/25 mgm. in all. If the baby was in healthy surroundings or had been segregated for several weeks, two or more cutireactions were always performed at 8 days' interval, to exclude tuberculosis. If the baby lived in a bacilliferous home and gave a negative cutireaction, it was isolated for one month. If the skin test at the end of this period was again negative, then only was the baby vaccinated.

Parisot and Saleur used a single dose of 1/100 mgm. for 269 subjects of 1 to 16 years; 139 had been in tuberculous contact and 130 in healthy surroundings. The babies were examined clinically and radiologically, 2 skin tests also being performed. The local reactions were observed especially in the beginning of the experiment, the dose employed at this stage being 1/4 mgm. In only 9 cases, or 3 per cent, was there breaking down and an ulcer, but no general reaction was produced even in cases in tuberculous contact.

At the Ulleval Hospital of Oslo, Heimbeck vaccinated the probationer nurses by injecting 1/20 mgm. subcutaneously. The country being very thinly populated, a large number of adults are negative-reactors to tuberculin. It is therefore not astonishing that the majority of nurses are tubercle-free and contract the disease after attending tuberculous cases. Fifty-seven out of the 457 probationer-nurses were affected with the disease and could be classified as follows:—

Two hundred and sixteen cases giving a positive skin test—2 cases of tuberculosis (9.9 per cent).

Two hundred and forty-one negative reactors—55 cases of the disease (23 per cent).

It was thus clearly demonstrated that the positive reactors had a marked resistance to the disease as compared to the negative reactors.

In 1927, 44 negative reactors consented to be vaccinated, and all remained free from tuberculosis. Twelve cases giving a negative skin test refused vaccination; 5 of them became tuberculous.

In Norway, Sheel found that the medical students who gave a negative skin reaction before working in the tuberculosis wards were three times as liable to fall a prey to tuberculosis as the allergic students. The morbidity of the negative reactors was reduced by half if they were vaccinated.

The allergic reactions make their appearance in 78 per cent of cases 2 to 4 months after oral vaccination. If repeated injections are given and the dose is increased 100 per cent become allergic.

Wallgren injected B. C. G. intradermally in non-allergic babies, a mild local reaction was produced, the nodule never became more than pea-size in diameter and disappeared altogether in a few weeks. The ante-allergic period is inversely proportionate to the amount of the vaccine injected. The dose of 0.5 to 1 mgm. causes a positive reaction after 3 weeks, 0.25 mgm. after 4 weeks, 0.1 mgm. after 6 weeks, 0.05 mgm. after 7 weeks. If there be no reaction, gradually increasing doses are given till a positive reaction is obtained.

Wallgren especially chose for vaccination the babies from tuberculous homes. Such cases were separated from the family immediately after birth and were kept in a building especially reserved for the purpose. They were fed on the breast and were returned to their families only when the positive skin test was obtained. The minimum time of separation was 6 months in 6 cases and up to 2 years in certain others. The tuberculous contact lasted from 4 to 72 months.

Out of 230 cases, more than a third were vaccinated at birth, others at school age. They were x-rayed at least once a year and were kept under observation as out-patients.

Only 1 out of the 230 showed a hilum tuberculosis; the father and elder brother of the case had had pulmonary tuberculosis. The stomach contents showed the presence of Koch's bacilli; the baby was completely cured by the end of the year.

In 4 cases, the hilar shadows were slightly larger than normal.

In 7 cases, it was not found possible to say if the hilar shadows were normal.

Two hundred and sixteen cases presented normal appearances.

Two out of these 230 cases in tuberculous contact died of other diseases than tuberculosis.

The prophylactic vaccination was introduced in Gothenberg in 1927.

The mortality figures tabulated for every five years were 4.3, 4.2 and 3.4 per 1,000 before the vaccination was introduced. The year 1927 being a period of transition showed a mortality rate of 3.9 per 1,000. From 1928 onwards, vaccination was rigidly enforced, only 1.4 per 1,000 succumbed during the next 5 years. This showed a decrease in mortality by less than 60 per cent. In 1933, the death-rate fell still further to 0.3 per 1,000. On the other hand, the general mortality from tuberculosis, especially pulmonary, did not show the same diminution. The sources of infection were not reduced but the mortality from tuberculosis fell, and this could only be due to B. C. G. vaccination.

Wallgren, William Park, C. Kereszturi and Bela Schick prefer the subcutaneous or intradermal route to the oral. These authors consider the method to be more reliable, producing allergic reactions more regularly. They utilize

0.0001 to 0.05 mgm. for the subcutaneous injection and 0.003 to 0.15 mgm. for the intracutaneous. Sixty per cent of the subcutaneous vaccinations produce cold abscesses and 90 per cent of cases give positive tuberculin tests. The allergy disappears in 26 to 33 weeks. These authors prefer the intradermal route because abscess formation is avoided, but the allergy produced is less intense and less frequent. None of their vaccinated cases died of tuberculosis, but 3 per cent of controls went to the grave.

Criticisms

As happens with all new methods, certain objections have been raised against this vaccination. Certain authors have stated that B. C. G. cannot be absorbed by the intestinal route, therefore the oral vaccination is ineffective. It has already been shown that young rabbits and guinea-pigs which have received B. C. G. *per os* become allergic, although slowly. The same holds good for newly-born babies as has been shown by Robert Dehre and his collaborators. Other proofs of the absorption of B. C. G. are its presence in the organism and the leucocyte or histological changes observed in the vaccinated infants.

A. Calmette, B. Weill-Halle, A. Saenz and L. Costil have shown in the case of 5 non-allergic sucklings aged 6 months to 2 years the absorption of B. C. G. administered by the oral route. When the blood was cultured by the method of Loewenstein, B. C. G. was demonstrable 3 to 5 hours after its administration in 3 of the cases. Zeyland and Madam Zeyland obtained positive cultures from the organs of babies vaccinated 6 months before or earlier and dead of non-tuberculous disease. In the case of babies vaccinated *per os*, Pittaluga and Garcia demonstrated an early monocytosis rising to 15 per cent on an average, accompanied or more often followed by a prolonged lymphocytosis and corresponding diminution of neutrophils, with a slight deviation to the left of Arnehl's index. These leucocytic changes denote a defensive activity of the vaccinated organism resembling the changes occurring after a natural infection; if anything, they are more rapid in onset. Pittaluga and Garcia conclude from this the existence of absorption of B. C. G. by the intestinal mucosa.

The histo-pathological study of vaccinated animals and babies has revealed the same phenomenon. In the guinea-pig vaccinated 2 to 5 days after birth and sacrificed at different intervals, Jensen, Moreh and Orskov have observed the agglomeration of epithelioid cells and fibroblasts in the liver and lungs. The lesions cicatrize between 6 to 7 months. The same changes have been observed in vaccinated infants by Ciuca, Francke and Vitner Rosenthal. The mesenteric glands and liver have shown marked proliferation of reticuloocytes and also of macrophages and fibroblasts, and a less common infiltration by granulocytes.

Another proof of intestinal absorption was furnished by Sayce. His radiographic studies of vaccinated infants revealed the presence of benign lesions, which could not be due to anything else but B. C. G.

These data show definitely that the intestinal route can be utilized for vaccination.

Certain clinicians have propounded the hypothesis that B. C. G. may become virulent after remaining as a parasite for a long time. No facts have been adduced in favour of this contention. In fact the bile-treated bacilli are eliminated little by little, and disappear completely later on. At this moment immunity also disappears in its turn. Autopsies of vaccinated infants have never revealed tuberculous lesions. Zeyland and Madam Zeyland isolated B. C. G. from the organs of the vaccinated and found it to be inoffensive by animal passage.

Certain clinicians have attributed to B. C. G. the onset of tuberculous meningitis in the vaccinated. So far no proof in favour of this idea

has been brought to the notice of the Permanent Commission on B. C. G. An overwhelming majority of such babies has been brought up in tuberculous surroundings and has not been separated from the contacts after vaccination. We feel therefore right in affirming that the meningitis is due to infection contracted soon after birth before the immunity by B. C. G. can be established. It must not be forgotten that no method of vaccination is effective against massive and repeated infection, as occurs when a newly-born baby is brought up by a tuberculous mother.

People with ideas of an opposite order fear that B. C. G. has become too attenuated in virulence to be an active immunizing agent. They can rest assured that the experiments on laboratory animals have shown it to be as active as ever in its immunizing properties.

The use of B. C. G. in different countries of the world has shown definitely its efficacy in combating tuberculosis.

Medical News.

INDIAN MEDICAL COUNCIL

In exercise of the power conferred by clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), the Central Government is pleased to nominate Lieutenant-Colonel B. Z. Shah, M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., Director of Health Services and Inspector-General of Prisons, Sind, to be a member of the Medical Council of India, from Sind, with effect from the 6th July, 1938, *vice* Lieutenant-Colonel M. J. Holgate, I.M.S., resigned.

RAI SHAMBHU DAYAL SAHIB GOLD MEDAL

A gold medal called the 'Rai Shambhu Dayal Sahib Gold Medal' will be presented for the best prize essay on a public health subject to be announced each year.

The subject of the next essay is 'A Scheme to fight against Tuberculosis in these Provinces with ways and means for raising money for the campaign'.

The competition will be open to the general public, including the medical and the public health workers in the United Provinces.

The essay is to be written in simple Hindi and should not exceed 3,000 words in length.

Essays should reach the Medical Officer in charge Provincial Hygiene Institute, United Provinces, Lucknow, by 15th November, 1938.

The name and address of the competitor must be distinctly written on each essay submitted and the envelope should have the words 'Prize Essay' in the top left-hand corner.

The Director of Public Health, United Provinces, shall judge the merit of the essay and his decision with regard to the award of the medal shall be final.

No correspondence will be entered into on the subject of the competition. No essay will be returned.

INTERNATIONAL MEDICAL POST-GRADUATE COURSES IN BERLIN

THE Berliner Akademie für ärztliche Fortbildung is holding the following medical post-graduate courses in autumn of 1938:—

1. Course in the field of internal diseases in which lives are suddenly endangered (from 3rd to 8th October). Fee: RM 50.

2. Post-graduate course on the subject of ailments of muscles and joints (from 10th to 16th October). Fee: RM 50.

3. Progress in the field of hormones and vitamins (from 17th to 22nd October). Fee: RM 50.

4. Course on tuberculosis in the Berlin Municipal Hospital for Tuberculosis (from 24th to 29th October). Fee: RM 50.

5. Course in diseases of the ear, nose and throat (from 26th September to 8th October). Fee for the whole course: RM 150; for the theoretical part of the course: RM 100.

6. Course in accident-surgery (from 17th to 22nd October). Fee: RM 70.

7. Post-graduate course on the subject of neurotic diseases (from 24th to 29th October). Fee: RM 50.

8. Special courses in all branches of medicine with practical work at the bedside and in the laboratory, to be held every month. For these courses participants are requested to communicate their wishes in order to find a complete programme on their arrival.

Courses 1 to 7 will be held in German, and the special courses also in foreign languages.

For programmes and further information apply to the Geschäftsstelle der Berliner Akademie für ärztliche Fortbildung, Berlin NW 7, Robert Koch-Platz 7 (Kaiserin Friedrich-Haus).

Foreign doctors and German doctors resident abroad are granted a reduction of fare of 60 per cent on the German Railways Company's lines; a foreign doctor can reduce the cost of his stay considerably by utilizing the so-called 'registered marks'; it is advisable to arrange matters with the local bank before starting.

Reviews

THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE. Under the General Editorship of Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., M.D., D.Sc., D.C.L., LL.D. 1938. Butterworth and Company (Publishers), Limited, London. (To be completed in 11 volumes, of which seven have already been published.) Sold in complete sets only. Cash price, Rs. 25 per volume. Also available on the instalment system at Rs. 10 per month. Price, Rs. 26-8 per volume. Only available from Messrs. Butterworth and Company (India), Limited, Calcutta. Volume II. Pp. 767 plus xxiii plus 63

THE second volume of this encyclopædia commences with apraxia, covers the whole of the B's, and in the last few pages commences the C's, with caisson disease, cancer (a short general chapter), cancerous oris, canities, and carriers in infectious disease.

Of special interest to readers in India will be found Major W. S. Patton's article on arthropods and disease, Sir Rickard Christopher's on blackwater fever, and Dr. Hamilton Fairley's on bites and stings.

Of the subjects of more general interest Dr. George Bray has contributed a useful and concise chapter on asthma and the chapter on backache and lumbago by Dr. James Mennell gives one of the most precise descriptions of the examination of a patient suffering from back pain that we have ever seen: it is a chapter that should prove of immense value to the practitioner, who is continually being consulted by his patients about this troublesome condition. Under aviation details are given for the examination of pilots; though the final examination for the air services will obviously be carried out by a trained expert, it is useful for the practitioner to be able to indicate what physical shortcomings are likely to disqualify his patient who may thus be saved disappointment later.

There is a chapter of nearly fifty pages on blood examinations by Dr. Lionel Whitby; this is an important chapter which we are glad to see entrusted to a hæmatologist who, whilst maintaining the best traditions of the British school, does not consider that this necessitates being ten years out of date, in these rapidly moving times: the chapter includes two excellent coloured plates.

The chapter on blood transfusion by Dr. F. A. Knott is another that we can commend for its practical value; the various circumstances under which transfusion may have to be given are taken into consideration and simple as well as the more complicated apparatus described.

The high standard of this excellent publication is well maintained in this volume.

THE PHARMACOLOGICAL SHOCK TREATMENT OF SCHIZOPHRENIA.—By Dr. Manfred Sakel, M.D. Authorised Translation by Joseph Wortis, M.D. Revised English Edition. 1938. Nervous and Mental Disease Publishing Company, New York and Washington. Pp. xviii plus 136. Illustrated. Price, \$2.75

It has long been known that a certain number of patients, some of whom have been well advanced in a psychosis, have recovered after experiencing some sort of 'shock', for example, that initiated by being knocked unconscious or bitten by a snake. Further, many drugs and other therapeutic agents which have appeared to produce remissions in individual cases are of shock import. Dr. Julius Schuster, of the University Psychoneurologic Clinic at Budapest, was the first to make the striking observation that a series of mental patients were under-sensitive to insulin and from this fact he concluded that treatment with insulin might improve their condition. Pharmacologic treatment of schizophrenia, as described in this monograph

by Dr. Manfred Sakel, has now become an established procedure in many hospitals for mental disorders. As Dr. Nolan D. C. Lewis states in the introduction he has written to this monograph, there exists at present a consensus of opinion which grants (1) that the clinical aspects of the disorder can be removed or favourably influenced in a relatively large percentage of certain types of patients, at least for a period of time, (2) that some types are not favourably influenced, but continue as before in their disorder, (3) that there is a considerable variety of psychological and physiological reactions during the therapeutic procedure itself, apparently depending not only upon the inherent individual integrations of the patient, but also upon the nature of the insulin, and the technique of the physician, (4) that the results have brought more forcibly to mind a possible reversibility in at least some of the physiopathological and psychopathological processes involved in the disorder, and (5) that metabolism is influenced by the insulin situation as indicated by the reported changes in the blood sugar, amino acids, potassium, inorganic phosphorus, cholesterol and serum proteins, with the degree of change not always dependent upon the size of the dose of insulin administered. Dr. Sakel differentiates between 'insulin hypoglycemia', that is, the insulin treatment used for morphinism and 'hypoglycemic shock treatment' which consists of the deliberate production of severe shocks and the extension of the duration of hypoglycemia. Dr. Sakel begins by describing the methods of administering this treatment which he divides roughly into four phases. The 'shock', according to Dr. Sakel, may consist of either coma or an epileptic seizure. In the former case, the shock starts with profuse perspiration hence this is termed a 'wet shock'. The progressive somnolence may be interrupted by psychotic excitement but ends typically in coma. Less commonly than this type of shock is a 'dry shock'. This consists of a sudden severe and typical epileptic seizure with tonic and clonic spasms, tongue biting, etc. According to Dr. Sakel, it is not possible to predict in advance the epileptic type of hypoglycemic reaction. Further, there are two varieties of epileptic convulsion met with in hypoglycemia: the 'dry' shock or early epileptic seizure which occurs in the second or third hour after the initial injection and a later epileptiform seizure which occurs in the fourth or fifth hour of hypoglycemia and not infrequently in the course of a wet shock. This late epileptic convulsion must be regarded as a danger signal and is an indication for an immediate interruption with intravenous glucose. After a careful description of the method of treatment, Dr. Sakel goes on to discuss subsidiary features, including psychotic reactions, of which the most common is paranoid attitudes. Of the theoretical aspects of the treatment, Dr. Sakel advances a tentative theory which will repay study, the essence of which is that the effect produced depends first upon 'neutralization of the excitant hormone' and second, 'on the vagotonic muffling of the cell'.

The introductory preface by Dr. Foster Kennedy is so extremely interesting that it alone makes the book worth buying. It is to be hoped that this important monograph will obtain the reception it deserves in India where psychiatry is still in a more or less embryonic stage.

O. B-H.

PNEUMONIA AND SERUM THERAPY.—By F. T. Lord, M.D., and R. Heffron, M.D. Revised Edition of Lobar Pneumonia and Serum Therapy. 1938. The Commonwealth Fund, New York. Oxford University Press, London. Humphrey Milford. Pp. xlv plus 148. Illustrated. Price, 4s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THE successful treatment of certain types of pneumococcus pneumonia has been made possible through advances in the investigation of the pneumococcus and pneumococcal serum. But difficulties in obtaining early bacteriologic diagnosis, cost of serum, lack of

familiarity with its use, and fear of reactions have delayed the wide adoption of the method.

This book is a product of valuable research on pneumonia, carried out in Massachusetts and financed by the Commonwealth Fund. It was first published in 1936 under the title of 'Lobar pneumonia and serum therapy', which has now been changed to the present one, as recent investigations have shown that specific therapy is also applicable to atypical cases and even to some cases of bronchopneumonia. The present edition furnishes new information on dosage, the use of rabbit antiserum and the results of specific treatment of types I, II, V, VII, VIII and XIV pneumonia.

The book also refers to clinical diagnosis and selection of cases for treatment and describes, in a practical manner, the Newfold method of typing, procedures for initiating serum therapy and the precautions that are necessary prior to its administration.

R. C.

NEUROLOGY.—By Roy R. Grinker, M.D. Second Edition. 1937. Ballière, Tindall and Cox, London. Pp. 1000, with 406 figures. Price, 38s.

This is an excellent book on neurology written by an author who has devoted his whole attention to the study of the diseases of the nervous system in one of the important institutions in America. That this volume has passed through a second edition within a short period of three years is enough evidence to prove its usefulness to the medical profession. Errors and omissions are fully rectified and all modern and up-to-date knowledge incorporated, the author has succeeded in bringing the book to a high standard.

The writer has devoted nearly a hundred pages to the consideration of the anatomy, physiology and embryology of the nervous system, specially in so far as it is necessary for the study of the pathology and symptomatology of nervous diseases. A considerable amount of space has also been used to discuss the general pathological reactions occurring in the nervous system and also the methods of neurological examinations. This has been done in a masterly way and will be very useful to students and practitioners. The treatment of the vegetative nervous system and its disease processes is also to be praised. The chapter on intracranial tumour is very comprehensive and the pathological study of these new growths has been undertaken in a manner which leaves hardly anything more to be added. There are numerous figures illustrating their anatomical and histological appearances and extensive use has been made of arterial encephalography and ventriculography in the diagnosis and localization of cerebral tumours. In discussing the prognosis and treatment of this malady, the writer has maintained a judicious conservatism which befits a physician of Professor Grinker's experience and reputation.

The chapter on infective diseases of the nervous system may be read with interest not only for its usefulness but also for the ignorance which has been displayed by a neurological specialist in modern bacteriology. 'Mucosis capsulatus causes a greasy sticky exudate' is meaningless. The term influenza has been used to denote the bacterial organism, *Hæmophilus influenzae*. In his eagerness to discuss the bacteriology of purulent meningitis, the writer has forgotten to observe even the common rules of grammar. These could have been avoided if arrangements had been made for careful proof reading.

However, in the compass of 1000 pages the author has been able to collect an abundance of facts which have been carefully put together and, in this way, he has rendered a great service not only to those who are specially interested in neurology but also to students and practitioners in general. There is a plethora of illustrations which are not only well chosen but also of excellent quality. The paper, printing and the general appearance of the book are excellent and the publishers deserve to be congratulated for this.

This book should not only find a place in every library but should be read and kept for ready reference by every medical man.

M. N. D.

PEDIATRIC SURGERY.—By Edward C. Brenner, M.D., F.A.C.S. 1938. Henry Kimpton, London. Pp. 843, with 293 illustrations. Price, 45s.

It is not very often that we have the pleasure of reading such a well-balanced and attractive book on one of the special branches of surgery. By virtue of his varied experience and sympathetic understanding of the little patient, the author is well qualified for this difficult undertaking. The reader will be delighted with the motto of this book, which reads 'In corpore pueri non est locus chirurgi violentæ'. It was the author's intention to present a volume, neither encyclopædic nor compendial in character, but of practical value to the pædiatric surgeon. The reader will soon discover that the result has more than justified the attempt.

The text of the book has been divided into nine parts each consisting of well indicated sections, making for easy reading and quick reference. The author has been ably assisted by his colleagues in the writing of chapters on special subjects. There is no doubt that anaesthesia in children requires great skill and discrimination. On this subject the contribution of Dr. Drysdale Buchanan is both interesting and up to date. Dr. Lester Unger has written the chapter on 'blood transfusion' with the authority that his experience commands. Improved technique in recent times, of the operative procedures in 'cleft-palate' and 'hare lip' has been described with excellent diagrams by Dr. Harold Vaughan. The section on thoracic surgery in children, always a difficult subject, is in the capable hands of Dr. Louis Davidson to whom the reader will be grateful for many a useful hint. A whole volume could be written on urology in children but Drs. Clarence Bandler and Albert Milbert have omitted very little of importance in this section.

This is a book which we can strongly recommend to the practising surgeon and the general medical practitioner. The binding, printing, and illustrations are excellent, but the absence of a bibliography is to be regretted. The author and his collaborators deserve the success they have achieved. They also deserve our gratitude for emphasizing that 'the child's body is no place for heroic surgery'.

P. N. R.

ATHLETIC INJURIES—PREVENTION, DIAGNOSIS AND TREATMENT.—By A. Thorndike, Jr., M.D. 1938. Henry Kimpton, London. Pp. 208. Illustrated with 104 engravings. Price, 14s.

This small book should be of great value to any practitioner who is medical officer to an athletic club, school or university sports society, as he will find in a small compass information on practically all the injuries liable to occur during the playing of games.

Such information is otherwise only obtainable in books on general surgery or medicine and is therefore liable to lack the slight extra touch of practical experience in dealing with such injuries that this book provides.

It is divided into three parts. Part I (apart from chapter 1 which gives an outline of the development of the medical department of Harvard University in respect to athletics) is devoted to a brief but adequate outline of anatomy and physiology applied to athletics. This will be of particular value to the laymen associated with games, that is coaches, trainers and the athletes themselves. Part II deals with injuries and their treatment in general terms and part III is devoted to special injuries which should be useful to medical officers in enabling them to diagnose readily the signs of rupture of a small muscle for example, which they otherwise might fail to recognize. The special treatment for these conditions is also briefly and clearly outlined.

This is a book that all medical officers to athletic organizations should possess, and it will also be found useful by many general practitioners because in these days when practically every man, woman and child, that is able to do so, takes part in strenuous exercise none of us know when he may be suddenly called upon to diagnose and treat an 'athletic injury'.

NEURO-OPHTHALMOLOGY.—By R. Lindsay Ross, B.Sc., M.D., M.Ch., F.R.C.S. 1938. William Holmstrom (Medical Books), Limited, London. Pp. xxii plus 568. Illustrated with numerous text-figures and coloured plates. Price, 42s.

This book, consisting of 516 pages, has been produced by the author as one of moderate proportions to form a connecting link between ophthalmology and neurology.

The invention of the reflecting ophthalmoscope by von Helmholtz in 1851 followed by the invention of the perimeter by Foster in 1857 opened up a new world with the result that the knowledge of the anatomy, physiology and pathology of the visual tracts has been gradually unfolded and so the ophthalmologist is provided with a means of giving valuable information and help to the neurologist. The contents of the book consist of 17 chapters on the equipment necessary for the examination of the eyes, the pupil and its reactions, the muscles and nerves of the eye and its adnexa, papilloedema, optic atrophy, the visual tracts and cortical representation of vision, the interpretation and location of lesions in the visual pathway as shown by the perimeter, the macula, the localizing value of ocular symptoms in the diagnosis of diseases of the brain, congenital and degeneration abnormalities and subarachnoid hæmorrhage, tumours of the optic nerve, the region of the optic chiasma and pituitary body, the ocular manifestations in diseases of the nervous system, affections of the vegetative nervous system, the ocular manifestations of head injuries, the poisons which affect vision and finally headache and amaurosis.

There is in addition an extensive bibliography which readers can consult for more detailed knowledge.

The book is well provided with excellent coloured drawings and illustrations. It is written in a clear, simple style. The author is to be congratulated on his work, which supplies a long-felt want in making much useful information in neurology available to the ophthalmologist and he has admirably succeeded in keeping his book to moderate proportions. To medical men in India who are interested in neuro-ophthalmology we strongly recommend this work.

E. O'G. K.

THE ADRENAL CORTEX AND INTERSEXUALITY.

By L. R. Broster, C. Allen, H. W. C. Vines, J. Patterson, A. W. Greenwood, G. F. Marrian and G. C. Butler. Chapman and Hall, Limited, 11, Henrietta Street, Covent Garden, W.C.2, London. Pp. xii plus 245. Price, 15s.

It has long been recognized that some functional relationship exists between the adrenal cortex and the gonads, although the exact mechanism by which the clinical features of this connection are governed is obscure. The adreno-genital syndrome is essentially bisexual in nature and refers to the appearance of male secondary sex characters in the female with retrogression in the female sex characters. The authors have observed over one hundred of these cases; the case histories of many of them have been presented in this book, with illustrations.

The subject has been studied from clinical, surgical, pathological, psychological and biochemical points of view in collaboration with different experts, exhibiting a good example of team-work. Laborious research has led to the discovery of fuchsin-staining cells in the suprarenal cortex as evidence of virilism in women. An androgenic principle has been isolated from the urine of patients with the adreno-genital syndrome,

and so also the adrenosterone or corticosterone, a crystalline sterol which is specific for virilism and is derived from the fuchsinophile cells in the cortex. Unilateral adrenalectomy has been performed in thirty-three cases for virilism, with one death due to post-operative shock. The operative results have been very striking; there is an early restoration of the menstruation, the male hairs are shed and the complexion improves.

The book begins with a foreword by Sir Walter Langdon-Brown and owes its existence to the generosity of Lord Wakefield of Hythe.

R. C.

A GUIDE TO HUMAN PARASITOLOGY FOR MEDICAL PRACTITIONERS.—By D. B. Blacklock, M.D. (Edin.), D.P.H. (Lond.), D.T.M. (Liverpool), and T. Southwell, D.Sc., Ph.D., A.R.C.Sc., F.Z.S., F.R.S.E. Third Edition. 1938. H. K. Lewis and Company, Limited, London. Pp. viii plus 259, with 2 coloured plates and 122 illustrations in the text. Price, 12s. 6d.

It is only about two and a half years ago that the second edition of this book was reviewed in this journal. It must have been quickly exhausted for we note that it was reprinted in August 1936 and already a third edition has been called for. There is little need to recommend a book with such a record and we feel we cannot do better than quote from the opinion expressed in our review of the second edition as this edition has only been altered in one or two sections to bring it up to date, and our opinion has obviously been confirmed by the book's reception.

'To sum up, this book is the best the reviewer has seen for the use of a student when he has a teacher at his elbow. . . .'

TREATMENT IN GENERAL PRACTICE: THE MANAGEMENT OF SOME MAJOR MEDICAL DISORDERS. Second Edition. 1938. (Articles republished from the 'British Medical Journal'.) H. K. Lewis and Company, Limited, London. Pp. x plus 259. Price, 8s. 6d.

Our readers' attention is drawn to the review of the first edition of this book in our October number, 1936. It is seldom that a book of this nature goes into a second edition or is even reprinted, but the immediate popularity of these already reprinted articles necessitated another reprinting within a year and a second edition a year later.

No changes have been made in many of the articles but in others a paragraph has been added here and there, e.g., in the articles on new growths of the lung, scarlet fever, septicaemia, and congestive failure. In the last named, thyroidectomy and insulin treatment are discussed and details given for the drainage of oedema with Southey's tubes.

Whilst the few additions do not warrant the replacement of the first edition, we strongly recommend practitioners who have no copy of this valuable book to seize this unexpected opportunity and to purchase it.

PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM AND SPECIAL SENSES.—By N. J. Vazifdar, L.M. & S., F.C.P.S., Captain, A.I.R.O. (Retd.). Seventh Edition. Revised and Enlarged. 1938. Popular Book Depot, Bombay, 7. Pp. 307 plus vii with 49 illustrations. Price, Rs. 5-4

DR. VAZIFDAR has achieved a great feat in compiling this book, and many medical students preparing for the examination will thank him for it. The present edition has been revised and enlarged keeping in view, however, the original character and scope of the book depicting an excellent outline of the anatomy and physiology of the nervous system and special senses based upon standard textbooks. There are many useful tables, and the book is illustrated by good line diagrams.

R. C.

THE SHIP SURGEON'S HANDBOOK.—By B. J. Macaulay, M.D., L.R.C.P., L.R.C.S. 1938. John Wright and Sons, Limited, Bristol. Pp. 66. Price, 3s. 6d.

This is a very small book, little more than a pamphlet, which is not likely to be found of much value to a ship's surgeon, for it is doubtful if any doctor goes to sea without taking at least one or two good textbooks on medicine and surgery (if they are not supplied by the company as part of the dispensary equipment) which will give him much more information than this condensed booklet can hope to provide.

THE HISTORY OF THE FORCEPS: AN INVESTIGATION ON THE OCCURRENCE, EVOLUTION AND USE OF THE FORCEPS FROM PREHISTORIC TIMES TO THE PRESENT DAY (WITH A SUMMARY IN DANISH).—By V. Møller-Christensen. 1938. Oxford University Press, London, Humphrey Milford. Pp. xx plus 297. Illustrated. Price, 20s. Obtainable from Oxford University Press, Bombay and Calcutta

This book may be described by quoting the opening paragraphs of the author's summary.

'The present work contains an account of the history of the forceps. Standard terms are introduced for the various parts of the instrument and the technical features of its functions.

By means of detailed studies it has been possible for the writer to separate forceps into sharply defined groups and to form an opinion on the possibilities of using the various groups of the instrument.

Comparative investigations have enabled the writer to submit evidence that the European surgical forceps had its origin in Egypt, where, in the writer's opinion, the earliest forceps of about 3000 B.C. must be regarded as *surgical forceps*. In support of this hypothesis evidence is offered, i.e., quotations from papyrus, which prove that the physicians of ancient Egypt used forceps'.

This volume is an interesting contribution in pure history and one cannot but admire the enthusiasm of the author which has led him to spend so much time and money on the production of a work that can bring him little pecuniary or material advantage.

THE ESSENTIALS OF MATERIA MEDICA PHARMACOLOGY AND THERAPEUTICS.—By R. H. Micks, M.D. (Dub.), F.R.C.P.I. Second Edition. 1938. J. and A. Churchill, Limited, London. Pp. xli plus 378. Price, 12s. 6d.

The progress of pharmacology since the publication of the first edition of this book three years ago has not been of such a nature as to require drastic changes, but it has nevertheless been such as to necessitate modifying certain portions and rewriting certain chapters, to incorporate all the recent advances. A number of new drugs which have appeared during the last three years have been included and the author has been very wise in exercising a judicious caution in their selection. The sulphanilamide group of drugs which is still in an experimental stage has received adequate attention. The book has been well written and brings out with great clarity the really important actions and therapeutic uses of all drugs. It will be useful to medical practitioners and to students preparing for examination, as a handy book of reference.

R. N. C.

GLAISTER'S MEDICAL JURISPRUDENCE AND TOXICOLOGY.—Edited by John Glaister, M.D., D.Sc., Barrister-at-Law. Sixth Edition. 1938. E. and S. Livingstone, Edinburgh. Pp. xlii plus 747, with 107 illustrations and 8 plates. Price, 25s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 17

The excellent book is perhaps the most comprehensive one of this size on the subject. Space has

been found even for war gases which 'have now become a menace to the civil population'.

Legal criminal procedure and medical evidence are dealt with in an interesting manner and more fully than is usually done in books on forensic medicine. Illustrative cases and references to original publications of medico-legal interest are plentiful. Regarding reconciliation of two different views, stated by eminent criminal judges, on the question of professional secrets of a medical man, however, the situation seems plainer to the reader than to the author. In differentiating between a knowledge of a comparatively trivial failing of human conduct, such as an unmarried mother's termination of her own pregnancy, and a knowledge of serious lawlessness, such as murder, there should not be much difficulty: and a medical man is not essentially a police detective.

Brash's procedure of identification of the skull, in the Ruxton case, by the aid of a known photograph, is an advance and so are the maggots in determining the age of the remains in which they may be found.

Comments may be made on the subject of blood. In the spectrum of haemochromogen the band in the green does not appear to be broader than the band in the yellow in spite of diagrams to that effect in books. In dealing with heredity of blood groups von Dungern and Hirschfeld's theory may now be thrown overboard. Important information regarding heredity of M and N has not been included. Sutherland's technique of performing a precipitin test for detecting the source of blood has not been mentioned although a reference has been made to his 'exhaustive work on bloodstains'.

Nothing has been said for or against employing x-ray in the diagnosis of early pregnancy.

Only one error in spelling and one in printing arrest attention. On page 316 'Dungeon' should be 'Dungern' and on page 145 in the first line after *deaths* there should be a comma and not an apostrophe.

The author has not found it easy to use his pen on the manuscript of another. We, however, remember his association with the late Dr. Glaister in the last edition of the book.

The book should be on the desk of all medico-legal workers. Do students read works of this magnitude nowadays? If they do, they are decidedly tamer than they used to be, say, 20 years ago.

S. D. S. G.

A TEXTBOOK OF NEURO-RADIOLOGY.—By Cecil P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E., F.A.C.S., F.R.A.C.S. (Hon.), and Alexander Orley, M.D., D.M.R.E. 1938. Baillière, Tindall and Cox, London. Pp. xiv plus 336, with 229 illustrations. Price, 25s. Postage, 6d. Abroad extra

This volume deals with radiology of the skull and vertebral column with special reference to neurology and neuro-surgery.

Radiography of the skull is extremely well described and includes the special techniques for the accessory nasal sinuses and mastoids. It is rather surprising to find no mention of Graham Hodgson's technique in regard to the sinuses; the authors appear to favour American methods as exemplified by those of Granger.

The subject of radiology of the skull in relation to injuries is acquiring increased importance as a result of the appalling toll of the road. A very large proportion of the victims in motor accidents these days appear to suffer from skull injuries. It is sometimes exceedingly difficult in these cases to differentiate a linear fracture from normal skull markings. The authors have dealt with this part of the subject concisely but adequately. We think, however, that the necessity for stereoscopic radiography in many of these cases has not been sufficiently stressed.

The section on lesions of the cranium is extremely well done, and includes a valuable table of differential diagnosis embodying both clinical and radiological features.

The introduction within recent years of the methods of encephalography and ventriculography has led to a wealth of information regarding intracranial lesions

The authors are to be congratulated on the able manner in which they have dealt with this part of the subject.

A whole chapter is devoted to cerebral arteriography. Opinions about the late effects of thorotrast are divided. The number of accidents have been described recently, and animal experiments have shown definite degenerative changes in the liver and spleen. It has also quite conclusively been shown that this material appears to be retained indefinitely in the reticulo-endothelial system causing a blockage of the cells here. The radio-activity of thorotrast retained in this way is also a matter which deserves serious consideration. We personally have not had the courage to advocate this method, though arteriography in other situations is quite easily done by the injection of per-abrodil or similar preparations.

The latter portion of the book deals with lesions of the spine and spinal cord with a last chapter on neuropathic disturbances. A very complete bibliography and index are provided.

A very welcome feature of this publication is the thorough manner in which the normal anatomy and appearances are treated before describing the variations from the normal.

We cannot speak too highly of the excellence of this work. It will be welcomed alike by the surgeon, neurologist and radiologist.

G. G.

THE PREPARATION OF SCIENTIFIC AND TECHNICAL PAPERS.—By Sam F. Trelease, Ph.D., and Emma S. Yule, Ph.D. Third Edition. 1936. Baillière, Tindall and Cox, London. Pp. 125. Price, 7s.

This manual is intended for the use of students who are writing articles on scientific or technical subjects. Many of the rules given are based upon recognized authorities, listed in the bibliography at the end of the volume. The book is short, lucid and practical. Anybody, going through it carefully, will learn how to avoid errors, how to present conclusions of his researches in a logical way and how to prepare manuscript and correct galley and page proofs for the printer.

R. C.

SYNOPSIS OF PHYSIOLOGY.—By N. J. Vazifdar, L.M. & S., F.C.P.S., Captain, A.I.R.O. (Retd.). Fourth Edition. 1938. Popular Book Depot, Bombay, 7. Pp. 729 plus xi, with 107 illustrations. Price, Rs. 7-8

The appearance of the fourth edition of the *Synopsis of Physiology* by Dr. Vazifdar shows its popularity and growing demand. The book has been

revised, enlarged and brought up to date. It is a useful compilation in a condensed form, which will serve as a guide for students to revise the subject quickly while preparing for examinations. Certain sections, for instance, that on the nervous system which is very good, have been dealt with in a systematic manner, while the rest of the book refers to various important physiological principles. Brevity being the key-note of the book, a few sections are rather inadequate; this, it is hoped, will receive due attention in the next edition. The usefulness of the book is greatly enhanced by 107 illustrations, many of which are original.

R. C.

ILLUSTRATIONS OF ANATOMY FOR NURSES.—

By E. B. Jamieson, M.D. 1938. E. and S. Livingstone, Edinburgh. 62 Plates. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 5

This is a selection from the second edition of *Illustrations of Regional Anatomy* by the same author.

It includes 62 plates which, with the exception of four, are identical with those in the above publication. It is bound in the same handy loose leaf method so that any plate may be removed and used under an epidiascope for illustrating a special lecture.

It should be extremely valuable to teachers of anatomy to nurses, for whom it has been produced.

P. A. M.

OTHER BOOKS RECEIVED

The Evolution of Chronic Rheumatism with Treatment to Correspond—The Preventive Clinic as a First Line of Defence.—By R. F. Fox, M.D. (Lond.), F.R.C.P. 1938. H. K. Lewis and Company, Limited, London. Pp. 26, with 5 text-figures. Price, 2s. 6d.

This is a reprint of a lecture, delivered at Margate, at the Congress of the Royal Institute of Public Health and The Institute of Hygiene, May 1937, which has already been published in the *Journal of the Royal Institute of Public Health and Hygiene*.

For those who are interested in the subject of establishing rheumatism clinics, it is convenient to be able to obtain copies in pamphlet form.

The Use of Quinine in Obstetrics.—By Dr. H. P. A. Smit. 1938. Cinchona Instituut. Bureau Tot bevoororderen Van Het Kinine-Gebruik. V. Limburg Stirumstraat 43. Postbus 215, Amsterdam-W. Pp. 20.

This is a pamphlet issued by the Cinchona Institute, Amsterdam; its scope is as the title implies. It emphasizes the fact that quinine is *not* an abortifacient, but is a useful prophylactic.

Abstracts from Reports

TUBERCULOSIS IN THE RURAL DISTRICTS OF THE EAST. (FROM THE REPORT OF THE PREPARATORY COMMISSION, HEALTH ORGANIZATION OF THE LEAGUE OF NATIONS, BULL. INT. UNION AGAINST TUBERCULOSIS, 1937)

For the last ten years attention has often been drawn to the increase in the frequency of tuberculosis in the Far East. However, Japan is the only country for which there are accurate statistical data, as elsewhere only estimations and tentative enquiries have been made. In the list of the causes of death, twenty years ago, tuberculosis occupied the sixth or seventh place. To-day, in a number of eastern countries, it comes third; in Japan tuberculosis comes second and in the Philippines this disease even heads the list.

Obviously, this does not mean that the incidence of tuberculosis has increased, in absolute figures.

Improved prophylaxis with regard to diseases such as smallpox, cholera, malaria and typhoid has resulted in a lesser death rate from these infections, so that tuberculosis has become conspicuous. Another cause for this relatively increased incidence is to be found in better diagnostic methods and a more accurate recognition of the various forms of the disease. For instance, tuberculosis of infants and children, which was formerly supposed to be uncommon in Asia, is, in fact, fairly widespread.

In several countries, enquiries have been made in order to determine more accurately the incidence of latent and manifest cases of tuberculosis, as well as the modes of infection. These enquiries, which are difficult to carry out, have been so far fragmentary and do not justify any general statement, nor a comparison with the data collected in Europe. One gets from them a definite impression that in a number of countries tuberculosis is, already one of the most

widespread social diseases and that its extension to vast and relatively unaffected rural areas constitutes one of the most serious and urgent public health problems in Asia.

In order to institute a logical anti-tuberculosis scheme, with special regard to the protection of uncontaminated or scarcely contaminated areas, it is necessary to be acquainted with the state of affairs not merely in each country but in each province and to consider separately the cities and the rural districts, as well as, among the latter, those who supply industrial or agricultural labour and those who do not. To seek to apply the same measures against the spread of tuberculosis in uninfected rural areas, against its pseudo-epidemic dissemination in a recently infected environment, or against endemic tuberculosis in the cities would be as nonsensical as to institute, against malaria, the same anti-larval measures in deltaic, mountainous or urban districts.

In order to find out to what extent the populations are infected, one may use the statistics of the causes of death, but it will be necessary, by means of tentative enquiries (through careful retrospective interrogations among rural families, or by a series of autopsies in the cities), to determine the probable margin of error above or below existing figures which are based on the diagnosis of incompetent village chiefs or of registration clerks.

It will be particularly advisable to find out the rate of positive tuberculin reactions among respective samples of the rural and urban population, and to make a clinical and, if possible, an x-ray examination of these cases.

If one wishes to obtain comparable results between different regions one should adopt a uniform and accurate tuberculin test technique as well as a standard tuberculin, either that recommended by the Permanent Commission of Biological Standards of the Health Organization, or a tuberculin prepared on a purified synthetic medium.

The data thus obtained and the complementary epidemiological enquiries will enable one to determine whether the population under investigation is or is not tubercularized and, in the first case, at what age and under what conditions tubercularization occurred. This knowledge will serve as a basis for the adoption of practical measures of prophylaxis.

The problem under consideration is not to make a choice between the artificial pneumothorax, gold salts or simple sanatorium cure in the treatment of manifest cases but to define and apply a prevention policy which will meet simultaneously the epidemiological situation and budgetary resources.

One may consider that it is actually useful to educate the people—school children and adults—with regard to public health, to the modes of infection of tuberculosis, to the best feeding and living conditions likely to increase their resistance; but this education must be perfectly adapted to local conditions and not be a mere modification of the public health propaganda suitable for the inhabitants of Western Europe or the United States of America.

With regard to poor and ill-nourished populations for whom an improved standard of living and therefore an increased resistance can only be foretold in the distant future, specific protection through vaccination is particularly important.

To this date, in Asia, B. C. G. has been systematically used only in Indo-China. The conference should be able to know the results of B. C. G. vaccination in that country in order to decide whether its use can be recommended in other countries. There, again, a logical adaptation will be necessary: quite justifiably, in heavily infected French, Rumanian and Indo-Chinese cities, B. C. G. is inoculated to newborn children as this vaccine, to be efficient, must be given previous to any tuberculosis infection, and the latter may take place early when the disease is endemic. Likewise, in heavily infected eastern cities, B. C. G.

ought to be given to newborn babies. But this does not apply to practically uninfected regions where only a few individuals have become tuberculous while staying in the cities where they had been employed.

It is on their arrival in the towns or in industrial areas that one ought to vaccinate uninfected rural workers; through whom one will thus protect indirectly the villages where they will return some day with their savings.

While general subcutaneous vaccination of tuberculin-negative cases is justified in areas where tuberculosis is spreading, there is evidently no advantage in vaccinating children in uninfected rural areas which are but little exposed to infection. In fact, in the absence of exogenous reinfections which keep up the immunity conferred by B. C. G. vaccination, this immunity would progressively subside until its ultimate disappearance.

Adaptation to local conditions is no less indispensable if one considers the institutional treatment of the tuberculous. In cities where tuberculosis is endemic and where fibrous forms are common, the campaign may be organized through the dispensaries where artificial pneumothorax can be applied and through sanatoriums where the rest and education cure can be started, and even completed when the necessary resources are available.

But in areas where tuberculosis is spreading and where cases of massive caseification are common, one must provide in the first place for the isolation rather than for the treatment of patients and for the protection of healthy subjects through vaccination or any other method.

A mere imitation of the tuberculosis organization schemes of European countries with their network of dispensaries, hospitals and sanatoriums, would lead to a wasting of public funds, as it would necessarily be incomplete, owing to lack of adequate resources; moreover it would not meet the particular needs of oriental populations.

A preventive measure which seems everywhere imperative is the control of individuals belonging to professions involving special risks with regard to the spread of bacilli; this remark applies chiefly to the teachers.

As far as one knows, bovine tuberculosis is not common in Asiatic countries, so that it need not be taken into account in the organization of the campaign against tuberculosis.

PAPWORTH VILLAGE SETTLEMENT (DIRECTOR'S REPORT, 1936, SUBMITTED TO THE ANNUAL MEETING OF THE INTERNATIONAL UNION AGAINST TUBERCULOSIS, LISBON, 1937)

THE Director of Papworth in his annual report usually takes some particular aspect of the tuberculosis problem for discussion with which to preface his report. This report which was recently published takes the question of prolonged treatment and its relation to Papworth and normal industry.

Defining the desired results of treatment to be a restoration of working and earning capacity in the outside world for the tuberculous patient, the question is asked as to what is to be done for those men and women who must work for their living, and who, as a result of prolonged absence from work owing to prolonged treatment, are not able to secure a position in industry. The question is whether normal industrial concerns are going to revise their regulations and take in tuberculous workers or whether some scheme will be set up for their benefit.

Attention is drawn to the criticism that Papworth is too small to benefit the total tuberculous population of the country; and it is shown that Papworth was designed as a demonstration to show that substandard men and women could succeed in earning their living and maintaining the beneficial effects of treatment in such sheltered conditions.

It is for normal industry to shoulder the burden now that it has been shown to be possible in sheltered conditions; and if normal industry is unable to meet this obligation they must consent to co-operate in the establishment of similar undertakings to the Papworth scheme for substandard labour.

The development of the treatment centres of Papworth is remarkable because so many people tend to regard the scheme as solely industrial and to forget that there are three modern hospitals with a chain of seven medical units as ancillary departments: dental, ophthalmic, ear, nose and throat, orthopaedic, collapse-therapy and radiology. There is, in addition, a fully equipped series of research departments devoted to pathology, biochemistry and physiology respectively. The report is printed at Papworth with illustrations and bibliography of all publications during the course of the year; and if any members of the Union request a copy they will receive one as soon as possible.

The records show that one-third of the settlers have been steadily employed for ten years and over; and another third for five to ten years.

AFTER-CARE AND REHABILITATION (PRINCIPLES AND PRACTICE). By E. BRIEGER. (FROM THE REPORT PRESENTED TO THE CONFERENCE OF THE INTERNATIONAL UNION AGAINST TUBERCULOSIS, LISBON, 1937)

This report, issued by the committee for after-care and rehabilitation of the International Union, gives a full and comprehensive account of many schemes in different countries. As is mentioned in the introduction to the report, the highest measure of success can be attained only when three fundamental aspects of the work—care (dispensaries), treatment (sanatoria) and after-care—are so organized that harmonious co-operation between them is secured. There are three parts to the report: the first dealing with prognosis and after-care, the second with social rehabilitation, and the third with the multiple unit for institutional care and after-care.

No criticism of any kind can be laid against the thorough method employed by the compiler (Dr. Brieger) in his treatment of the three essential sections of his work. In his general conclusions Dr. Brieger says that complete recovery depends mainly on the maintenance of such conditions as enable the benefits of treatment to be retained, and that the restoration of the working capacity of the tuberculous is supposedly the ultimate objective of all measures for care and treatment. Rightly also he emphasizes that organized rehabilitation and re-employment of the tuberculous are important, not only for the well-being of the tuberculous worker but also for the economic well-being of the community at large. The economic value of the substandard worker can only be assessed by his employment in industry where his physical and economic efficiency can be controlled by continuous clinical care. The recovered case may be able to achieve a degree of stabilization which will allow return to work in normal industry. Sheltered occupation is most necessary for those who constitute what is known as 'middle stage' cases; from their physical condition they are unemployable in ordinary industry. It is for this latter group that industrial settlements like Papworth and Preston Hall have been developed and which give to the tuberculous man or woman a smooth path through all the various phases of medical, social and industrial convalescence.

The report is, of course, a strong plea for the village settlement conception, but it is to be regretted that certain of the criticisms which have been laid at the door of village settlements have not been answered as thoroughly as might have been the case. Nor is there reference in any detail—and their accomplishments deserve some detailed description—of the many care and after-care committees in England, Canada, and the United States of America which have done much to administer to the medical and social needs of thousands of patients for whom the village settlement

is not more than a dream which can never come true. Although the report does not state specifically that village settlements are the solution to the entire tuberculosis problem, this view is implied in many of the pages, and there are few indeed who would subscribe to this opinion. That the village settlement is important and useful is not to be denied, but in a report which deals with after-care as well as rehabilitation it might have been well to mention the limitations of village settlements as well as to praise them.

Altogether this report provides a useful account of many schemes for rehabilitation, contains a valuable bibliography of the subject and is an important contribution to one aspect of care and after-care.

KING EDWARD VII SANATORIUM, BHOWALI, U. P. ANNUAL REPORT FOR 1937

ON 1st January, 1913, there was accommodation available for 18 patients only; this was raised to 47 during the same year. Since then there has been a gradual increase in the accommodation with the result that 54 beds were available in 1920, 98 beds in 1930 and 122 beds in 1936. A further addition of 20 beds was made in the year 1937.

The following improvements were brought about during the year under report:—

Nursing arrangements.—These were markedly improved. The strength of the nurses was raised to twelve—six female and six male. Nursing forms the backbone of the treatment in a disease like tuberculosis. Proper nursing arrangements in the sanatorium were long overdue.

The female nurses home has been remodelled and improved. There are six suites of rooms, each nurse getting a suite consisting of a bedroom with glazed verandah in front and privy and bathroom behind. No attendants are allowed to stay with the female nurses who are looked after by the nursing superintendent. Food is provided from a common mess for which a cook has been provided from the sanatorium.

The male nurses home has also been remodelled and each male nurse is provided with a suite of rooms. Male nurses are allowed to keep their families as they have to make their own arrangements for board.

Arrangements have been made in this block for the accommodation of four patients. No arrangements existed in the sanatorium till now for the proper nursing and treatment of serious complications. All such cases will henceforth be brought together in one place in order to facilitate their nursing and treatment.

The addition of a ward-boy's room to the Red Cross block will enable a ward-boy to be available throughout day and night for the patients occupying this block.

A recreation hall has been constructed at a cost of Rs. 11,000 out of which Rs. 4,000 was provided from the Silver Jubilee Fund. The hall is a magnificent structure capable of holding a large audience and has been particularly designed to serve the needs of the patients. The recreation hall is a great acquisition to the sanatorium and is centrally situated. The sanatorium now possesses separate recreation halls for the use of male and female patients.

Owing to the construction of the recreation hall in its proximity, the carpenter's workshop became unsuitable for its purpose on its present site. It was, therefore, converted into a comfortable guest house where visitors to the sanatorium could be received. The guest house can accommodate three visitors at a time. No proper arrangements for the reception of guests and visitors existed in the sanatorium before.

The road has been improved so that motor cars can now be driven right up to the administrative building. The presence of a motorable road will be a source of great convenience to the patients who can drive right up to the sanatorium office instead of waiting for the 'dandy' at the gate.

Dr. Y. G. Shrikhande was appointed Medical Superintendent from 16th January, 1937, and Dr. D. N. Sanyal and Dr. M. Zubair were appointed Senior and Junior Assistants to the Superintendent respectively from the same date.

The importance of amusement and recreation in the treatment of pulmonary tuberculosis is acknowledged by all who are entitled to speak on the subject. Everything that tends to take their minds off their complaint is a definite aid to treatment of patients and should be utilized to the full. With this object in view a number of social events and recreative diversions are arranged in the sanatorium from time to time.

There is a radio set to enable the patients to enjoy the daily programmes of different places.

A small cinema machine has very kindly been presented by the Right Hon'ble Sir Tej Bahadur Sapru and patients are entertained with small films from time to time.

An American optical lantern has been presented by Rai Rajeshwar Bali Sahab, Taluqdar of Dariabad, and instructive slides on diseases like cholera, plague, typhoid, etc., are shown to the patients.

The sanatorium possesses a fairly good general library containing books on various subjects in Hindi, Urdu and English. The library is used freely by the patients. The sanatorium also subscribes to several newspapers and illustrated journals and periodicals for the use of the patients, and is very lucky in getting free copies of the *Statesman*, the *Pioneer*, the *Illustrated Weekly of India* and the illustrated weekly edition of the *Leader* and our thanks are due to the Editors of these papers. The Horlick's Malted Milk Co., Ltd., are supplying free copies of the *Sphere*, *Strand*, and *Tit Bits* for some years and we are very grateful to them for this generous gift.

The Virol agents gave one dozen bottles of Virol; the Bovril gave one dozen bottles of Bovril; and the Horlick's Malted Milk gave three dozen tins of the milk and one dozen mixers. These preparations were distributed to the poor patients and the sanatorium is very grateful to the manufacturers for their generous gifts.

The sanatorium was visited by the Hon'ble Sir S. M. Sulaiman, President of the Sanatorium Trust Committee, on 26th June, 1936. As he has been appointed a Judge of the Federal Court of India, this was his last visit to the sanatorium and he took the opportunity of visiting almost all the cottages and wards and bidding good-bye to the patients.

The Hon'ble Sir J. P. Srivastava, *interim* Finance Minister, visited the sanatorium to select a suitable site for the construction of a block of six rooms for female patients which he proposes to donate to the institution.

The sanatorium was visited by the Hon'ble Pandit Govind Ballabh Pant, Premier of U. P., on 9th October, 1937, when he went round and saw different wards and cottages and the newly constructed recreation hall. He advised the patients not to take part in politics as long as they were patients but to concentrate on getting well soon in order to make room for other deserving cases. He also announced that Government would be pleased to grant money towards the improvement of the recreation hall.

The sanatorium was also visited during the year by Dr. W. Burrige, Professor of Physiology, Medical College, Lucknow, and Dr. B. K. Sikand, Organizing Secretary of the King George Thanksgiving Fund.

The sanatorium was officially inspected by Colonel J. A. S. Phillips, C.I.E., V.H.S., D.P.H., I.M.S., Inspector-General of Civil Hospitals, U. P., on 11th June, 1937.

The committee meets twice annually—the winter meeting being held in Allahabad and the summer meeting in Bhowali. The meeting at Allahabad was held on 16th January, 1937, and at Bhowali on 26th June, 1937. The Hon'ble Sir S. M. Sulaiman presided over both the meetings.

An extraordinary meeting was convened in Allahabad on 13th November, 1937, in order to consider the amendments necessary in the constitution of the Sanatorium Trust Committee in view of the changes brought about by the Reforms Act of 1935. The Hon'ble Mr. Niamat Ullah, Acting Chief Justice of the Allahabad High Court, presided over the meeting.

The finances of the sanatorium remained satisfactory. The three main sources of income are:—

1. Interest on Endowment Fund amounting roughly to Rs. 14,000.

2. Annual grant-in-aid from the Government of Rs. 17,000.

3. Income from fees realized from paying patients, which amounted during 1936-37 to Rs. 40,995.

The pressing needs of the sanatorium at the present moment are:—

- (1) Electrification of the sanatorium.

- (2) A 'talkie' equipment for the recreation of the patients.

GOVERNMENT TUBERCULOSIS CLINIC (COLVIN HOSPITAL), ALLAHABAD, U. P. FIRST TRIENNIAL REPORT

THE Government Tuberculosis Clinic at Allahabad, which started functioning from August 1936, under Dr. R. N. Tandon, has been founded by the Government of U. P. on a provincial basis in the premises of the Colvin Hospital, with modern equipment including an x-ray plant for up-to-date treatment of pulmonary tuberculosis. A new block has been erected for the outdoor section of the clinic and one ward of the Colvin Hospital has been vacated for indoor patients in indigent circumstances suffering from the disease. Amongst its staff are three health visitors, who go to the homes of people to detect patients, bring contacts, and carry on propaganda among them.

ANTI-TUBERCULOSIS WORK IN CHINA. BY G. F. BUME, M.D., ASSISTANT PROFESSOR OF MEDICINE, AND CHIEF OF THE TUBER- CULOSIS SECTION OF THE NATIONAL MEDI- CAL COLLEGE OF SHANGHAI. (QUOTED FROM THE BULLETIN OF THE INTER- NATIONAL UNION AGAINST TUBERCULOSIS, APRIL 1937)

In most countries with a western civilization the campaign against tuberculosis has been associated with the development of modern methods of diagnosis and treatment: roentgenology, surgery, pathology, immunology, etc. This campaign, moreover, has been intimately connected with the institution of dispensaries and sanatoria which were at first subsidized by private initiative before the whole movement was taken up by the state and assumed its present and scientific position.

In China, a consciousness of the necessity of organized anti-tuberculosis work is gradually gaining ground and it is to be hoped that this country, as a result of the experience acquired by other nations, will be spared the phase of unorganized private endeavour which, to a certain extent, has held up the growth of the movement in many communities. As a member of the Chinese Medical Association, the leading medical organization in the country, I may bear witness to the earnest attention with which my colleagues consider this problem.

Actually, anti-tuberculosis work is faced in China with worse difficulties than in any other part of the world. First of all the size of the country is an obstacle to all attempts at establishing a central administration; yet it must be admitted that the influence of the Nanking government is steadily spreading every year to the remotest provinces and cities, as they are made less inaccessible through the development of roads and air traffic. Whether improved transport facilities have a tendency to favour the spread of the disease is a moot point; in the author's opinion there is no region in China where tuberculosis is not one of the most widely distributed diseases. Furthermore, the isolation of the various regions has never been such as to constitute a barrier against the spread of infection.

A further difficulty in any attempt to control tuberculosis is the absence or inaccuracy of statistics of the birth rate and death rate. Cities like Nanking, Peiping, Shanghai, Hong-Kong and a few others are an exception to this rule. The reason for this state of affairs is twofold: the influence of the old-fashioned *heb-doctor* is by no means extinct; moreover, in districts which own a public health department under the control of the central, provincial or municipal authority, the powers of this department are too limited to enforce the compulsory notification of infectious diseases. However, it cannot be denied that conditions are constantly improving; the Chinese Medical Association is taking a leading part in this progress. In 1933 a National Anti-tuberculosis Association was organized under the sponsorship of the Mayor of Greater Shanghai, General Wu Teh-chen, with a threefold object; to carry out a public health education programme, to raise the necessary funds for the campaign against tuberculosis, and to organize this campaign on a large scale. Since that date the National Anti-Tuberculosis Association has opened three tuberculosis clinics in the city of Shanghai; a sanatorium of 500 beds for all categories of patients is being built and affiliated committees are being organized in several provinces.

The rather indifferent attitude of some authorities with regard to tuberculosis can be understood to a certain extent. While decisive progress has been made with regard to acute infectious diseases, nothing is done for tuberculosis. This is due to the fact that the acute infections, such as typhoid, cholera, dysentery, smallpox, etc., can be controlled at much less cost and with spectacular results which impress the yet rather sceptical population. While tuberculosis constitutes such a huge problem, any measures in this direction are bound to be immediately expensive and effective only in the remote future. Phthisiologists disapprove of this attitude on the part of the authorities, although they can understand their point of view. They feel that something must be done if China is to retain its place in the circle of civilized nations. Private initiative has been responsible for whatever results have been obtained so far. It is now felt that some central authority should take the lead, for instance, the public health department of the Nanking government, who should pass a Tuberculosis Act and grant a financial subsidy. The moral support and the uniform direction of the tuberculosis movement throughout the country resulting from such a step would be of far greater importance than the financial assistance, which, for obvious reasons, can only be limited but would nevertheless constitute an official token of approval.

Very little can be said about the causes for the increased death rate in Hong-Kong and the decline in Peiping; in countries with more ancient and perhaps more reliable statistics opinions are divided about the causes of the general decline of the tuberculosis death rate. Yet it is a fact that during the period covered industrialization made great progress in this city. Furthermore, during the year 1927, large sections of the population emigrated after Peiping had been deprived of its dignity as the capital of the Empire and after the Kuomintang had become established at Nanking. Whether industrialization may really be held responsible for the increased death rate at Hong-Kong or the diminished density of the population for the decline observed in Peiping remains to be proven. With regard to Peiping it is at least questionable whether the rapid decrease in the density of the population could have brought about in such a short time so considerable a decline in the tuberculosis death rate.

The results of the tuberculin tests carried out among various groups of the Chinese population are not of equal value. The figures published by Korns are so much below those of other authors that one can hardly explain the discrepancy otherwise than by a possible error of technique. An investigation of 1,007 x-ray films of young Chinese adults by Hall and

Chang, in Peiping, the city where Korns carried out his test, yielded a proportion of radiological signs of early infection of 71.5 per cent. This compares well with the findings of Lai, Kao and Chien as the result of their tuberculin tests in the same age-groups. If one considers the frequency of latent lesions which cannot be detected by the x-rays although they give rise to a positive tuberculin reaction, the findings of Hall and Chang would indicate that the percentage of positive tuberculin reactors in Peiping, in the age-groups in question, would be somewhat higher than the number of positive x-ray results. Korns' report must therefore be accepted *cum grano salis*. With regard to the data of Bume and Liu the figure of 200 cases is too small to be conclusive. This experiment includes all age-groups over 14 and was carried out among hospital patients of all kinds, ruling out cases with active tuberculous lesions, whether pulmonary or surgical. The work of Lai, Kao and Chien is by far the most interesting and elaborate of this series because it includes the greater number of tests and is well drawn up with regard to age-groups and to sex. As far as tuberculin tests are concerned, it must be considered the standard work for China.

The reports of Anderson and Wylie are of interest chiefly because, although they deal with different parts of China, their percentage of positive reactors is almost identical in the respective age-groups with that of Lai, Kao and Chien, although Wylie's material is much smaller, while the number of Anderson's cases is unknown.

In a country with an area of 4,008,200 sq. km. and a population of 406,191,653 inhabitants, which corresponds to an average density of 101 per sq. km., tuberculosis workers are obviously faced with a fantastic problem, the complexity of which is increased by the fact that some areas like the large cities are much more densely populated, while in the rural districts and smaller towns conditions are quite different. In comparing an urban series with that of a small country town, Lai, Kao and Chien found a much smaller percentage of positive tuberculin reactions in the latter as compared with the population of the business centre of Shanghai.

The difficulties of tuberculosis work are made worse by certain peculiarities of the orientals, for instance, their widespread habit of spitting. In public places, in the theatre, in the street and at home anyone may spit where and whenever he likes without committing a breach of good manners and without giving rise to any objection on the part of his neighbours. One must also mention the patriarchal custom according to which all persons eat at the same table and help themselves with their chop-sticks out of the common bowls of food, while it is considered polite to serve your neighbours with your own chop-sticks. If one remembers the enormous density of population in the large cities and in some villages it will be readily understood that people live and sleep very near one another and that it probably rarely happens that one person, whether healthy or sick, can sleep alone in a bedroom.

Our tuberculosis dispensaries are yet too young to have gathered enough material to prove this point, but thanks to our files and registration forms we hope to be able to do so in the near future. Many authors underestimate the possibility of infection through tubercle bacilli included in dried sputum scattered by wind. It may be permitted to report here the results of an investigation carried out at the request of the National Anti-tuberculosis Association of China. Specimens of sputum collected in the streets, cinemas, theatres, etc., of Shanghai were examined by my assistants: out of a first series of 100 specimens collected in 100 different areas, without the help of concentration methods, cultures or inoculation into the guinea-pig, merely through the ordinary Ziehl-Neelsen staining process, they were able to identify tubercle bacilli in 16 instances. While these figures are too small to enable one to draw definite conclusions yet the percentage of 16 is very striking; should further

researches corroborate these findings the question of infected sputum must be taken into serious consideration when discussing the spread of the disease and its prevention in Chinese cities. Whether, however, dried sputum contains living and virulent bacilli which are a potential source of infection, or whether the bacilli are dead or attenuated and thereby susceptible of giving rise to allergy and to a certain degree of immunity, is open to question and may lead to further interesting investigations.

The housing and food problems are of yet more vital importance.

A very strong feeling of mutual responsibility exists between the members of a family or clan, even in modern China, based probably to a certain extent on the worship of ancestors. One frequently finds that a man who is out of work is kept by his brother or nephew with his wife and all his children; this occurs in all classes of the population and naturally leads to excessive overcrowding of houses, flats and single rooms and to considerable impairment of the economic status of otherwise fairly well-to-do families. The same living conditions are observed among small craftsmen and shopkeepers as well as in the minor factories where the apprentices and younger employees sleep in overcrowded and unventilated dormitories and eat at a common table in the manner we have described. Board and lodging is, in fact, the only remuneration the younger working man most commonly receives in compensation for his services.

Under these conditions the circle of persons exposed to the risk of infection from contact with an open case of tuberculosis is immensely enlarged. That this must necessarily involve widespread infection and a thorough epidemiological distribution of the disease is obvious. But, whether in consequence of this fact the amount of active disease is relatively higher in China than in other countries has not been conclusively settled. It is at least possible that owing to the ubiquity of the bacillus imperceptible infections may occur and give rise to a certain degree of immunity. The relatively good resistance to the disease noted by Hall and Chang and observed by the writer, at least in some parts of the country, would corroborate this theory.

While, on the one hand, family and working conditions may favour the spread of tuberculosis in China, on the other, the sense of mutual responsibility already alluded to between the members of a family or clan is often a great help to the dispensary and to the visiting nurse. The problem of sanatorium beds is very urgent; sickness insurance does not exist and there is no legal provision for the support of a patient by the local authorities. In case of need, however, a near or distant relative can always be found, who, abiding by an unwritten law, assumes responsibility for the cost of the patient's treatment in a sanatorium or hospital. It may happen that a patient is unwilling to confront his uncle or nephew with a demand for funds. A routine enquiry is therefore made by the dispensary into the financial condition of relatives and, when this seems necessary or advisable, the nurse acts as a mediator between a destitute patient and his wealthier connections.

This method, which is intended to make up to a certain extent for the absence of sickness insurance, was carried out for the first time, with a fair measure of success, by the tuberculosis division of the first hospital of the Red Cross Society of China in Shanghai.

Health education obviously plays a considerable part in the tuberculosis campaign in China. Here again one has to face tremendous difficulties, in the first place the illiteracy of most of the rural population; to this day, anti-tuberculosis work has hardly proceeded as far as the rural districts. In some parts of the large cities, especially on their outskirts, conditions are, in many ways, similar to those in country, towns and districts. Floods and famines at times drive the country population in great masses to the large cities

where they live in narrow, self-built straw huts outside the living quarters of the city dwellers. The inhabitants of these temporary, unregistered huts, as well as other sections of the illiterate population, are difficult to control as, apart from other drawbacks, they do not trust western civilization nor its sanitary methods. The same remark applies to the large section of the populace who have no permanent domicile but spend their whole life on boats, earning their living by transporting goods in their craft, along the numerous creeks which are formed by the Yantze-Delta and along the ramifications of this river which extend into remote regions in the interior.

In accordance with the method adopted by Stampar under similar conditions in Yugoslavia it is proposed to send among these classes of the population travelling health instructors who will try and explain the dangers of tuberculosis and how they may be avoided by personal talks, lectures, pictures and cartoons adapted to the Chinese mentality. Before it is possible to penetrate into these lowest strata of society, however, an enormous amount of work will have to be done which will involve considerable expense.

There is yet a long way to go before we are in a position to exert a definite influence on the death rate, especially as in China, to a greater extent perhaps than in any other country, tuberculosis is a social and economic, rather than a medical, problem. There is no reason to be too pessimistic and it is a matter of great satisfaction to know that the Chinese Medical Association has appointed a Tuberculosis Committee which will investigate into the ways and means of unifying anti-tuberculosis activities throughout the country. One of the first steps taken by this committee to which I have the honour to belong has been to discuss tuberculosis teaching in the medical schools; a report to this effect has been forwarded to the educational authorities. In this report the committee advocates that tuberculosis be recognized as a special subject on an equal standing with pediatrics, dermatology, neurology, etc.; that the medical curriculum be made to include lectures on this subject, and that post-graduate courses in tuberculosis be instituted. For several years post-graduate courses in tuberculosis have been held by the author and his assistants in the Division of Pulmonary Tuberculosis of the National Medical College of Shanghai.

If one considers the apparently unsurmountable difficulties which have to be met, the activities of the National Anti-tuberculosis Association of China will be better appreciated. Excellent work is being done in the three dispensaries established and subsidized by the association, in different districts of the city of Shanghai, as will be seen from the first report to be published shortly. Although it has only been in existence three years the association has been able, not only to create and to maintain these dispensaries, but to provide for the construction of a large sanatorium. Its Patron, General Wu Teh-chen, and its President, Mr. Loh Pa-hung, deserve our congratulations for their energy and skill.

Service Notes

APPOINTMENTS AND TRANSFERS

BREVET-COLONEL B. C. ASHTON to be Officiating D. D. M. O. W., Army Headquarters. Dated 30th July, 1938.

Lieutenant-Colonel J. E. Ainsley is reverted to the Military employment and posted as Second in Command, Indian Military Hospital, Nowshera.

Lieutenant-Colonel N. K. Bal on return from leave to rejoin appointment as District Medical Officer, Superintendent, Government Headquarters Hospital.

and Medical Officer, Central Jail, Trichinopoly, *vice* Sri U. Anantayya.

Lieutenant-Colonel B. Sahai to be O. C., C. I. M. H., Fort Sandeman. Dated 28th June, 1938.

Lieutenant-Colonel T. R. Khanna to be O. C., C. I. M. H., Loralai. Dated 28th June, 1938.

Lieutenant-Colonel R. A. Warters to be O. C., C. I. M. H., Bannu. Dated 16th July, 1938.

Lieutenant-Colonel R. L. Vance to be Officiating A. D. M. S., Waziristan District. Dated 13th July, 1938.

Subject to the approval of the Secretary of State for India to the transfer of Major A. N. Chopra, that officer is appointed as a leave reserve officer under the Central Government and is posted temporarily as Additional Assistant Director-General, Indian Medical Service, with effect from the 1st April, 1938.

Major E. S. S. Lucas on return from leave to be Civil Surgeon, Agra.

Major D. P. Lambert transferred from Fyzabad to Meerut, *vice* Major C. V. Falvey.

Major C. V. Falvey transferred from Meerut to Bareilly, *vice* Major M. R. Sinclair.

Major P. J. Kelly to be District Medical Officer, with effect from the 24th June, 1937.

On return from leave, the services of Major H. W. Mulligan, an officer of the Medical Research Department, are placed at the disposal of the Government of Madras for appointment as Director, Pasteur Institute, Coonoor, with effect from the 5th July, 1938.

The services of Major M. L. Ahuja, an officer of the Medical Research Department, are placed at the disposal of the Government of Assam for appointment as Officiating Director, Pasteur Institute and Medical Research Institute, Shillong, with effect from the 30th June, 1938.

Major Gerard Kelly, First Resident Medical Officer, Presidency General Hospital, Calcutta, is appointed to act as Professor of Clinical Medicine, Medical College, Calcutta, *vice* Dr. M. N. De.

Transferred to civil employment

Major J. Singh on 12th July, 1938, to the Medical Research Department.

Subject to the approval of the Secretary of State for India to the transfer of Major S. S. Bhatnagar to the Civil Branch of the Indian Medical Service, that officer is appointed to the Medical Research Department on probation, for 2 years, with effect from the afternoon of the 26th June, 1938, and is posted as Officiating Assistant Director, Central Research Institute, Kasauli.

Captain M. Sendak, whose services have been placed at the disposal of the Government of the C. P. and Berar, is attached to the office of the Civil Surgeon, Nagpur, for training at the Mayo Hospital and Central Jail, Nagpur, from 30th July, 1938.

Captain Sangham Lal to be District Medical Officer, with effect from the 14th November, 1934.

Captain B. J. Griffiths transferred from Agra to Allahabad.

Captain F. W. Allinson, Civil Surgeon, Midnapore, is temporarily appointed to be Civil Surgeon, Darjeeling, *vice* Major J. C. Drummond, on leave.

Captain S. Narain to be D. A. D. P., Kohat District. Dated 1st July, 1938.

Captain S. Sunkavally to be Officiating Surgical Specialist, Deccan District, Jubbulpore. Dated 13th June, 1938.

To be Lieutenant (on probation)

William Laurie, 15th May, 1938, with seniority 10th September, 1936. The period 29th January, 1937, to 2nd July, 1937 (inclusive), counts for purposes of promotion and increments of pay but not for retired pay or gratuity.

The undermentioned officers are reinstated to the establishment since 1st May, 1938. The seniority of these officers is ante-dated to the 1st May, 1937:—

Lieutenants (on probation):—

G. A. Graham.

D. McC. Black.

LEAVE

Brevet-Colonel J. W. Vanreenan, O.B.E., O. C., C. I. M. H., Abbottabad, proceeded on 2 months' privilege leave *ex-India*, with effect from the 23rd July, 1938.

Lieutenant-Colonel H. Chand, Civil Surgeon, Jullundur, granted an extension of leave on average pay for 2 months in continuation of the 2 months' leave granted, with effect from the 13th May, 1938.

Lieutenant-Colonel H. H. Brown, D. D. M. O. W., Army Headquarters, proceeded on 2 months' privilege leave *ex-India*, with effect from the 30th July, 1938.

Lieutenant-Colonel C. H. N. Baker, M.C., O. C., I. M. H., Ferozepore, proceeded on 2 months' privilege leave *ex-India*, with effect from the 28th July, 1938.

Lieutenant-Colonel P. R. Vakil, O. C., I. M. H., Jullundur, proceeded on 12 months' combined leave *ex-India*, with effect from the 13th July, 1938.

Lieutenant-Colonel R. Lee, O. C., I. M. H., Jubbulpore, proceeded on 3 months and 6 days' combined leave *ex-India*, with effect from the 16th July, 1938.

Lieutenant-Colonel R. F. D. MacGregor, M.C., an Agency Surgeon, is granted leave on average pay for 2 months and 22 days combined with leave on half-average pay for 3 months and 8 days, with effect from the afternoon of the 15th April, 1938.

Previous notification is hereby cancelled.

Major Sangham Lal is granted leave on average pay for a period of three months, with effect from the 10th June, 1938, or date of relief, whichever is later.

Major M. R. Sinclair granted 1 year's leave from 1st August, 1938, or date of relief.

Captain W. S. Morgan, O. C., I. M. H., Gyantse, proceeded on 12 months' combined leave *ex-India*, with effect from the 16th July, 1938.

PROMOTION

Lieutenant-Colonel to be Colonel

N. S. Sodhi, M.C. Dated 12th August, 1935, with seniority from 1st March, 1929.

Majors to be Lieutenant-Colonels

H. Das. Dated 11th July, 1938.

A. I. Cox. Dated 14th July, 1938.

Lieutenants (on probation) to be Captains (on probation)

W. McI. Wilson. Dated 19th May, 1938, with seniority from 1st August, 1937.

A. E. B. deCourcy-Wheeler. Dated 19th May, 1938, with seniority from 1st January, 1938.

G. B. Jackson. Dated 18th May, 1938, with seniority from 1st January, 1938.

W. L. Fennell. Dated 23rd May, 1938, with seniority from 1st January, 1938.

T. A. Cunningham. Dated 17th May, 1938, with seniority from 1st January, 1938.

D. R. Hanbury. Dated 19th May, 1938, with seniority from 1st January, 1938.

F. C. Griggs. Dated 10th June, 1938.

Lieutenants (short service) to be Captains

Dated 12th July, 1938

B. P. Bhattacharjya.

B. I. S. Bhalla.

P. N. Bardhan.

R. L. Mehra.

H. Akhtar.

H. N. S. Gupta.

V. W. Clifford.

M. B. Menon.

G. H. K. Niazi.

F. Z. H. Khattak.

Dated 15th July, 1938.

B. C. Roy.

RELINQUISHMENT

Captain N. P. P. Pillai relinquishes his temporary commission, 14th August, 1933.

Captain Sris Chandra Ray relinquishes his temporary commission, 1st August, 1927, and retains the rank of Captain.

Lieutenant (on probation) A. F. Goode relinquishes his probationary appointment, 10th March, 1938.

RETIREMENT

Lieutenant-Colonel K. R. K. Iyengar. Dated 5th July, 1938.

Lieutenant-Colonel M. D. Wadia, Civil Surgeon, Ambala. Dated 5th July, 1938.

Lieutenant-Colonel S. S. Vazifdar. Dated 1st August, 1938.

Notes

NORWAY AND NORWEGIAN FISHERIES (LOFOT)

NATURE has gifted Norway with a very liberal distribution of sea, roughly 4,000 square miles in area. The country is very mountainous, only a small percentage of land being agricultural. In short, Norway is a land of mountain and flood.

The value of Norwegian fisheries has been known to the world from olden times. Norway still ranks first in the fishing industry of the world.

Owing to the peculiar depth and the sea currents along the mountainous coast, this region has been found a most suitable migrating centre by the cod fish for its annual spawning. The most important fishing centre of Norway is Lofot. These are a group of islands, situated in the Arctic circle, between the latitude 67° to 69°.

The chief visitors to these islands being the tourists to see the midnight sun, the cod fish, and the Norwegian fisherman. The cod fish forms 60 per cent of Norwegian fisheries. The average size of cod fish varies from 30 to 32 inches and weighs 10 to 12 lb. The liver averages 14 inches in length, 9 to 11 ounces in weight and is about 2½ inches thick at its central part. The weight of roe and milt average 13 to 20 ounces. Exceptions to the above do occur and cod fish 5 feet in length and over 90 lb. in weight are at times caught. Cod fish attain maturity at the age of six to seven years and reach an age of 20 years.

A female cod fish produces every year about 100,000 eggs for each pound of its weight, i.e., an average spawner is responsible for a family of 1,200,000 every season.

The North Atlantic and Arctic oceans are said to be the home of the cod though its exact habitat is not known; but annually immense shoals of cod fish resort to the Norwegian sea-coast.

First shoals of cod appear in first week of January, but they are in full force in first week of March, and throughout the month of March the fishing is at its best. In the end of March, spawning begins and lasts for a few days. The mass of ova and milt liberated is enormous and sometimes causes the sea for miles around to assume a milky appearance. After spawning the cod fish soon return to their original abode and by the end of April the fishing season is over. Cod fish are obtained in large numbers where the temperature of water is near 50° centigrade.

There is no record fixing the exact date when cod-liver oil was first used, yet we know that it is a long established remedy. The oil used by the primitive people of the North Pole was a very crude product, but recently great advances have been made in its preparation.

For the successful manufacture of cod-liver oil the following conditions are necessary:—

- (a) A supply of absolutely fresh livers.
- (b) Temperature during fishing season should be near freezing point, in order that livers may not decompose soon.
- (c) Supply of raw material should be such as to keep the factories continuously running.

At no other fisheries in the world all these conditions are as well fulfilled as in Norway.

The steam process of manufacture is quite simple. Healthy and fresh livers are washed thoroughly with water, of blood and other impurities, and the gall bladder removed; they are then put in boilers and steam is allowed to act. Within an hour, the oil is extracted by the action of moderate heat. It is allowed to cool, solid fats removed, and on filtration a light yellow oil, with practically no taste or odour, is produced. All barrels, tins and bottles are sealed under Government control and cannot be exported with certificate unless chemical investigation has proved the oil pure and genuine. It has all the therapeutic advantages of old type cod-liver oil and its value for medicinal purpose is established all over the scientific world.

SUGGESTION FOR SUNBURN

ONE of the most common ailments of the summer season is sunburn. Usually not serious, it is, however, extremely uncomfortable and often quite painful.

To soothe the skin, reduce the inflammation and withdraw the fluid from the blisters and blebs of sunburn, an antiphlogistine dressing applied cold is markedly efficient. Put on before retiring and left until morning, it will frequently make the patient quite comfortable.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

LATENT SYPHILIS IN THE TROPICS

By S. D. S. GREVAL
MAJOR, I.M.S.

P. C. SEN GUPTA, M.B.

and

B. C. DAS, B.Sc.

Department of Serology and Immunology, Calcutta
School of Tropical Medicine

THIS study on latent syphilis was commenced in August 1937 in the Carmichael Hospital for Tropical Diseases. It involved doing a Wassermann reaction as a routine procedure on every patient admitted, and a critical examination of all cases giving a positive or a doubtful reaction but not admitted to the hospital for complaints obviously syphilitic. Method number 4 of the Medical Research Committee (1918) reinforced by the use of two additional antigens (for details see appendix) has been employed. The end in view is the obtaining of useful information on (I) existence of latent syphilis in the unselected hospital population of Calcutta, the patients not being admitted for obviously syphilitic complaints, (II) the effect of syphilis on the course of tropical diseases, (III) the effect of tropical diseases on syphilis, (IV) association of syphilis with diseases other than tropical diseases, (V) conditions other than syphilis which give a positive Wassermann reaction, and (VI) the significance of a positive Wassermann reaction and the Wassermann-positive rate in India.

I. Existence of latent syphilis in the unselected hospital population of Calcutta

Under this heading are studied the cases of latent syphilis proper. In them, the ordinary signs and symptoms, with or without treatment, have been absent. Signs and symptoms of other diseases have manifested themselves and defied all treatment (non-specific) which in some cases included operative measures.

Clinical notes regarding a few typical cases will serve as illustrations of this condition :—

Case 1.—Mrs. K. B., a Bengalee Mohammedan female, aged 33 years, was admitted for irregular attacks of fever and digestive disturbances, viz. indigestion, vague epigastric pain, constipation with occasional attacks of diarrhoea. She gave a history of chronic ill health since marriage four years previously. There was no pregnancy. She was curetted once, two or three years previously. She had some skin disease a year ago. On examination no abnormality was found anywhere. The only positive laboratory finding was a strongly positive Wassermann reaction [subsequently designated WR in case notes]. This was obviously a case of latent syphilis. She was advised a course of anti-syphilitic treatment and discharged.

Case 2.—S. M., a Bengalee Hindu male, aged 39 years, was admitted for attacks of fever which was sometimes remittent and sometimes intermitteat. On examination the liver and the spleen were found to be enlarged and the aldehyde test was positive (though

not strongly positive). This seemed to be a case of kala-azar—but on sternum puncture and also on liver puncture and culture no leishmania was found. On enquiry it was found that the patient had acquired syphilis about 22 years ago. WR was strongly positive. He had then been given some injections. The patient was put on anti-syphilitic treatment. Improvement soon commenced.

Case 3.—Mr. W., an Anglo-Indian male, aged 30 years, was admitted for investigation of persistent pain in the heels. Nothing positive was found on both clinical and laboratory examination except the presence of a benign tertian malarial infection and a positive WR. Malarial infection was first eradicated, but this did not have any effect on the pain in the heel. Enquiry into past history revealed that the patient had syphilis five or six years previously and that he had received two courses of injections.

He was put on anti-syphilitic treatment with favourable results.

Not many cases of latent syphilis are encountered.

II. The effect of syphilis on the course of tropical diseases

Under this heading are studied straight-forward cases of syphilis and tropical diseases occurring in association. We have collected some cases under this group and a comparative study of the effects of syphilis on tropical disease is being carried on. One case is given as an illustration :—

Case 1. Kala-azar and syphilis.—A. B., a Bengalee Hindu female, was admitted for kala-azar. The aldehyde test was strongly positive and spleen puncture showed numerous L.-D. bodies. She was given a course of neostibosan and was discharged apparently cured. She was admitted again after 11 months suffering from fever off and on for five months. This time also the aldehyde test and spleen puncture were positive and she was given a course of solustibosan. This brought down the fever for a short period only. The liver and spleen did not go down to any marked degree. Her WR had all along been positive and her past history was suggestive of leucic infection. She was next put on anti-syphilitic treatment. This brought down the titre of her WR very slightly, but the aldehyde test was still strongly positive. The liver and the spleen went down to some extent. Another course of anti-syphilitic treatment was given followed by treatment for kala-azar. General condition much improved. Discharged from hospital three months ago. Will return on recurrence of fever. Has not yet returned.

This patient was one of the resistant cases of kala-azar, whether this marked resistance had anything to do with the presence of syphilitic infection is a question which can be answered only when large numbers of resistant cases have been studied with special reference to coincident syphilitic infection*.

III. The effect of tropical diseases on syphilis

Malaria therapy for syphilitic disease of nervous system is included in this group. Incidentally, syphilitic disease of the nervous

* Those with experience in the treatment of kala-azar have recognized syphilis as one of the complicating infections which tends to make patients resistant to treatment; a course of anti-syphilitic treatment will sometimes make a patient more amenable to subsequent treatment with an antimony preparation. But this provides no explanation for the majority of the 'resistant' kala-azar cases.—EDITOR, I. M. G.

system is the only obviously syphilitic complaint for which patients are occasionally admitted to the hospital. The following case is an illustration :—

A case of *tabes dorsalis* associated with optic atrophy was admitted for investigation and treatment by malaria therapy. Even after a provocative injection the WR of the blood was negative though the WR of the cerebro-spinal fluid was strongly positive. Malaria therapy was instituted. After seven rigors it was deemed advisable to stop the fever. The pains in the limbs, which were not described very intelligently by the patient and which might have been 'lightning pains', disappeared almost entirely after malaria therapy. It is too early to say whether the progress of the optic atrophy has been arrested or not. The blood WR became doubtful after the malaria therapy.

We are keeping in touch with this patient who will be readmitted for observation and treatment.

IV. Association of syphilis with diseases other than tropical diseases

Under this heading is studied association of syphilis with diseases other than tropical diseases. The following are the illustrative cases :—

Case 1. Anæmia and syphilis.—K., a Bengalee Hindu male, 20 years old, was admitted for anæmia, enlargement of the liver and splenomegaly. There was no evidence of malaria or kala-azar. WR was positive. On examination it was found that he had some suspicious scars on the perineum, though he denied exposure or sore. No other abnormality was detected.

As the patient had hypochromic anæmia, he was given a course of ferrous sulphate—but there was no improvement. He was then given a course of anti-syphilitic treatment. Still there was no improvement in anæmia. The next course of ferrous sulphate which was given after the course of anti-syphilitic treatment rapidly cured the anæmia.

Case 2. Rheumatoid arthritis and syphilis.—Mrs. M. L., an Indian female, aged 35 years, was admitted for rheumatoid arthritis—duration one year. On a thorough investigation no septic focus was discovered anywhere and the only positive finding was a positive WR. There was a history of two miscarriages. Anti-syphilitic treatment brought about remarkable improvement. A bedridden patient was soon walking about in spite of the cold weather, when it is usual for cases of this type to get worse.

V. Conditions other than syphilis which give a positive Wassermann reaction

Under this heading are studied many conditions. We have come across eleven cases suffering from what appears to be a syndrome. The syndrome comprises dysfunctions of the gastro-intestinal tract with enlargement of the liver, or of the liver and spleen, irregular pyrexia, and loss of weight. The Wassermann reaction is not always strongly positive. Presumption of syphilis from physical examination, history and family history is on the whole weak. Anti-syphilitic treatment compatible with the hepatic lesion has given satisfactory results. Brief notes from two cases are worth including :—

Case 1.—R. D., a Bengalee Hindu female, aged 20 years, was admitted suffering from fever off and on for ten months ever since the last childbirth. The temperature rose sometimes with chill and rigor up to 104° or even 105°F. Other complaints were indigestion, anorexia, irregularity of bowels, dry cough and loss of weight. On examination the patient was found to be anæmic. The liver was enlarged and tender and the

spleen was also enlarged. No other abnormality was detected. Laboratory examinations revealed moderate degree of leucocytosis with neutrophilia. WR was weakly positive. There were no other positive findings. Skiagram of the chest showed old healed infantile tuberculous lesion. Barium meal skiagraphy showed nothing to explain fever. Cholecystography showed that the dye had not entered the gall bladder.

The patient continued to have irregular attacks of fever. One bout was prolonged and the Widal test was once positive against *B. typhosus* (H : 1 in 1,600 and O : 1 in 200) though the clinical picture was unlike that of enteric fever.

The patient received treatment for malaria, amœbic hepatitis, cholecystitis, but to no effect. Ultimately she was transferred to Prince of Wales Hospital as a case of splenomegaly for splenectomy. But this operation was not performed, apparently on account of her weak condition, and she was sent back.

The patient was next given some stock cholecystitis vaccine but to no effect. She was then given an injection of bismuth. This was followed by a drop in temperature and the subsequent injections of bismuth led to a cure. Before discharge the patient was afebrile for three weeks, had gained 3 lb. in weight and her liver and spleen had diminished in size.

In this case the WR was 'weakly' positive to start with. After first injection of bismuth it was 'positive'. The blood of the husband was negative and there was nothing in the marital history to suggest syphilitic infection—three healthy children, no history of miscarriage. (This patient's blood is not included in the WR results given in the appendix.)

Case 2.—G. B., an American boy, aged 9 years, was admitted for low pyrexia for two to three months. On examination, the liver was found to be enlarged and firm. No other abnormality was detected anywhere else. The only positive laboratory finding was a strongly positive WR. On examination for scars, etc., nothing suspicious was found. No history of miscarriage was obtained from the mother. A course of bismuth injections was given. The fever subsided after the second injection and the boy steadily increased in weight and improved in general health. The liver decreased in size. The patient was discharged with advice to continue treatment.

In this case too presumption of syphilis is weak. The WR was negative in his parents and other children in the family. On the 8th March, 1938, after only two courses of bismuth injections (16 injections in all) and a mixture containing mercury and iodide, the WR was completely negative. General health was good.

Other conditions are bouts of pyrexia from any cause, eosinophilia and allergic conditions acute, or chronic. We describe a few illustrative cases :—

1. Malaria giving rise to positive Wassermann reaction

R. C., an Anglo-Indian male, aged 19 years, was admitted for frequent attacks of malarial fever, duration about 14 months. He had an enlarged liver and spleen and his indirect van den Bergh reaction was strongly positive. No other abnormality was detected and there was nothing in the past history or family history, nor were there any signs of syphilitic infection. WR was positive. After the patient had been cured of the malarial infection and his blood condition had improved (no anæmia and a negative van den Bergh), WR was found to be completely negative.

2. Kala-azar giving rise to positive Wassermann reaction

P. B., a Bengalee Hindu female, aged 28 years, was admitted for kala-azar. The aldehyde test was strongly positive and leishmania were present in the spleen puncture smear. WR was positive. There was nothing in her marital history suggestive of syphilis. The patient was treated with a course of neostibosan.

After the course of treatment and improvement in her general condition the WR became negative.

3. *Blackwater fever giving rise to positive Wassermann reaction*

S. N. R., a Bengalee Hindu male, aged 28 years, was admitted for blackwater fever. He had an enlarged liver and spleen. The heart was slightly dilated. No other abnormality was found and there was nothing in the history or physical examination to suggest a syphilitic infection. WR done on admission (during fever) was positive. When it was repeated during convalescence it had become doubtful. The patient left hospital before the final test could be done.

4. *Fever and dysentery-like symptoms giving rise to positive Wassermann reaction*

H. D'A., an Anglo-Indian female child of 6 years, was admitted with a history of irregular attacks of fever for one year and dysentery for two to three days. Her liver was enlarged. No other abnormality was detected. Stools did not show any *Entamoeba histolytica* nor any dysentery bacillus. WR was positive. The child recovered after treatment for dysentery and a course of hydrag. cum creta for ten days. During convalescence WR was done again and it was found to be negative.

5. *Eosinophilia associated with a positive Wassermann reaction*

S., a Hindu female, aged 13 years, was admitted for low fever and cough and enlarged tonsils. She had 80 per cent eosinophils and WR was positive. No other abnormality was detected. When her tonsils were removed the patient became afebrile. She was then given a course of arsenic injections. After six injections her WR was negative. Her total eosinophil count had also decreased to 12 per cent.

6. *Asthma associated with a positive Wassermann reaction*

C. S. W., an Anglo-Indian male, aged 29 years, was admitted for asthma—duration 12 years. Usual signs of asthma present. Examination of blood showed an eosinophilia of 45 per cent. WR was positive. History and signs of syphilis were absent. Injections of peptone were given for asthma after the acute phase had subsided. There were no further attacks in hospital. WR repeated and found to be doubtful. Eosinophils were now only 5 per cent. Before discharge the reaction was completely negative.

VI. *The significance of a positive Wassermann reaction and the Wassermann-positive rate in India*

These two apparently unrelated items are discussed together because they have been linked together by nearly all the previous workers in India. The workers have first established or accepted a high Wassermann-positive rate for an unselected Indian male population. They have then rejected the possibility of there occurring a non-specific positive Wassermann reaction in certain tropical diseases, because the percentage of the reaction in the diseases was not higher than the percentage for the unselected population. Our positive Wassermann reaction in diseases other than syphilis has been followed up. Many of them have turned doubtful or negative, a fact which proved definitely the occurrence of a non-specific reaction in certain tropical diseases. By reversing the process of the previous workers we argue that

our initially low percentage for the unselected Indian population should be lowered still further because of the occurrence of non-specific reaction in the tropics.

1. *Review of previous work*

Sutherland and Mitra (1915) tested 50 cases of malaria, 34 cases of leprosy and 38 cases of kala-azar. Regarding malaria they came to the conclusion that an attack of malaria after the return of the temperature to the normal and chronic malaria were not the cause of a positive Wassermann reaction. Regarding leprosy they summarized all work done up to 1915, but expressed no opinion. Like others they found cases of leprosy with a positive Wassermann reaction. In kala-azar they found 10 cases with positive reaction. The reaction in two of them was stronger than in the remaining eight. Again they expressed no opinion as to whether or not kala-azar was the cause of a positive Wassermann reaction. Their technique was evolved in this laboratory. A specially selected antigen and a rather high single dose of complement were used.

Iyengar (1919) employing method number 4 of the Medical Research Committee did a Wassermann reaction on 400 unselected apparently healthy Indian males attending the Pasteur Institute of India, Kasauli; 22 per cent of them were positive. This percentage Iyengar regarded as the positive rate for the male Indian. After establishing the positive rate he (1919a) did a Wassermann reaction on 100 cases of leprosy and obtained a positive rate of 41 per cent; he came to the conclusion that leprosy was the cause of a positive Wassermann reaction. Later (1920), he did a Wassermann reaction on 84 cases of malaria and obtained a positive rate of 8.3 per cent; he came to the conclusion that malaria was not the cause of a positive Wassermann reaction. Later still (1923), he did a Wassermann reaction on 30 cases of kala-azar and obtained a positive rate of 20 per cent. In view of his original positive rate for the apparently healthy male Indians, he came to the conclusion that kala-azar was not the cause of a positive Wassermann reaction.

Megaw and Mullick (1928) commenting on Wassermann reaction of 400 hospital cases, tested by Sutherland's technique, inclined to the view that there were more positive reactions in the 90 kala-azar cases than in the remaining 310 non-kala-azar cases. They inferred that either kala-azar was the cause of a positive Wassermann reaction or syphilitics were more liable to develop kala-azar than normal individuals.

Lloyd, Napier and Mitra (1930) first reviewed the work on the subject and agreed with Iyengar's Wassermann reaction positive rate in India, 22 per cent, which according to them 'approximates very closely to the estimated syphilis rate of the Calcutta hospital population which is believed from evidence of various kinds to be round 20 per cent'. Then they

gave their own findings. They found 105 positive reactions in 474 kala-azar cases, or a positive rate of 22 per cent, which they considered to be normal positive rate for India. They came to the conclusion that kala-azar was not the cause of a positive Wassermann reaction. They used Sutherland's technique.

These writers referred to another series of 101 cases of kala-azar in which they found 29 positive reactions. This figure they considered somewhat higher than the percentage ordinarily yielded.

Lloyd (1932) commenting on the interpretation of Wassermann reaction in India again states that 'the occurrence of positive reactions in malaria is partly a question of technique and partly a question of concomitant syphilis'. In his work on malaria, even with a supersensitized antigen (cholesterinized Bordet antigen) he found no positive reactions.

2. Our work*

In our series of 400 unselected Indian cases from the Carmichael Hospital for Tropical Diseases, Calcutta, there were 51 positive cases giving a Wassermann reaction positive rate of 12.75 per cent which is appreciably lower than Iyengar's positive rate of 22 per cent.

Further, as we have shown that conditions (acute, subacute and chronic) other than syphilis are the cause of a positive Wassermann reaction, our rate of 12.75 per cent is the crude rate, not the corrected rate. In order to obtain the latter, from 51, representing the positive cases, should be deducted 10, representing the cases with negative histories, no signs of syphilis and negative Wassermann reactions on subsequent tests, without any or very inadequate treatment for syphilis. The deduction leaves 41 positive cases in 400 or a 10.25 per cent corrected rate. How many more cases with negative histories and no physical signs of syphilis could be deducted, if facilities for longer observation existed, is a problem worth investigation. The presumption is that more deductions would be possible. That in the tropics defined and undefined infections are the cause of a positive Wassermann reaction has been observed. That some reactions should last longer than others is a reasonable supposition.

The number of Wassermann reaction positive cases in our series of 200 Europeans (and others included in the same group) was 20, giving a positive rate of 10 per cent. Deducting 4 cases with negative histories, no signs of syphilis and negative Wassermann reactions on subsequent tests, the figure would be reduced to 8 per cent. The Wassermann-positive rate of both groups is of about the same order.

Sutherland and Mitra, in their paper referred to above, mentioned that 'Meier and Bonfiglio were reported by Wassermann to have found that in the tropics no case of suspected syphilis should have its Wassermann reaction taken

unless it has been free from malaria for three months and no case of any kind should have the Wassermann reaction taken unless the patient has had no fever for a month previous to the examination of his blood'. They called this view pessimistic. Our study has made us mindful of pessimistic possibilities in the interpretation of a positive Wassermann reaction in the tropics.

The corrected positive rate for an unselected Indian population should be *under* 10.25 per cent. In America, according to Becker (1937), it is only 10 per cent. Becker considers the 10 per cent rate a public health problem; a 22 per cent rate would be a public health crisis.

In India, a higher figure would not be compatible with the social and economic order of things. The bulk of the population of marriageable age is married and therefore so situated that its main concern is alimentation, not gratification of sexual desires, illicitly.

The only explanation we can offer of the marked difference between the previous workers' figures and ours is that quite a large number of reactions read as positive must have corresponded to what the senior writer (Greval, Yesudian, and Choudhury, 1930) described as 'irregular reaction'. It is not unusual in a day's work to find more than half of the apparently positive reactions really irregular (= doubtful). Such readings are fully supported next day in the ward and confirmed later by further blood tests.

An erroneously high reading is obtained in method number 4 if a trace of lysis in both the tubes containing antigen is ignored. In a method employing a large single dose of complement nothing is easier than to obtain an erroneously high reading. In a 'moderately positive' reaction a trace of lysis is not excluded. 'Weakly positive' and 'doubtful' reactions are both associated with more than a trace of lysis. Most of these reactions are really doubtful reactions. First diagnosis of syphilis is not to be based on a doubtful reaction.

Incidentally, we do not intend to belittle the significance of a doubtful reaction. (1) In cases of chancre, proved microscopically, it confirms the diagnosis of syphilis; (2) in early infections, up to three to five years (depending upon circumstances) it indicates a continuation of the usual treatment; (3) in late infection after three to five years it indicates a thorough examination of the patient and employment of special measures, if necessary, in preference to the usual treatment; and (4) it disqualifies a donor of blood.

It may be observed that with the exception of our 200 European and Anglo-Indian cases the figures referred to in this communication, on which important conclusions have been based, are of about the same order, viz :—

- (1) Iyengar's 400 unselected Indian cases for the Wassermann reaction positive rate in India, from Kasauli in 1919.

* For figures see Appendix.

- (2) Megaw and Mullick's 400 unselected cases from the Carmichael Hospital for Tropical Diseases, Calcutta, in 1928.
- (3) Lloyd, Napier and Mitra's 474 cases of kala-azar from the same hospital reported in 1930.
- (4) Our 400 unselected Indian cases from the same hospital this year (1938).

The conclusions emerging from this study have yielded definite information on the two items discussed under this heading (VI). In view of the importance of the items and the information obtained the title of this paper could have been *The significance of a positive Wassermann reaction and the Wassermann reaction positive rate in India*.

Summary and conclusions

A study of latent syphilis has been undertaken in the Carmichael Hospital for Tropical Diseases, Calcutta, with a view to obtaining information on (i) latent syphilis in the hospital population, (ii) effects of syphilis on tropical disease, (iii) effect of tropical diseases on syphilis, (iv) association of syphilis with other diseases, (v) conditions other than syphilis which give a positive Wassermann reaction (attention is drawn to a syndrome comprising dysfunction of gastro-intestinal tract with enlargement of liver or liver and spleen, pyrexia and loss of weight; the Wassermann reaction is positive or doubtful; personal and family history are against a diagnosis of syphilis; results of treatment by arsenic or bismuth are good), and (vi) the significance of a positive Wassermann reaction and the Wassermann-positive rate in India (conditions other than syphilis are definitely the causes of a positive Wassermann reaction in India); properly corrected Wassermann-positive rate, indicative of syphilis, for Indians should be *under 10.25 per cent* and for Europeans—and others included in the same group—*under 8 per cent*; the difference is not significant.

Details of the technique followed and the results of the Wassermann reaction of 600 cases, under observation in the wards of the Carmichael Hospital for Tropical Diseases, are given in the appendix.

Acknowledgments

It was only possible to undertake this study after the Director and the Governing Body of the Endowment Fund of the School of Tropical Medicine had found it possible to place the services of a worker at the disposal of the senior writer.

The clinical work involved in the study, apart from establishing or ruling out a diagnosis of syphilis, was undertaken by the physicians of the Carmichael Hospital for Tropical Diseases, to whom our thanks are due for their co-operation.

APPENDIX.

- I. Technique.
- II. Reading of results.
- III. Results of Wassermann reaction in 400 Indian and 200 European (and other) cases from the Carmichael Hospital for Tropical Diseases, Calcutta.
- IV. Procedure with cerebro-spinal fluid.
- V. Preparation of and remarks on Bordet's antigen.

I. Technique

Method number 4 of the British Medical Research Committee was employed with the following modifications:—

1. The serum control was put up with the functioning dose of the complement, *i.e.*, 2 M.H.D. instead of 3 M.H.D.
2. The complement and the antigen were mixed and the mixture added to the serum.
3. The r.b.c. suspension was standardized in accordance with the senior writer's scheme (1930).
4. Three antigens were used:—

(i) The ordinary antigen used in the method. But the heart extracts were specially selected for sensitiveness and specificity, after testing with strongly positive and negative sera. Only suitable heart extracts were cholesterinized. The antigen was put up with the usual quantity of the serum and 3 M.H.D. and 5 M.H.D. of complement.

(ii) The uncholesterinized heart extract (after selection) diluted 1 in 15 with saline. This fluid was put up with the usual quantity of the serum and 4 M.H.D. of complement. It is not anti-complementary; 4 doses of complement, therefore, correspond to the 5 doses used with the cholesterinized antigen which is anti-complementary to the extent of 1 M.H.D.; there are 4 functioning doses present in each case.

(iii) Bordet's antigen (for preparation see item IV of this appendix). This antigen has been in use in this laboratory for a very long time. Three parts of the final alcoholic extract were mixed with 2 parts of a 1 per cent alcoholic solution of cholesterol. One part of the cholesterinized extract was diluted with 49 parts of

saline. 0.25 c.cm. of this fluid was put up with the usual quantity of the serum and 2 M.H.D. of complement. The fluid is not anti-complementary; 2 doses of complement, therefore, correspond to the 3 doses used with the ordinary antigen.

5. Incubation. The final incubation, after adding the r.b.e., lasted half an hour.

6. Second reading. The tubes not showing a column of colourless fluid on top of sedimenting r.b.e. and the tubes showing lysis bordering on complete lysis were left in the cold overnight and re-examined next day for :—

(i) Traces of lysis in tubes showing apparently complete inhibition on the first day. A trace of lysis converted + into T.

(ii) Comparing the colour in tubes bordering on complete lysis on the first day and negative controls. An equality of colour and absence of a coloured deposit at the bottom of the tubes converted \pm into ? — (reported negative).

II. Reading of results

1. Complete inhibition of lysis with the plain alcoholic heart extract = +++ (strongly positive).

In this case there is a complete inhibition in all other tubes also.

2. No inhibition of lysis with the plain alcoholic heart extract but complete inhibition with the ordinary antigen both with a M.H.D. and 5 M.H.D. = ++ (positive).

In this case there is a complete inhibition with Bordet's antigen also. (With the plain alcoholic heart extracts there may be an incomplete inhibition).

3. Complete inhibition with the ordinary antigen and 3 M.H.D. of complement with or without partial inhibition with 5 M.H.D., also complete inhibition with Bordet's antigen and 2 M.H.D. of complement = + (weakly positive).

Such reactions are not common.

4. Traces of lysis or considerable lysis in both the tubes of the ordinary antigen (with 3 M.H.D. and 5 M.H.D.) = irregular reaction = \pm = doubtful.

In this case there may or may not be an inhibition with Bordet's antigen. The fact is noted as +, T, \pm , ? — or — Bordet.

5. Partial lysis with ordinary antigen and 3 M.H.D. complement = \pm (doubtful).

In this case there may or may not be an inhibition with Bordet's antigen. The fact is noted as +, T, \pm , ? — or — Bordet.

6. Lysis almost complete but not quite with the ordinary antigen and 3 M.H.D. complement = ? — (reported negative).

In this case a similar reaction with Bordet's antigen is noted and ignored for the purpose of a report. But a stronger inhibition of lysis is against reporting the case negative.

The question is being studied whether or not a serum giving a doubtful reaction with the ordinary antigen and a clear negative reaction

with Bordet's antigen should be reported negative.

7. Lysis complete with ordinary antigen = —, negative. Reaction with Bordet's antigen in this case, if other than negative, is ignored.

In reading these results the serum control may be free from an inhibition of lysis or may show a slight inhibition in 1 and 2. It should be completely free from an inhibition in 3, 4, 5 and 6; otherwise a corresponding degree of inhibition in the tubes of the test proper must be ignored; in 3 the test must be repeated with further dilution of serum until the serum control is free from inhibition of lysis. When there is no lysis or only a trace of lysis in the serum control, the serum is reported anti-complementary, if enough of it is not left for further detections and tests.

III. Results of Wassermann reaction in a series of 600 cases from the Carmichael Hospital for Tropical Diseases, Calcutta

	Indian	European, Anglo-Indian and others
Strongly positive	400	200
Positive	6	1
Weakly positive	43	18
Doubtful with both antigens	2	1
Doubtful with Bordet's antigen only	74	32
Doubtful with ordinary antigen only	13	3
Anti-complementary	55	14
Negative	8	3
	199	128
TOTAL	400	200

The figures indicate the highest reading of the positive cases (after a provocative injection in some cases) and the first reading of the doubtful cases. Anti-complementary cases were discharged before the test could be repeated to obtain a reading. No case has been included twice. A large number of doubtful cases and some positive cases were found negative on subsequent tests done at suitable intervals.

Giving effect to the suggestion that a doubtful reaction with one antigen only should be disregarded, the Indian figures will be :—

Strongly positive	6
Positive	43
Weakly positive	2
Doubtful	74
Anti-complementary	8
Negative	267
TOTAL	400

The figures in the corresponding series of 400 cases reported by Megaw and Mulliek (1928) ten years ago from the same hospital are :—

Strongly positive	25
Moderately positive	76
Doubtful	34
Negative	265
TOTAL	400

It is evident that the sole cause of difference is the category 'moderately positive'. The

number of negative cases is almost identical. We presume that about half the cases grouped under the category 'moderately positive' would correspond to our doubtful cases.

IV. Procedure with cerebro-spinal fluid

Partly following Wyler (1929) the fluid, without inactivation, was put up for the test in two strengths: (1) undiluted fluid, and (2) two volumes of undiluted fluid instead of one volume. 5 M.H.D. tube was omitted. Inhibition of lysis in the tube containing two volumes of undiluted cerebro-spinal fluid, even when complete, was not accepted as positive unless there was also a definite inhibition of lysis in the tube containing one volume of undiluted fluid.

The results were read:—

- +++ = Strongly positive, when complete inhibition of lysis occurred with the uncholesterinized heart extract in one or both tubes.
- ++ = Positive, when complete inhibition of lysis occurred in both the tubes put up with cholesterinized antigen.
- += Weakly positive, when inhibition was complete with two volumes of the fluid and partial but well marked with one volume, with cholesterinized antigen.
- ± = Doubtful, when partial but well marked inhibition occurred in one or both tubes, with cholesterinized antigen.
- = Negative, when no inhibition or inhibition of a poor quality occurred, with cholesterinized antigen.

A tube was also put up with Bordet's antigen (cholesterinized), one volume of fluid and 2 M.H.D. of complement. An inhibition of lysis in this tube supported the inhibition of lysis in the corresponding tube put up with the ordinary antigen.

V. Preparation of and remarks on Bordet's antigen

This antigen, which has been in use in this laboratory for a long time, is prepared as follows:—

1. One hundred grammes of human heart muscle cut into pieces (not minced) is left in contact with 125 c.cm. of absolute alcohol, in a stoppered bottle, for a week.
2. The alcohol is poured off and the muscle dried in an incubator for 24 to 48 hours (should be like pieces of wood).
3. The dried muscle is left in 200 c.cm. acetone for a week, in a stoppered bottle.
4. The acetone is poured off and another lot of 200 c.cm. added.
5. After 24 hours the second lot of acetone is also poured off and the muscle dried in an incubator until free from smell (3 days or more).
6. The dried muscle is powdered and the powder extracted with 200 c.cm. of absolute alcohol for 10 days, in a stoppered bottle.
7. The stoppered bottle is shaken and the contents filtered through a filter paper. The filtrate is Bordet's antigen.
8. To 30 c.cm. of Bordet's antigen is added 20 c.cm. of 1 per cent of cholesterol in absolute alcohol. The mixture is cholesterinized Bordet's antigen.

(Continued at foot of next column)

A NOTE ON RACIAL VARIATIONS IN LEPROSY WITH PARTICULAR REFERENCE TO INDIAN AND BURMESE RACES

By JOHN LOWE, M.B., CH.B.

Research Worker in Leprosy under the Indian Council of the British Empire Leprosy Relief Association
Calcutta School of Tropical Medicine

ON various occasions I have expressed the view that in different races in different countries, there may be considerable variation in the clinical manifestations of leprosy and also in certain aspects of the epidemiology of the disease. I have suggested that these variations are probably due to differences in the susceptibility of different races to leprosy, i.e., to differences in their physiological and immunological 'make up' as manifested by differences in the way their body tissues react to invasion by the leprosy bacillus. I have expressed these views rather tentatively since my experience of leprosy in races other than Indians is not great. A few other workers, particularly Cochrane (1935), Wade (1937), Ryrie (1934), have expressed similar views, although accurate data on the subject are very limited.

Recently, I paid a visit of three and a half weeks' duration to Burma in order to study the leprosy problem. Now, Burma is a country where, particularly in the Irrawaddy Delta, there is a mixed population chiefly of Burmans and Indians; there is also a considerable incidence of leprosy. It, therefore, affords a splendid opportunity of making a comparative study of leprosy in these two races. Unfortunately in the short time spent in this area (only a few days) it was impossible for me to make a very thorough study of the subject. It is hoped that opportunity will occur for a much more thorough study in

(Continued from previous column)

The cholesterinized Bordet's antigen in a 1 in 50 dilution in normal saline is not anti-complementary when used in the place of the ordinary antigen in method IV. This fact saves one titration of complement and one hour if no other antigen is employed in the test. Further, the antigen has enjoyed a local reputation of being more sensitive than the ordinary alcoholic antigen cholesterinized. We have used it merely as an extra antigen and assigned to it a secondary importance. No serum completely negative with the ordinary antigen has been taken as doubtful because of a partial inhibition of lysis with Bordet's antigen. Nor has a serum doubtful with ordinary antigen been taken as weakly positive because of a stronger reaction with Bordet's antigen. Only sera not completely negative with ordinary antigen and definitely doubtful with Bordet's antigen have been taken as doubtful; there are not many reactions of this type.

On the comparison between the two antigens more will be said elsewhere.

which bacteriological and histological examinations will be included. The information collected during my recent visit was almost entirely clinical, and although it is very incomplete, it is, I think, not without interest.

1. Type distribution

Racial variations in leprosy show themselves in variations in the type distribution of leprosy cases, *i.e.*, the number of cases of 'neural' type compared with the number of cases of 'lepromatous' type. In a recent statistical survey in Bengal, cases of neural type were found to form 82 per cent of the total. A similar survey in the Philippine Islands has shown 50 per cent of cases of neural type. A report from one part of Africa has indicated a proportion of 95 per cent.

During my visit to Burma no detailed statistical survey could be made but certain information was collected which bears on the subject.

(a) *Type distribution of cases in Indians and Burmans in Rangoon.*—For information on this subject I am very deeply indebted to Dr. L. Kun Lwin who, at my request, prepared a statement of the clinical classification and results of bacteriological examination of 464 patients in his charge at the Rangoon Leper Asylum and at the clinic at the Rangoon General Hospital. From his statement the following figures are prepared:—

Rangoon Leper Asylum

	Lepromatous type	Neural type
Burmans ..	269 202 (75 per cent)	67 (25 per cent)
Indians ..	106 41 (39 per cent)	65 (61 per cent)

Of course these figures collected in a leper asylum do not indicate the type distribution of cases in the general population, but they give a strong indication of a marked racial difference.

(b) *Figures collected in leprosy clinics in Burma.*—These are as follows:—

	Lepromatous type	Neural type
Burmans ..	1,013 566 (56 per cent)	447 (44 per cent)
Indians ..	55 17 (31 per cent)	38 (69 per cent)

Here the figures for Indians are very small and were all collected only at the Rangoon General Hospital by Dr. L. Kun Lwin. The figures for Burmans were collected and verified by me in various outpatient clinics chiefly in central Burma where Indians are very few.

(c) *Figures collected in villages in Burma.*—These figures relate only to Burmans since the number of Indians in the villages visited was negligible.

	Lepromatous type	Neural type
Burmans ..	900 479 (53 per cent)	421 (41 per cent)

These figures are based on reports of surveys carried out by Dr. U. Tha Din, Special Leprosy Officer, Burma, and on my own reports of a number of villages visited during my tour. My own findings are in agreement with those of Dr. U. Tha Din. It is highly probable that in these villages some slight cases of neural type

were missed, but these figures differ very strikingly from the reports of similar rough survey work done in India, in which the number of cases of neural type is sometimes three or four times greater than the number of cases of lepromatous type.

(d) *Conclusions*—I think that the figures quoted indicate very strongly that the type distribution of leprosy cases in Burmans differs markedly from that of Indians domiciled in Burma or in India, and that in Burmans cases of lepromatous type form a much higher proportion of the total.

2. The age distribution of leprosy in Burmans and Indians

Only a small amount of information on the subject was collected. Of 208 Burman male patients in the Rangoon Leper Asylum 71 per cent were under the age of 30 and the average age was 25.

Of 103 Indian males in the same institution only 40 per cent were under the age of 30 and the average age was 34.

In spite of this lower average age of the Burmans, the Burmans showed, as reported above, a much higher incidence of the severe lepromatous form of leprosy.

Another interesting point observed in Rangoon was the difference in the age distribution of slight cases of neural leprosy in the two races. Of 21 such cases seen in Burmans, only 7 (33 per cent) were over the age of twenty, while of 36 similar cases seen in Indians, 28 (78 per cent) were over the age of twenty. These figures are rather small, but they correspond to the findings made in Indians in India, and in Burmans in other parts of Burma visited. In India we find slight cases of neural leprosy in all age groups of the population although they are commonest in young people. During my tour in Burma I tried to find such cases amongst adult Burmans but very few were seen among nearly 2,000 patients.

A difference was also seen in the age distribution of severe cases of lepromatous type in the two races. In Indians severe lepromatous forms of the disease are seen chiefly in adults though they do sometimes occur in children. Among Burmans however the severe lepromatous cases in young children are very much more common, and also more severe. In India it would be very difficult to collect so many children with such severe leprosy as the Burmese children in the Rangoon Leper Asylum. They reminded me strongly of the Chinese leper children in Malay.

What is the significance of these findings? I surmise that both Indians and Burmans commonly get infected in childhood or adolescence, and usually show, to begin with, a mild neural form of the disease. In Indians this form may persist for a long time and possibly throughout life, but in Burmans the disease much more often progresses, and progresses with greater rapidity,

Fig. 1.—Healing of ulcerating tuberculoid lesions. Note very extensive scarring.

Fig. 2.—Back of same patient. Some ulcers not completely healed.

Fig. 3.—Face of similar case. Healing complete. Note destruction of ear lobe.

Fig. 4.—Back of same patient, showing extensive scarring.

Fig. 5.—Close view of back showing scarring and atrophy of skin.

Fig. 6.—Patient showing marked nodulation of one ear and no other visible lesion.

Fig. 7.—Boy showing very marked nodulation with apparently normal skin between the nodules.

Fig. 8.—Leprous infiltration on body. Note 'islands' of normal skin.

to the severer forms of the disease, sometimes of neural type but very often of lepromatous type. It is also surmised that the severe lepromatous form of leprosy seen in Burmans may more frequently cause death than the milder forms seen in Indians, and that this may influence the age distribution of the cases in the two races, old Burmans suffering from leprosy being rare.

3. *Differences in clinical manifestations of leprosy in Indians and Burmans*

On this subject I can quote only my own general impressions after seeing nearly 2,000 cases of leprosy in Burma and comparing them with cases of leprosy in Indians in Rangoon and in India, numbering many thousands, seen under similar conditions.

In Indians the classification of cases into neural and lepromatous types usually presents little difficulty. Here and there is found a case difficult to classify. In Burma however for reasons which appear later, the classification of cases presented much more difficulty, many cases showing lesions not entirely characteristic of either type as seen in India.

In Indians the characteristics of neural leprosy may be summarized as follows:—clearly defined and circumscribed macules of different kinds, with sensory change, thickening of cutaneous nerves and of nerve trunks, with anaesthesia and trophic lesions, and usually the absence of lepra bacilli from smears taken from the lesions. The characteristics of the lepromatous type of leprosy in Indians are the lepromatous infiltration of the skin, sometimes nodular but much more often diffuse, with many bacilli in the lesions.

In Burmans the two main types of leprosy were much less clear cut. We will discuss the different types of lesions seen in Burmans.

(a) *Neural type*.—Macules. These lesions were on the whole very similar to those seen in Indians except that the skin of Burmans being lighter, depigmentation was less marked, and erythema was more easily detected. The sensory change in macules was usually very definite. In Burmans however the thickened frankly tuberculoid lesions so commonly seen in India were much less common, most being of the flat, simple or very 'minor tuberculoid' variety. This finding is probably connected with the fact that most of the neuro-macular lesions were seen in children while the frank tuberculoid lesions are always more common in adults. However, lesions of the 'major tuberculoid' variety were seen in considerable number in Burma, even in children, and I also saw two cases of tremendously marked ulcerating tuberculoid lesions similar to those which have been described by Ryrie as occurring in Chinese in Malaya (see plates XII and XIII).

Nerve thickening. Thickening of cutaneous nerves and of nerve trunks was very commonly seen, almost as commonly as in Calcutta, but the degree of thickening was on the whole much

less than that seen in Calcutta. Only one case of definite nerve abscess was seen and that was a small abscess on a small nerve supplying a macule. Several very thick nerve trunks, probably caseous, were seen, but they were less common than in Calcutta.

Trophic lesions, deformities, etc., in Burmans showed nothing of particular interest except that, as in India, trophic ulcers of the sole were usually associated with marked lesions of the posterior tibial nerve at the ankle.

(b) *Development from neural to lepromatous type*.—A considerable number of cases were seen in which the lesions were either 'reacting' tuberculoid lesions in which smears showed an abnormally large number of bacilli, or else were lepromatous lesions developing from a previously existing tuberculoid lesion. In addition there were many patients in whom the lesions were definitely of lepromatous type, but the peculiarly localized nature of the lesions and their peculiar distribution, and the fact that involvement of cutaneous nerves supplying the lesions was found, indicated very strongly that these lepromatous lesions had developed from previously existing tuberculoid lesions.

This phenomenon, tuberculoid reaction being followed by lepromatous change, is sometimes seen in Indians, but in Burmans it appears to be much more common.

It is this intermediate type of case met with so commonly in Burma which is so difficult to classify.

(c) *Lepromatous type*.—It is in the lepromatous type of lesion that the differences between Indian and Burman leprosy are most marked. In Indians, leprosy of this type is usually diffuse and not localized, and not infrequently there is infiltration of the skin of the whole body without the presence of definite nodulation anywhere. In Burmans, however, this is much more rarely seen, and there is a far greater tendency to the production of marked local lesions without any apparent general skin involvement. Even when there is such a general involvement, marked nodulation in certain sites is a striking feature of the disease. Such cases are sometimes seen in India but not nearly so commonly as in Burmans. The term 'nodular', previously used of leprosy of the lepromatous type, is not open to much objection when applied to leprosy in Burmans.

I will quote a few cases, possibly rather extreme cases, but all indicating this tendency to localization of the lesions.

A male, aged about 35, showed marked nodules on one ear lobe and no other obvious sign of leprosy anywhere in the body (see plate XIII, figure 6).

A boy, aged 12, showed very marked nodulation on the face and some similar lesions elsewhere in the body but in between the lesions the skin appeared perfectly clear and there was no evidence of diffuse infiltration as would be seen in such cases in Indians. It would be rare

to find such a severe case in an Indian boy of this age but in Burma such cases are very common.

A male, aged 18, showed a large plaque-like lesion on the back with very indefinite margins fading into the surrounding normal skin. There was slight sensory change in the lesion but no detectable nerve thickening. Smears from the lesions show an enormous number of bacilli. There was no other lesion visible in the body.

Another patient showed a similar lesion on the arm but here there was very definite evidence of a previous tuberculoid lesion since there was more anaesthesia and also definitely thickened cutaneous nerves.

The last two cases illustrate a finding commonly made in cases of leprosy in Burma, namely, the development of lepromatous change in lesions which apparently were previously of tuberculoid nature. This finding may help to explain the peculiar localization and distribution of lepromatous lesions seen in some patients.

4. *The significance of these findings*

Such findings as I have here reported indicate clearly, I think, that there are differences in the clinical manifestations and in the course of the disease in Burmans as compared with Indians, and suggest strongly that the Burman has much less natural resistance to leprosy than the Indian. I think that the findings also have an important bearing on treatment and prophylaxis. Results of treatment in cases such as I have described in Burmans will probably not be so good as in the milder cases seen in Indians. Even in Indian cases, treatment has very great limitations, and in Burman cases the limitations will be even more marked. The findings also emphasize the paramount importance of isolation in the control of leprosy in Burma. Even in India, with perhaps only 25 per cent of cases infectious and with a general population not highly susceptible to leprosy, isolation of infectious cases is regarded as the chief measure in prophylaxis. In countries such as Burma, where perhaps 50 per cent of cases are infectious, where the mild cases are more likely to become infectious, and where the people as a whole are probably more susceptible, the argument for isolation is even stronger.

5. *Causes of racial variation*

When we try to give a reason for racial variations of leprosy we step into the realm of conjecture for little is known of the subject. It has been suggested that climatic, social, economic and dietetic conditions may help to cause these differences. The influence of climate in producing these differences in Burma can be disproved by the fact that in this country, different races show leprosy in forms varying with the race, the climatic conditions being constant.

The diet of the average Burman is in many ways similar to that of the average Indian, being based on rice, but the average Burman seems

to be better fed owing probably to food being more abundant. Also Burmans not being vegetarians probably have a more balanced diet with a greater protein and fat intake. One peculiarity of the Burman diet is the consumption of 'nappi', a stale fish product. (This fact reminds one of Sir Jonathan Hutchinson's theories in their various forms). It seems to me unlikely that diet is an important factor in causing racial differences.

The social and economic conditions of villages seem on the whole better in Burma than in India. The general health also does not seem to have any important influence on the problem. The great health problem of Burma is malaria, but, in the parts of Burma where leprosy is most common, malaria is less common than elsewhere.

Another possible cause of variations in leprosy in different races and countries is a variation in the pathogenicity of different strains of the causative organism. The evidence however is against this idea. Indians infected in Burma and other countries apparently develop the forms of leprosy characteristic of the disease in India.

Thus it appears that the lack of resistance to leprosy of Burmans is racial and hereditary.

Regarding racial resistance to leprosy little is known. Long endemicity of other diseases in any country is often followed by a gradual diminution in the incidence of the disease and in the severity of the symptoms. This is often attributed to the development of racial immunity. Can such a phenomenon be demonstrated in leprosy? It has been suggested that this is the reason why leprosy practically disappeared from most of Europe at the end of the Middle Ages.

The history of leprosy is uncertain, but it has been surmised that leprosy originated in Africa and spread early to India and later to the far east. It seems that there is a considerable amount of evidence to suggest that in Africa and in India the disease is generally seen in a relatively mild form, but that as one travels farther east one sees the disease in forms steadily increasing in severity. These are suggestions and not really proved facts. Can these ideas be proved? Is it possible that in countries and peoples which have more recently been infected, the disease shows itself in its severer forms owing to the lack of time for the development of racial immunity?

On the other side it may be argued that there is no proof that leprosy originated in Africa and spread to the far east *via* India; that leprosy has been prevalent for thousands of years in the far east, probably for far longer than it was prevalent in Europe, and that racial immunity, if it occurs at all, has already had adequate time to make itself felt in far eastern countries. It may also be argued that in recently infected countries (*e.g.*, Nauru), the disease does not necessarily appear in a severe form.

OXYCEPHALY

By M. M. CRUICKSHANK

LIEUTENANT-COLONEL, I.M.S.

Madras

THE comparative rarity of true oxycephaly and the difficulty in differential diagnosis may warrant the report of a single case.

A female child, aged 6, was sent to me for investigation as a case of possible intracranial tumour, and until certain investigations were completed the question of a Hands-Schüller-Christian syndrome was considered, but before final cranial measurements could be taken the child was removed from hospital.

The history, given by the grandmother, was that the child had been blind, if not from birth, at least before it was one year old, at which age protrusion of the eyeballs was noticed. The child had during the last 12 months suffered from periodical fainting fits, the nature of which could not be clearly elicited.

Family history revealed nothing of note. Father and mother alive and well; three elder sisters and one younger brother also alive, and presenting no abnormality.

The patient's birth, occurring at full term, had presented no difficulties. With the onset of the trouble, it was noted that the child breathed through its mouth, snored in its sleep and occasionally had a discharge from the nose. Two years ago, a swelling was noted on the top of the child's head. The condition, it was stated, had definitely progressed during the last one or two years.

Examination revealed a rather under-developed child with enlarged tonsils and adenoids. There was marked proptosis of both eyes forwards and slightly upward with a divergent strabismus. Pupils were dilated and inactive to light, the child groping its way around, but remarkably alert in guiding itself by the sound of voices. Eye movements were limited in all directions. The forehead was flat, almost vertical, and the skull culminated in a rounded peak at the bregma. The occiput was small and flattened. There were three protuberances on the skull over which the skin moved freely, the largest at the junction of the left parietal and frontal bones, the smaller ones over the left frontal and occipital regions. This observation suggested at first lipoid granulomatosis.

Muscular power and reflexes were normal; gait normal and no evidence of wasting. The hands were strikingly squat, the fingers being almost equal in length, the so-called trident hand. The child appeared happy but was definitely deficient mentally, being unable to talk properly and grimacing at intervals for no known reason.

The blood sugar was 0.067 per cent, urea 20 mgm. per cent, cholesterol 180 mgm. per cent.

Radiograms revealed well marked 'digital depressions' all over the skull, corresponding to the entire

cerebral surface. The skull was sutureless and an ill-developed superior longitudinal sinus was noted. Sutures between the facial bones also were not visible. There was marked thinning of the calvarium and a definite absence of diploë though in a child of six or seven the formation of a diploic space has not normally advanced in any definite degree. The pituitary fossa was definitely malformed, appearing narrow and deep.

Greig (1926) in his exhaustive monograph on the subject of oxycephaly stresses the point that every misshaped head is not necessarily a case of oxycephaly, however vaguely it may simulate such a condition. He points out that confusion has arisen because of the want of differentiation between true, delayed and false oxycephaly, and he, with his wonted accuracy, defines true oxycephaly as 'a congenital malformation associated with synostosis and though there may be coincident developmental defects, presents as the constant feature a characteristic deformation of the skull'. True oxycephaly according to Greig is primarily a congenital defect, due to a general craniofacial synostosis often associated with other deformities, more often of the extremities. Delayed oxycephaly on the other hand is a premature general synostosis of the cranium manifesting itself in childhood but not associated with deformities of the extremities. In false oxycephaly, in contradistinction to the general synostosis of the true, the synostosis is limited to a few or even one suture, the facial sutures are never affected; the condition occurs during cerebral growth, is often of definite origin and is not congenital. In true oxycephaly the height of the head is an essential feature and depends on the fact that the membranous areas are kept open by the growing brain, but 'when and where the bones touch they fuse, the true oxycephalic skull is sutureless'. Greig stresses this point repeatedly, and states that 'this curious property is exercised during intrauterine life and the rapidity of brain growth during infancy produces an exaggerated deformity. In delayed oxycephaly the synostosis comes later and the deformity may be striking but need never become obtrusive'.

The alteration in size and shape of the pituitary fossa, well seen in some of the radiograms, is due according to Greig, to the small size of the basilar process, which is short and narrow. This feature Greig states is 'pathognomonic of true oxycephaly and distinguishes it at once from all spurious varieties. It is the natural result of early fusion and cessation of growth'. Apparently the disturbance in shape of the fossa has no effect on the efficiency of the pituitary gland.

Though true oxycephaly is certainly not to be defined as a cranial deformity associated with exophthalmos, yet the eye symptoms, proptosis, nystagmus, and defective ocular movements are amongst the most important features of the condition. Dislocation of the eyeball, reported by several writers, is probably the result of the shallow orbits, and the proptosis

(Continued at foot of next page)

(Continued from previous page)

It must, however, be accepted that racial differences in leprosy are seen. It is just possible that a study of racial susceptibility in relation to the history of leprosy in the affected races may give interesting results.

CONVULSION THERAPY IN SCHIZOPHRENIA

By M. TAYLOR, M.D., D.P.H.

MAJOR, I.M.S.

Medical Superintendent, Ranchi European Mental Hospital, Kanke, Ranchi, Bihar

SCHIZOPHRENIA (*dementia præcox*) is one of the most frequent forms of the major psychoses, constituting the majority of first admissions to mental hospitals, and, in view of the tendency to chronicity, and that, in many instances, it does not shorten life, it is usually found that about 60 per cent of the population in mental hospitals is made up of schizophrenics. It is a greater social menace than any other illness. Yet the average medical practitioner cannot even recognize it.

In its treatment many a will-o'-the-wisp which at first appeared substantial has been followed, but so many of them have turned out to be

(Continued from previous page)

having reached a certain point, the action of the orbicularis palpebrarum would, by exerting pressure behind the globe, tend to dislocate the eyeball forward.

Of the cranial nerves the second is the only one to be affected. The atrophy is the result of an antecedent papilloedema, occurring in early life. The pathogenesis of the optic atrophy seems to be in doubt. Greig states that 'intracranial pressure alone does not seem to be the cause of the optic neuritis and, in true oxycephaly, there is neither osteophytic growth nor thickening to narrow the optic canal. Indeed the usual disturbance seems to be brought about by a variety of causes acting together in which smallness of foramen and increase of intracranial pressure may take their share, but much more important is the upward deflection of the nerve with the displacement of the brain, the defective arterial blood supply and the restriction of the venous return'.

Though many anomalies may be present with oxycephaly, no single one is constantly represented. The only constant combination is that of cranial deformity and synostosis and these alone, as Greig puts it, constitute the syndrome of oxycephaly. Just as in achondroplasia, and later on in fetal life in acromegaly, conditions presenting cranial deformities with associated deformities in the extremities, so in true oxycephaly the local fault occurs during intrauterine life, at the time when the fingers and later on the joints are being formed. The deformity of the digits is subservient to that of the skull.

I am indebted to Dr. Pillai, the Medical Superintendent of the Barnard Institute of Radiology, for the radiograms.

Greig, D. M. (1926). *Edinburgh Med. Journ.*, Vol. XXXIII, pp. 189, 280 and 357.

mere fancies that it is not surprising that psychiatrists adopt a conservative attitude towards any new therapy. According to some recent work done in Europe and the United States of America it is claimed that 'shock therapy' produces cures or remissions in early cases, and beneficial effects on long-standing cases of schizophrenia. Two methods are employed—the 'hypoglycæmic' by the use of insulin and the 'cardiazol' method.

Insulin method.—Dr. Isabel G. H. Wilson (1936), Medical Commissioner to the Board of Control (England and Wales), who studied the 'hypoglycæmic shock-treatment' of schizophrenia, as introduced by Dr. Manfred Sakel in Vienna, has issued a lengthy report. She concludes that the method merits ample clinical trial, and that it is neither too dangerous nor too unpleasant to be used in a serious disorder.

The technique of Sakel consists in giving progressive doses of insulin, from 20 units upwards, until a state of insulin coma lasting, on the average, about one and a half hours is produced. Patients are brought round by the administration of cane sugar (7 oz. sugar in one pint of tea) by the nasal tube, or by glucose (20 to 40 c.cm. 20 per cent solution) intravenously if the coma becomes too deep. Coma is produced thrice weekly for about five or six weeks. The patient is said to become more accessible, and psychotherapy is used in helping the patient to re-adjust.

Cardiazol method.—When Sakel in Vienna was investigating the hypoglycæmic method of shock therapy, Dr. Ladislaus von Meduna was experimenting with animals in the laboratory of the Royal State Mental Hospitals in Budapest. From clinical records and observations, von Meduna came to the belief that in the development of schizophrenia and epilepsy there exists a fundamental biological antagonism which can, by artificial means, be made to serve therapeutic ends. After much research he selected cardiazol as being the ideal drug to use for the production of the epileptic state. The drug is soluble in water, and can be used intravenously, intramuscularly, and subcutaneously. When used in the right quantity, and with sufficient rapidity a typical epileptic convulsion is produced in 10 to 90 seconds after the injection. In cases treated by the intramuscular route in this hospital the time varied from 5 to 90 minutes after the injection before the convulsion occurred. Cardiazol is not cumulative in its action, and, it is claimed, has no disadvantageous effect on the normal heart. The treatment to the onlooker may appear somewhat cruel and 'cold-blooded', but when the convulsion occurs the patient immediately becomes unconscious, and is later amnesic, just as if given a general anæsthetic for a surgical operation.

Schizophrenia is, moreover, an illness from which few patients, if any, recover spontaneously, and any treatment which holds promise

of a cure, or even a remission, has ample justification. The treatment of many cases throws a very great strain on the medical and nursing staff of an institution, but nevertheless, if the claims of success are substantiated in such a hopeless illness as schizophrenia, the trouble and risk are worth while.

The nature of the treatment and the risks attached are fully explained to the relatives of patients, and before shock therapy is undertaken in this hospital the written consent of the relatives must be lodged with the medical superintendent. During the past six months the treatment has been offered to all early and a number of long-standing cases, and the consent of the relatives has been withheld in one case only.

One patient suffering from schizophrenia (simple) was successfully treated in this hospital by the insulin method, but the technique is difficult, and it was realized that the strain of treating large numbers with insulin would be too great to be undertaken with a medical and nursing staff which barely meets the routine requirements of the hospital. The work of investigators using the insulin method in Europe and America is reviewed in the *Year Book of Neurology, Psychiatry and Endocrinology*, 1937.

It was found, however, that a combination of insulin and cardiazol gave good results when cardiazol alone failed to produce convulsions. The practice in this hospital is to administer 20 to 50 units of insulin subcutaneously two hours before the cardiazol injection. The technique generally employed in this hospital is that of von Meduna and it is well described in his book *Die Konvulsionstherapie der Schizophrenie* of which a translated abstract is obtainable from Messrs. Knoll A.-G., Chem. Fabriken, Ludwigshafen a Rh., Germany.

The following notes are extracted from the case records of 26 patients treated during the first six months of 1938 :—

Case 1.—E. G., male, European, *æ*t. 23, single, soldier. Admitted on 18th January, 1935. Certified. Talk irrelevant, delusions, auditory hallucinations, apathetic.

Diagnosis—schizophrenia—hebephrenic.

Treatment—period 1935–37 had three courses of pyrexial therapy—(1) sulfosin, (2) sulfosin with gold chloride, (3) pyrifur—resulting in institutional social adjustment.

Shock therapy (cardiazol) commenced on 1st February, 1938. Marked improvement after first injection. After fourth convulsion conduct and conversation normal. Had in all eleven induced convulsions. Treatment discontinued on 28th February. In view of the past history he was detained in hospital for a further three months.

Result—discharged recovered on 24th May.

Case 2.—N. I., female, Anglo-Indian, *æ*t. 31, married.

Admitted on 13th April, 1938. Certified. Displayed oddities, silliness, incongruity, mannerisms, impulsive outbursts, and attitudinizing. Conversation rambling—answered all questions in a very loud tone of voice. Persecutory ideas and ideas of reference.

Diagnosis—schizophrenia, simple.

Shock therapy (cardiazol) commenced on 22nd April. Very strong reactions. In all eight convulsions.

Result—discharged recovered on 24th May.

Case 3.—F. N., male, European, *æ*t. 26, single, teacher. Admitted on 27th December, 1937. Certified. Displayed confusion, incoherence, verbigeration, disgusting habits, destructiveness, mannerisms of speech and action—lack of emotional tone, hallucinations.

Diagnosis—schizophrenia—catatonic (with excitement).

Shock therapy (cardiazol) commenced on 14th February, 1938. No reaction after first injection 5 c.c.m. 10 per cent solution. Good reactions from second till ninth injections. No reaction after tenth injection 9 c.c.m. 10 per cent solution. From the eleventh injection till the completion of the course, 40 to 50 units insulin were administered subcutaneously two hours before the intravenous cardiazol injections. Strong convulsions resulted with combined cardiazol-insulin therapy. In all ten cardiazol injections, and ten cardiazol with insulin.

Result—discharged recovered on 24th May.

Case 4.—D. E., male, Anglo-Indian, *æ*t. 33, married, engine driver.

Admitted on 14th December, 1937. Certified. Looking ill. History of insomnia, loss of appetite, depression, lack of energy, ambition, and interest in his work. Delusions of persecution, personal unworthiness, hallucinations, indifferent and apathetic to his environment; gazes vacantly into space; answers irrelevant. In the words of his wife: 'he became a recluse, utterly indifferent to his family and his friends, expressed no desires, reacted to nothing, and even failed to take his food'.

Diagnosis—schizophrenia—catatonic (with depression).

Shock therapy (cardiazol) commenced on 2nd March, 1938. Showed early improvement. In all ten convulsions.

Result—discharged recovered on 24th May.

Case 5.—R. L., male, Anglo-Indian, *æ*t. 26, single, student.

Admitted on 21st October, 1937. Certified. Looking ill, history of gradual mental deterioration—apathy and emotional dullness—confused; mannerisms; no delusions or hallucinations elicited.

Diagnosis—schizophrenia, simple.

Was given a course of pyrexial therapy but showed no improvement.

Shock therapy (insulin) commenced on 7th January, 1938. 1st dose 25 units—gradually increased daily until 75 units were given. This appeared to be the requisite dose in this case to produce coma. This dose was given thrice weekly until 14th February. Developed a severe attack of facial herpes. The herpes cleared up under orthodox treatment. Mental conditions greatly improved.

On 9th March, it was decided to re-commence shock therapy but in view of the heavy strain thrown on the medical staff by the use of the insulin method the patient was treated with cardiazol. Had eight induced convulsions by cardiazol.

Result—discharged recovered on 24th May.

Case 6.—L. C., male, Anglo-Indian, *æ*t. 22, single, pointsman.

Admitted on 31st January, 1938. Certified. Boisterous, violent, verbigeration. To all questions replied 'exactly', destructive; delusions.

Diagnosis—schizophrenia—hebephrenic (with manic attacks).

The manic attacks were controlled by hydrotherapy. The relatives at first refused to permit shock therapy. Patient showed slight improvement after a course of pyrexial therapy (sulfosin). Later, the relatives consented to shock therapy. Cardiazol was commenced on 28th February. Reactions good. In all 15 convulsions. In the last six the cardiazol injections were preceded by insulin 50 units subcutaneously, the insulin being administered two hours before the cardiazol.

Result—discharged recovered on 21st April.

Case 7.—K. C., female, Anglo-Indian, *æ*t. 29, single, typist.

Admitted on 22nd May, 1937. Voluntary boarder, displayed antics, mannerisms, emotional deterioration, senseless laughter.

Diagnosis—schizophrenia—hebephrenic.

Improved under a course of sulfosin. Institutional adjustment. Commenced cardiazol therapy on 18th January, 1938. Reactions good—showed early improvement. In all eleven induced convulsions.

Result—discharged recovered on 8th April, 1938.

Case 8.—G. N., male, European, *æt.* 35, widower, mess steward.

Admitted on 14th February, 1938. Certified. Apathy without expression of delusions and hallucinations. Had many jobs, inability to adjust in any of them. Vague and indefinite paranoid ideas. Well oriented for time, place and person. No defects of memory for remote or recent events. Disliked occupational therapy.

Diagnosis—schizophrenia—hebephrenic. commenced on 11th March. Reactions good. In all four induced shocks.

Result—discharged recovered on 23rd March.

Case 9.—E. S., female, European, *æt.* 27, single. Admitted (transfer from Lahore) on 14th February, 1936. Certified. History admitted to Lahore Mental Hospital on 27th March, 1935.

Diagnosis—dementia præcox (simple).

Had several courses of pyrexial therapy (sulfosin) with no apparent improvement. Shock therapy (cardiazol) commenced on 2nd March, 1938. Had six intravenous injections ranging from 4 to 6 c.cm. 10 per cent solution cardiazol. Good reactions. Intravenous route difficult. Seventh and subsequent convulsions induced by intramuscular route (6 c.cm. of 30 per cent solution cardiazol). In all 14 induced convulsions. Greatly improved socially. Commenced to take interest in singing, dancing and painting but continued to have outbursts of senseless giggling.

Result—improved, socially better; institutional adjustment and now good and steady worker. Not fit for discharge.

Case 10.—C. R., female, Anglo-Indian, *æt.* 34, married. Admitted on 8th June, 1935. Certified. Grandiose delusions, visual and auditory hallucinations ++.

Diagnosis—schizophrenia—paranoid type.

Showed no improvement after several courses of pyrexial therapy (sulfosin and pyrifer).

Shock therapy (cardiazol) commenced on 21st February, 1938. In all fifteen induced convulsions. Delusions and hallucinations did not recede—treatment discontinued.

Remarks—improved socially, and took more interest in diversion therapy and adjusts better to institutional life. Not fit for discharge.

Case 11.—B. N., female, European, *æt.* 27, single, typist.

Admitted on 8th June, 1937. Certified. Apathetic, disinterested, conversation disjointed, mannerisms.

Diagnosis—schizophrenia—hebephrenic.

Showed no improvement after pyrexial therapy (sulfosin).

Shock therapy (cardiazol) commenced on 7th February, 1938. Had 12 induced convulsions. Only showed slight improvement. Treatment discontinued on 9th March, owing to anæmic condition.

Remarks—slight improvement. To be considered for further treatment when physical conditions improved.

Case 12.—H. T., male, European, *æt.* 37, married, missionary.

Admitted on 25th November, 1937. Certified. Noisy, excitable, mannerisms, purposeless actions, destructive, shameless masturbation—aggressive—delusions and hallucinations.

Diagnosis—schizophrenia—catatonic (with excitement). Manic condition controlled by hydrotherapy and sedation. Relatives at first refused to permit shock therapy. Improved slightly after a course of pyrexial therapy (sulfosin). Manic state disappeared and he became apathetic. Relatives consented to shock therapy. Cardiazol injections commenced on 23rd March, 1938. Had 16 typical convulsions. Treatment discontinued on 16th May.

Remarks—slight improvement. To be considered for a second course after a period of rest.

Case 13.—A. D., male, Indian, *æt.* 24, single, student.

Admitted on 4th March, 1936. Certified. Mute and timid, sat crouched up in the corner of his ward. Refusing food, furtively watching all that went on around him. Physical health poor. Weight 99 lb. Showed slight improvement after a course of pyrexial therapy. Made a determined suicidal attempt on 7th September. Course of photodyne given in 1937 with no apparent improvement. Condition on 8th March, 1938, mute, apathetic and under constant supervision.

Diagnosis—schizophrenia—catatonic (with depression).

Shock therapy commenced on 8th March. Had 20 induced convulsions. Treatment discontinued on 12th May.

Remarks—patient showed much improvement, commenced talking, painting and sketching. Can do fairly difficult arithmetic sums correctly. Still apathetic and asocial. Attends physical culture and takes only walking exercise—working well—making a rug of intricate pattern.

To be considered for a second course after a period of rest.

Case 14.—G. G., male, Anglo-Indian, *æt.* 27, single, no occupation.

Admitted on 3rd July, 1936. Certified. Dull, mute, lethargic, will remain standing in one place for long periods, no co-operation. Gestures, grimacing, and grinning.

Diagnosis—schizophrenia—catatonic (with depression).

Two courses of pyrexial therapy (sulfosin). No appreciable improvement.

Shock therapy (cardiazol) commenced on 14th March, 1938. Discontinued on 23rd April. In all 16 convulsions.

Remarks—no improvement mentally, although patient has been working steadily in the carpentry section since.

Case 15.—N. N., female, Jewess, single, housewife.

Admitted on 2nd August, 1937. Certified. Impulsive—overactive—aggressive and makes sudden attacks on inoffensive bystanders. Delusions, auditory and visual hallucinations.

Diagnosis—schizophrenia—catatonic (with excitement). Slight improvement after hydrotherapy and pyrexial course (sulfosin).

Shock therapy (cardiazol) commenced on 16th February, 1938. Had two typical reactions. Patient became very excitable and troublesome, and refused to complete the treatment.

Remarks—the delusions and hallucinations are still very prominent, but her behaviour has greatly improved. She was formerly a most troublesome patient but now quiet and a good and steady worker (machinist).

Case 16.—N. D. R., female, Anglo-Indian, *æt.* 23, single.

Admitted on 20th July, 1936. Voluntary boarder. Father, a medical man, stated: 'patient had been suffering from dementia præcox for a few years'. Answers simple questions and giggles to herself for no apparent reason. Dirty and perverse habits—passes urine and faeces in bed.

Diagnosis—schizophrenia—hebephrenic.

Showed no improvement after sulfosin, photodyne and insulin treatment. Deteriorating rapidly.

Shock therapy commenced on 21st February, 1938. In all 20 convulsions.

Remarks—no improvement. Became extremely violent and destructive. Still deteriorating.

Case 17.—P. N., female, Anglo-Indian, *æt.* 24, single.

Admitted on 22nd June, 1936. Certified. Pregnant six months. Aggressive, abusive, negativism and automatism prominent features with outbursts of senseless laughter.

Diagnosis—schizophrenia—catatonic (with excitement).

Excitement controlled by hydrotherapy—gave birth to a healthy male child on 29th March, 1936. Antagonistic towards infant. Continued to have frequent outbursts of excitement, language obscene, senseless laughter,

troublesome, aggressive and irresponsible. Somatic delusions +.

Shock therapy (cardiazol) commenced on 28th February, 1938. Good reactions. Results dramatic. Improved greatly after first convulsion. Had six convulsions.

Remarks—discharged recovered 22nd March.

Case 18.—V. T., female, American, *æ*t. 34, married, missionary.

Admitted on 12th November, 1937. Certified. Early diagnosis of manic, depressive psychosis. Noisy, aggressive, obscene, erotic flight of ideas. No improvement after hydrotherapy, sedation, and prolonged narcosis. Later schizophrenic background suspected. Mannerisms, verbigeration, senseless laughter.

Diagnosis—schizophrenia—catatonic (with excitement).

Shock therapy (cardiazol) commenced on 18th March, 1938. Showed marked and early improvement. Treatment discontinued after eighth convulsion on account of fever and tachycardia. Relapsed mentally with extreme catatonic excitement (following visit from husband). Hydrotherapy required to control excitement. The patient is improving mentally and physically.

Remarks—to be given another course of cardiazol therapy as soon as physical condition warrants it. Prognosis good. On 5th May recommenced cardiazol therapy. Had three convulsions.

Result—discharged recovered on 28th June.

Case 19.—M. N., female, Anglo-Indian, *æ*t. 30, single. Admitted on 24th May, 1927. Certified. Long-standing case of schizophrenia exhibiting frequent outbursts of catatonic excitement (sister of case 17).

Shock therapy (cardiazol) commenced on 2nd May, 1938, at request of her sister (case 17). Had five strong convulsions. Showed slight improvement but treatment was discontinued owing to violent antagonism of patient.

Remarks—no permanent improvement. Has recently had frequent outbursts of catatonic excitement.

Case 20.—R. I., female, Anglo-Indian, *æ*t. 33, married. Admitted on 5th July, 1937. Certified. Long-standing case of schizophrenia with mental deficiency (first admission on 11th October, 1930). Frequent outbursts of catatonic excitement. Delusions and auditory hallucinations + +.

Shock therapy (cardiazol) commenced on 2nd May, 1938. Three convulsions appeared to accentuate the delusions, hallucinations, and excitement.

Remarks—in view of the superadded mental deficiency and the patient's marked objection to the treatment the course was discontinued. No improvement.

Case 21.—D. H., female, Anglo-Indian, *æ*t. 33, married. Admitted on 16th February, 1933. Certified. Destructive, dirty in habits, delusions and auditory hallucinations.

Diagnosis—schizophrenia—catatonic (with excitement). No improvement with pyrexial therapy.

Shock therapy (cardiazol) commenced on 31st March, 1938. Twenty convulsions.

Remarks—social improvement, but delusions and hallucinations still prominent. Conduct greatly improved, and taking an interest in diversion therapy.

Case 22.—F. C., male, Anglo-Indian, *æ*t. 37, married, clerk.

Admitted on 17th March, 1935. Certified. Impulsive, destructive, refusing food, mute, disorientated, says his age is 75.

Auditory hallucinations + +.

Diagnosis—schizophrenia—catatonic (with excitement).

Improved after hydrotherapy and pyrexial therapy—became a good worker (carpentry) but remained apathetic and exhibited no interest in his wife and child. Frequent outbursts of senseless giggling.

Shock therapy (cardiazol) commenced on 14th March, 1938. Appeared to improve, conversed rationally. Discussed his discharge from hospital and future plans—said he would return to his father, but not to his wife and child.

Remarks—had 16 induced convulsions. Appeared to be terrified of them, so they were discontinued.

Returned to carpentry where he was working well. On 2nd May had a sudden and acute relapse—condition similar to that on admission. Excitement controlled by hydrotherapy. Returned to work ten days later. Reports good—but still apathetic and disinterested.

Case 23.—E. P. I., male, Anglo-Indian, *æ*t. 21, single, telegraphist.

Admitted on 7th June, 1934. Emotional, responses shallow and inadequate, apathetic, delusions, and auditory hallucinations. Impulsive, aggressive.

Diagnosis—schizophrenia—hebephrenic type. Several courses of pyrexial therapy (sulfosin, solganol, sodium nucleinate, pyrifur). No improvement.

Shock therapy (cardiazol) commenced on 18th March, 1938. In all 18 convulsions.

Remarks—showed marked improvement. Conversation brighter, and more sociable with staff and patients. Working well in cane section. To be allowed out on parole when his relatives find it convenient to take him.

Case 24.—H. C., male, Anglo-Indian, *æ*t. 35, single, preventive officer.

Admitted on 2nd April, 1931. Certified. Mute, resistive, catatonic depression, unsociable and seclusive (brother of case 7).

Diagnosis—schizophrenia—catatonic (with depression). Had several courses of pyrexial therapy with no effect.

Shock therapy (cardiazol) commenced on 2nd May, 1938. In all 13 convulsions.

Remarks—no improvement. Treatment discontinued.

Case 25.—A. C., male, Indian, *æ*t. 19, single, student.

Admitted E. M. H. on 14th August, 1936. Discharged improved on 14th October, 1936. Next seen on 4th January, 1938. A quiet boy who never entered into rough games. Excellent school record, always stood high in his class until illness in 1934 (? meningitis). Asthenic physique, apathy, preoccupation and inactivity. Never expressed any delusions and denied hallucinations. Given a course of pyrexial therapy (sulfosin) with some improvement, but still deficient in attention and concentration.

Diagnosis—schizophrenia, simple.

Shock therapy (cardiazol) commenced on 5th April, 1938. Showed early and marked improvement. Commenced to write long and sensible letters to his relatives—rang them up on the phone frequently. Commenced to take an interest in himself and surroundings—look up tennis, boxing, and physical culture. Co-operated well. Begged that the cardiazol be discontinued after the ninth injection as he was 'perfectly cured'. Had a course of psycho-therapeutic sessions for one month after the shock therapy.

Remarks—recovered—now studying shorthand and typewriting.

Case 26.—P. L., male, Indian, *æ*t. 27, clerk, married.

First seen on 23rd March, 1938. History—brilliant school and college career. Appeared for I.C.S. examination in U. K. This was followed by 'serious type of nervous breakdown'. Returned to India. From 1922 to 1938 history of three attacks. Given several courses of Roy's pills and many other medicines, but condition 'got from bad to worse'. Refusing food, suspects poison in almost everything. Sometimes laughs and sometimes weeps—seclusive.

Seen first on 23rd March. Negativistic, resistive, violent delusions, auditory and visual hallucinations.

Diagnosis—schizophrenia—catatonic (with excitement).

Cardiazol therapy commenced on 24th March, 1938. First eight injections by intravenous route, 5 c.cm., 5 c.cm., 5 c.cm., 6 c.cm., 7 c.cm., 7 c.cm., 8.5 c.cm. of 10 per cent solution. Difficult veins and patient aggressive—subsequent administration intramuscularly (30 per cent solution of cardiazol), 9 c.cm., 9 c.cm., 10 c.cm., 10 c.cm., 10 c.cm. No apparent improvement. On 2nd May, 1938, commenced a course of pyrexial therapy (sulfosin). Had 10 injections—some improvement. On 10th June commenced cardiazol injections again by the intravenous route. Had five major convulsions up to 23rd June. Marked improvement.

Remarks—prognosis good.

Before the treatment is commenced a thorough physical examination is necessary. The following are definitely contra-indications :—

- (1) Evidence of cardiovascular disease,
- (2) abnormalities in laboratory findings,
- (3) acute febrile infections, (4) history of head trauma with subsequent unconsciousness,
- (5) tuberculosis, and (6) menstruation.

Summary.—Of the 26 cases treated 11 made complete recovery and on discharge by the committee of visitors showed no evidence of psychosis. Ten showed improvement and five showed no improvement. In at least two of the 10 cases which showed improvement the prognosis is good, and a second course of treatment has been commenced.

Of the 11 cases which recovered, three were less than three months under treatment in hospital, three less than six months, three less than 12 months. One patient was in hospital for one year and nine months and another three years and four months. Every case treated with less than six months' history recovered. All cases with less than 12 months' history improved, and 50 per cent recovered. These figures indicate the importance of early diagnosis and early treatment.

I am of the opinion that the treatment of schizophrenia by shock therapy alone cannot be successful. The psychiatric treatment is very important. In this hospital the patient is given a psychotherapeutic session the day after every convulsion—the mental sensations and any changes in the mental condition are fully discussed. In addition the resources of the hospital for occupational diversion, physical culture and recreation are freely utilized for the benefit of the patient.

In none of the above series of cases was the treatment followed by any alarming physiological results.

Many ramifications of the theory in the treatment of schizophrenia by shock therapy are possible, but it is not the intention to discuss them here. 'The most important factor in medicine is therapeutic success. It is of greater moment than all special investigations, be they ever so exact, than all ingenious theories'.

SUSPECTED BOTULISM: A REPORT ON TWO CASES

By COLIN D. TORPY, M.M.F. (B.), I.M.D.

House Surgeon, Presidency General Hospital, Calcutta

BOTULISM (from the Latin *botulus*, a sausage), or ichthyosismus, as it is otherwise described, is a disease produced by the ingestion of the toxin elaborated by the growth in food products of *Clostridium botulinum*, an anaerobic spore-bearing bacillus having as its natural habitat the soil.

Botulism is by no means a common disease. In the U.S.A. and Canada 146 outbreaks have been reported affecting 504 persons of whom 337 died, a case mortality of 67 per cent. These outbreaks were spread over a period from 1899 to 1925. In Germany 24 outbreaks of suspected botulism have been reported from 1907 to 1923. In the British Isles, only three outbreaks are on record, the largest of which occurred at Loch Maree in Scotland, where 8 persons were affected from eating potted duck paste and all died within a week, *Cl. botulinum*, type 'A', being isolated from the remnant of the paste. More recently 'vegetable brawn' was responsible for the London outbreak of 1935.

The type of food most likely to cause the disease is smoked, pickled or canned food that has been allowed to stand for some time before cooking, or probably after inadequate cooking. Vegetables such as beans and peas, fruit such as olives, and meat such as sausages, ham or potted goose or duck, are the foods mainly responsible. In several cases those who have consumed the affected food after cooking have escaped the infection, whereas those who consumed it prior to cooking have generally been affected.

It has been definitely established that botulism is an intoxication and not an infection. The causative organism, *Cl. botulinum*, multiplies in the food before it is consumed, and produces a powerful soluble toxin, which on ingestion is absorbed by the mucosa of the stomach and upper part of the intestine (its ability to pass through the mucosa unchanged differentiates it from tetanus or diphtheria toxin) giving rise to the characteristic disease. Edmunds who has done a great deal of work on its toxicology

suggests that the action of the toxin is not, like that of tetanus, directly on the neurons, but on the motor-nerve endings of voluntary muscle, i.e., it resembles that of curare with, in addition, a milder effect on the para-sympathetic system.

The incubation period is stated to be generally under 24 hours after the consumption of the affected food, but this period may quite easily be prolonged from 72 to 96 hours.

Prominent among the symptoms are blurring of vision and dizziness; nausea, vomiting, and obstinate constipation; inability to swallow, with a sense of constriction and dryness in the throat; abdominal cramps and pains; diplopia, photophobia, and lachrymation follow rapidly while a feeling of extreme muscular weakness may appear very early. The general consciousness and sensibility remain intact till the end, sometimes preceded by coma and delirium. The temperature and pulse rate usually remain normal unless complications set in. Death may take place within 24 hours of the onset of the disease and usually not longer than a week. In the very severe cases that survive, complete recovery, particularly in the ocular movements and the paralysis of the muscles of the lower extremities, may not take place for six or eight months.

As far as I am aware no cases of botulism or suspected botulism have so far been recorded from India. This, however, is not the only reason why I am taking the opportunity of recording these two cases that have come under my notice, but because they present many features of interest, some of which do not appear to have been met with or described in previous recordings.

Before the 12th May, 1937, Misses 'A' and 'B', aged 21 and 20, sisters, were in the best of health. On that day, they both attended with many others a cold supper and dance held in honour of His Majesty's Coronation. Both girls stated that shortly after they had started dancing (which was about an hour after the supper) they felt unusually tired, and complained of vague aching pains in the head and the limbs. The next morning 'A' complained of pains in the chest, arms, and lower limbs, while 'B' complained of pains in the lower limbs only.

On the following day, a doctor was called in and they were treated as suffering from 'influenza', the pains being acute on this day, and the disease prevalent at the time, but there does not appear to have been any fever, nor was their condition such as to excite any apprehension whatever. On Saturday (15th May) both girls felt much better except for slight pains in the head with slight blurring of vision. On Sunday, they had recovered sufficiently to get up and go about their ordinary occupations. On Monday morning there was apparently no trace of discomfort but it is noteworthy that both girls, who previously had never any trouble with their bowels, were now and had been obstinately constipated since the 12th May. On Monday night they attended a cinema and both complained when they had returned home of aching pains in the limbs that prevented them from falling off to sleep. In the morning they both felt quite ill, and 'B' was unable to get out of bed, while 'A' was just able to do so, and a slight drag of her right leg was noticed as she walked about. 'B' complained of a severe, sharp, lancinating pain which she appeared to localize from

the vagina upwards. A medical man was summoned: 'B' was found to be paralysed from the waist downwards, while 'A' was found to be paralysed only in certain groups of muscles of the right leg and thigh. There was a mild degree of pyrexia and nothing else of note. They were both removed to the local hospital, and on Wednesday their condition appeared to be unaltered. On Thursday, as the paralysis could not be satisfactorily accounted for, a second medical opinion was obtained.

It is a point of great interest that four or five of the other members at the same supper party from the same table complained of pains in the limbs, and general malaise the next day, and it is also worthy of note that 'A' and 'B' being strict teetotallers did not partake of any alcohol, whereas the rest of the party had consumed alcohol. The supper consisted of cold meat with salad in which a tin of peas had been incorporated. The tin of peas had not been heated prior to consumption.

On Friday, 21st May, 'A' became very ill. There was great difficulty in swallowing; air-hunger was present; pulse quick, feeble, and thready; abdomen acutely distended; bowels inactive; face, mask-like, pale with drooping eyelids; inability to see anything properly; diplopia present; only black shadows seen in room; consciousness intact and maintained. The rapidity in the breathing continued, and the diaphragm was seen to fail, and respiratory embarrassment became very severe, and, in spite of all treatment, 'A' died of respiratory failure, fully conscious to the end.

'B' was brought to Calcutta and admitted to the Presidency General Hospital on 22nd May.

On examination, patient of good physique, looks healthy. Oral hygiene, excellent; tongue, clean and moist. Chest, clear; heart sounds normal. Abdomen held rigid and difficult to palpate; bladder; distended and requires frequent catheterization; bowels, constipated, and open only with purgation.

Pupils equal, reacting to light and accommodation. No nystagmus, but diplopia present with haziness of vision.

Superficial abdominal reflexes, brisk, while the knee and ankle jerks are sluggish; sensory system, unaffected; abdominal muscles act normally; psoas and lumbar muscles unaffected; gluteus medii on both sides function feebly.

Paralysis of muscles of both extremities present with the exception of the flexor muscles of metatarsals of both feet.

Lumbar puncture carried out; cerebro-spinal fluid, clear and not under increased pressure. Globulin +; polymorphonuclear leucocytes 30 per cent; culture, normal.

Ophthalmoscopy—Fundi, normal.

A provisional diagnosis of 'botulism' was made and patient treated accordingly.

The chronic constipation continued for about two weeks after admission to hospital, and gradually cleared up with laxatives. The patient was practically afebrile throughout her stay in hospital, and even after three months since the onset of disease the paralysis has not cleared up, though the muscles are responding to massage, galvanism, and faradism.

Discussion

W. M. Scott, Medical Officer of the Ministry of Health, writing on botulism in the *British Encyclopædia of Medical Practice*, volume II, says 'Proof of botulism in an individual patient or in an outbreak depends on the demonstration either of the bacillus itself, or of its specific toxin in the suspected food material. In the absence of such demonstration the detection of the bacillus in the excreta of the patient or in his body; *post mortem*, would constitute strong corroborative evidence of clinical suspicion'.

Unfortunately in both these cases such proof is not available as both of them presented at the beginning of the disease such atypical features that a diagnosis of botulism did not seem likely, and, thus, much valuable material for the laboratory which 'is the final court of appeal in suspected botulism' was lost or not taken advantage of. Clinical diagnosis has had therefore to be relied upon in these two suspected cases, and there are many factors which point to such a finding being the correct one.

Both affected persons were attacked simultaneously, and were in the same group of people who shared the same food. Other members of the party were also obviously attacked, though admittedly to a much milder degree. Those who were so mildly affected happened to be people who consumed alcohol at the supper party, whereas the two who were severely affected were teetotallers. This is important and interesting as alcohol, it has been established, denatures the botulinum toxin, and prevents intoxication taking place.

A tin of peas, which was not heated prior to consumption, it is known, was used and had been incorporated in the cold salad eaten by all the members of the party, and there is strong presumptive evidence of it being the vehicle which carried the toxin.

The obstinate constipation, a characteristic feature observed in all cases of botulism, was present in both these cases, and was a marked feature of their disease.

The early symptoms, dimness of vision, diplopia, ptosis, photophobia, and lachrymation followed later by dysphagia, abdominal cramps, and still later by marked dyspnoea, and then, finally, with possession of all the mental faculties unimpaired, by death in the case of 'A', constitute a typical clinical picture of botulism.

'B', a less severe case, presents a much more modified and atypical clinical picture, and in her case, the paralysis of the muscles of the lower extremities is a most unusual feature of botulism, and if taken alone would lead one to make a diagnosis of poliomyelitis, except for the fact that the characteristic tenderness and stiffness of the neck seen so persistently in that disease was conspicuous by its absence in this case. In addition, it is not common to get two cases simultaneously infected with poliomyelitis in the same family, though in case 'B' it must be admitted that the fact of some permanent paralysis remaining on recovery, points to an acute poliomyelitis but this again is rendered the unlikely cause as there was even in case 'B' early involvement of the muscles supplied by the cranial nerves, which are seldom or never involved in poliomyelitis.

In concluding, I take this opportunity of thanking Major J. C. Drummond, I.M.S., the then Officiating Surgeon Superintendent, Presidency General Hospital, Calcutta, for his permission to publish these notes, and to Dr. F. E.

A CHOLERA EPIDEMIC IN SWAT STATE, N. W. F., 1937

By C. J. HASSETT

CAPTAIN, I.M.S.

Malakand

IN August this year an epidemic of cholera occurred in Swat State, Malakand Agency. This account may be of interest as cholera is not endemic in this province and no permanent foci of the disease are known to exist.

It is always imported from outside, generally by *Powindah* families when they are returning to Afghanistan through the province from India proper. Generally, these families are the first to suffer but in this instance the disease was solely confined to the population of Swat State. No cases occurred in the migratory population. At the same time cholera was not prevalent in the Punjab; only a few cases had occurred which were obviously importations from outside that province.

Epidemiology of the epidemic

The N. W. F. Province remained free from cholera until 6th August this year when the present epidemic began with explosive suddenness. The outbreak was first reported from Mingora town which is the principal trading centre in Swat State. On 6th August four cases occurred in one family in this town, all of which died. Next day it was reported that 25 more cases had occurred with 15 deaths.

The affected area was visited and the family in which the first cases occurred was interviewed. The sudden manner of the outbreak pointed to its being water-borne. The father of the family stated that he was obtaining his water from a *nullah* running north-west of the town, which takes off from the Swat river about one and a half miles away. Subsequently 20 more cases were seen and all reported that their water had been taken from this *nullah*. Secondly, all the cases seen were to the north-west and east of the town and were scattered about in various places in this area. Most of the families attacked had no contact with each other, thus eliminating house-to-house infection. Thirdly, there were no cases then or on the following three days in the south or south-west of the town. Most of the population in this area obtained their water from a large spring which was due

(Continued from previous column)

Laborda, Chief Medical Officer, the East Indian Railway, Calcutta, for supplying me with the detailed information regarding the history of case 'A' without which a diagnosis of botulism in case 'B' would have been extremely difficult, if not impossible.

MAP

south of the affected area. All evidence pointed to the above-mentioned *nullah* as being the source of infection. Later, a greater concentration of attacks subsequently occurred the nearer one got to this stream. The reason given for using the *nullah* water was that it was cold, as snow water is coming down from Swat Kohistan at this time of the year, and, secondly, the household wells had become brackish at the onset of the hot weather. The problem then was how had the stream become infected, as cholera is not endemic in this province? It is generally imported from outside, namely, the Punjab and the United Provinces. We then endeavoured to find out if any other cases had occurred in villages above this stream. There was only one village, Nawe Kalai, on the stream. It may be seen in the sketch map appended. In this village there were no cases of cholera although when visited several 'cholera' cases were shown which were mostly malignant malaria and dysentery. During the whole of the epidemic no cases occurred there.

It then transpired during the course of a conversation with a local *tehsildar* that a large number of Hindu *sadhus* had been visiting Swat State from the end of May onwards. They had come from down country. Their objective was Ilm, a mountain 9,000 feet high near Mingora town. A number of them had stayed in June and July in Mingora *dharamsala* and with the only three or four Hindu families in the place. This *dharamsala* was visited and the people there questioned as to whether there was any illness among them. We were informed that there was none. Then we endeavoured to find where these *sadhus* took their baths, and the keeper of the *dharamsala* accompanied us to the stream first suspected. It was above Mingora town and below Nawe Kalai village where up to now no cases had occurred. The site on the stream was opposite a divarication which led to the rice-fields. Here the *sadhus* took their baths. The question may be asked how did cholera only occur in Swat if it was brought up from the Punjab or the United Provinces, and no cases occurred in the Peshawar valley on the way up? Evidently a carrier or carriers were the cause of this outbreak and the *sadhus* were the innocent cause, as cholera seldom starts in the Mussulman population at the outset of an epidemic. Tomb and Maitra (1927) after researches in the Asansol mining settlement in Bengal state that the endemicity of cholera in any locality depends primarily upon the existence in the community of numbers of healthy carriers of non-agglutinating vibrios and upon the contamination of drinking-water supplies in a widespread and continuous manner with these non-agglutinating vibrios, which become in time converted into the agglutinating form owing to climatic conditions. No permanent carrier of agglutinating vibrios was ever found but 80 per cent of cholera convalescents were found to be carriers of the non-agglutinating form. They

concluded that non-agglutinating vibrios are the reservoir of cholera, both epidemic and endemic, and that mutation of these occur under certain bio-chemico-physical conditions in the human intestine. Thus these non-agglutinating vibrios seem to have been introduced into the drinking-water supplies of the people of Mingora by the pilgrims from the South bathing in these water-supplies some time previous to the outbreak of the epidemic. All evidence adduced seems to show this surmise to have been the correct one. No bacteriological examinations of the water could be carried out for the presence of these vibrios as we were more concerned with preventive measures to control the epidemic, and laboratory facilities were not available. After the epidemic had subsided some of these *sadhus* were questioned as to where they came from. The replies received were of interest. Some came from the Punjab and the United Provinces and some from Sind.

Every year there is a festival held in Ajudiya near Agra in the United Provinces to celebrate the birth of Ram Chandra Ji. This year the festival was held on the 19th of April. Afterwards pilgrims scatter and visit the various places Ram Chandra Ji is supposed to have visited during his exile. Ilm in Swat is one of these places. On this account it is a place of pilgrimage for these Hindu *sadhus*. This year pilgrims came from the United Provinces and even from as far away as Calcutta. On looking through the reports of the Public Health Commissioner with the Government of India (Russell, 1937) it was found that no epidemic of cholera had occurred in the Punjab, except for a few isolated cases which must be obviously importations from other provinces where cholera is endemic. The United Provinces are shown to have had cholera continuously from April onward. Therefore the disease must have been an importation by a chronic carrier or carriers of non-agglutinating vibrios, perhaps from the United Provinces. The pilgrims stayed sufficiently long for the water-supply to have been widely contaminated. No outbreaks seem to have occurred anywhere else on the way up as perhaps their stay was not sufficiently long for wholesale pollution to have occurred and also because conditions were perhaps unfavourable to the persistence or multiplication of vibrios in the Punjab and Frontier provinces. In the Malakand Agency and in Swat thunder showers are common in the hot weather and this increases the percentage of salts and organic matter in the surface water, making it a favourable medium for the rapid multiplication of vibrios in an infected water. Such conditions occur in Bengal, where it is noticed that existing cholera epidemics are increased. Tomb similarly found this to occur in the Asansol mining area when bacteriological examination of surface waters was carried out. The epidemiology of the present epidemic seems to have depended upon the above facts.

Preventive measures

The measures taken to combat the epidemic were as follows :—

1. The disinfection of the water-supplies. This at first proved difficult. The affected *nullah* to the north of the town was obviously the first line of attack. The Ruler was asked to close its entrance from the Swat river by means of a *bund* for ten days. But he refused to agree as the people of the town were dependent on it for the working of their grain mills and this would lead to a food shortage. Ultimately a compromise was made when it was closed for 24 hours and the whole bed of the *nullah* was limed for three-quarters of a mile

Graph showing daily total attacks and deaths.

from the village Nawe Kalai, well above the bathing site, to Mingora. The *bund* was then removed and the whole *nullah* flushed down. The effect of this was at once apparent. There were no further cases of cholera in Mingora five days after this was done. It was a very important factor in the control of the epidemic, as preventive inoculation with cholera vaccine could not have had time to be completely effective.

All wells were sterilized with potassium permanganate or bleaching powder so that by the end of three days every source of water-supply was sterilized. The stream to the south of the town was also disinfected and the people encouraged to draw their water from this source. It had its origin in a spring. It alone was sufficient to supply the whole town with drinking water, but we were at times opposed by the Pathans who thought they should take water from where they liked. After the first three or four days, co-operation was easier to secure in

this matter as they had become frightened and were only too anxious to give every help.

2. The civil and military authorities in the Malakand Agency and in the Peshawar District were warned. Headmen, *tehsildars*, and the *jirgas* throughout the State and Agency were also warned as to what measures they were to adopt. In the State itself all villages contiguous to the affected area had written instructions issued in the vernacular, explaining the nature, mode of spread and control of the disease. These were read out to the people who were collected by beat of drum. Recruitment of coolies was stopped for work on the Malakand hydro-electric scheme and for road making in Waziristan while the epidemic was on.

3. Disinfection of houses and isolation of the affected area was carried out by making arrangements with the State authorities and the *tehsildar* of Mingora to have lime issued to the families in the affected houses. They were also instructed to burn all clothes and *charpoys* belonging to people who had died of the disease. This was in most cases done but it was difficult at times to ensure that the affected households would carry it out. Isolation of the houses and the affected area was carried out as follows :—

All houses where the disease had occurred were noted and the inhabitants of nearby houses warned that exchange of food or eating with families in the affected houses was dangerous. The isolation of the affected area was a difficult matter as it may be seen that the disease spread down the valley to other towns. Most of these cases were found to have been brought originally from Mingora and these small sporadic outbreaks did not show any evidence of it being water-borne. If it was one would have expected a more explosive outbreak in these latter places. The nearest it ever got to the Malakand Agency was a place called Abua, two miles from the State and Agency boundary. Here two cases occurred. These were definitely importations from Mingora as a woman had come from there to visit her sister in Abua and whilst there she developed and died of the disease. Subsequently the sister also developed the disease. There were no more cases after this. The people of this village were by then alive to the danger of house-to-house contact.

When the spread downward occurred anxiety was felt as to whether the Malakand Agency would be affected. A posse of Lavy Sepoys with a sub-assistant surgeon was then stationed at Landaki post, the boundary between Swat State and the Malakand Agency.

Here this sanitary cordon functioned throughout the epidemic and all motor traffic and travellers were stopped and examined. The lorry drivers gave good co-operation, reporting at once any cases of illness which had occurred on the downward journey. A dispensary nearby at Thana was cleared and opened to receive any suspicious cases. One or two people were detained with vomiting, diarrhoea, etc. They

were subsequently proved to be malaria and dysentery. All fruit and vegetables were also prevented from being brought into the Agency at this point. The position of this sanitary cordon was luckily at a good place. If the sketch map is consulted it may be seen that the river is on one side and a range of hills on the other. Thus it guarded the entrance to the Agency and the first big town in the Agency is Thana. Of course it was difficult to guard against a stray carrier who might have wandered across the hills to Thana, but this was thought to be unlikely as all traffic moves through the Landaki post, as the only direct road from Mingora through Swat State passes through here.

4. An inoculation centre and a cholera camp was opened in Mingora. In all 29,590 inoculations were performed throughout the epidemic. The demand for inoculation was surprising on the first day. The centre in Mingora was rushed by the population and the crowd had to be regulated by the State troops. The inoculations proceeded throughout the epidemic and it was subsequently also carried out in the other villages down the valley. A cholera camp, one part for females and the other for the reception of male cases, was opened. This was near the inoculation centre situated to the north of the town, where most of the cases were occurring. It was thought best to localize it here as it was the best situation and away from the south part of the town where the water-supply had been sterilized.

Essential oil mixture was distributed freely to early cases and to all contacts. Collapsed cases were removed to the cholera camp and there given Rogers' alkaline and hypertonic saline solution intravenously. Difficulty was experienced with females who were keeping purdah. They were collected into one large compound of an empty house and there received treatment and inoculation as required.

Final course of the epidemic

Later during the epidemic the disease spread down the valley, as mentioned before, principally to the Barikot *tehsil* half-way between Mingora and Thana. These cases were at once investigated and were proved to have been contact cases from Mingora. Every subsequent case was investigated at once all over the State, as by this time every disease was being called cholera by the frightened population. An assistant surgeon was deputed to this duty. The epidemic continued in a sporadic manner after the disease had ceased in Mingora and eventually it died out. Inoculations and preventive methods were here also carried out vigorously. As mentioned before, the furthest down the disease spread was to within two miles of the Agency boundary.

PRAWNS AS A POSSIBLE VECTOR OF *V. CHOLERÆ*

By K. P. KUNDU, M.B. (Cal.), D.Bact. (Lond.)
*Director, Harcourt Butler Institute of Public Health,
Rangoon*

and

U. PA HOW
Assistant Bacteriologist

In the year 1936, an experiment was carried out at the Harcourt Butler Institute of Public Health, Rangoon, in connection with the viability of *B. schafferi* in natural water collections (*vide* Annual Report of the Institute for the year 1936, pages 12 and 13). During the course of these experiments, a fresh-water prawn came under observation and a vibrio, which gave the

(Continued from previous column)

From the 26th August no further cases occurred and the area was declared free from cholera at midnight of 2nd September, 1937.

Summary and conclusions

This epidemic presents several interesting points in that this province was free from cholera this year until the present outbreak. The *sadhus* who made a pilgrimage to Swat State in June and July appear to have been responsible. The latter is a very important matter from the public health point of view, as under present-day conditions the disease can be disseminated rapidly in a widespread manner on account of the rapidity of road and rail transport. The people who go on pilgrimage generally visit towns and villages, where they are given food and shelter by their co-religionists, to their detriment as happened in this epidemic. In this province the *Powindah* families, who are nomadic, generally introduce the disease while they are on their way back to Afghanistan. On this occasion this was not so. That the vagrant pilgrim population who may visit this province are of considerable danger is shown and that their presence may make itself felt long after they have left is well exemplified in this epidemic. Finally, the disease appears to have been carried a long distance before it became apparent and culminated in an explosive outbreak.

In conclusion I should like to thank Lieut.-Colonel W. E. R. Dimond, I.M.S., Assistant Director of Health, N. W. F. P., for his help during the epidemic and to Colonel R. S. Townsend, M.C., I.M.S., Inspector-General, Civil Hospitals, N. W. F. P., for permission to publish this article.

following reactions, was isolated on 23rd May, 1936, from this prawn :—

Motility	Lactose	Glucose	Saccharose	Maltose	Mannite	Salicin	Dulcitol	Adonite	Cholera red	Indol	Citrate	V.P.	M.R.	Litmus milk
++	-	A	-	A	A	-	-	-	-	+	-	-	+	Acid

It was decided to start an investigation into the presence of vibrios in prawns, lobsters and shrimps; experiments were accordingly started in 1937 and are still being continued.

In the course of these experiments a large number of vibrios have been isolated, all of which except two have failed to agglutinate with high-titre anti-cholera serum. It is proposed to publish details concerning these in a subsequent paper. The present article is intended to draw attention to the fact that on two separate occasions, typical cholera vibrios were isolated from prawns. These prawns were taken from consignments that were brought from the Delta districts of Burma to Rangoon, for sale in the public market.

The prawns are caught in the various creeks that abound in the Delta, and are brought in baskets, in launches to Rangoon. They are acquired in this laboratory by sending an attendant to the wharf, where they are landed. The attendant, prior to purchase, ascertains from the vendors the particular district in the Delta from which the prawns come.

In this way, on 23rd February, 1938, a prawn (prawn 'A') caught near Bogale in Pyapon District was examined and a typical cholera vibrio of Heiberg's type II was isolated. This vibrio on isolation agglutinated with 'H' and 'O' and also Inaba 'O' sera. The agglutination was done both on slide and in rack.

On a second occasion on 29th March, 1938, investigation of prawns from the same district showed in one (prawn 'B') the presence of a vibrio which on isolation agglutinated rapidly (slide agglutination) with 'H' and 'O' sera. In this case 'O' agglutination, however, was not observed until five minutes after the slide was prepared. Rack agglutination with Inaba 'O' serum examined after 18 hours showed an agglutination in a dilution of 1 in 125.

The last reported case of cholera from Pyapon District was recorded on 29th May, 1937. The first case recorded this year was notified on the 27th February, 1938. The history being as follows :—

Patient came from Kyonta village (which is very close to Bogale) to Dedaye, on the 27th February, 1938, in the day-time. In the evening he took 'Gyinthok and Laphet' (pickled ginger and pickled tea). He began having loose motions about midnight and also vomited once. Suppression of urine and cramps in his calves. Rice water stool. He died in the hospital late at night on the 28th February, 1938.

ANTI-MOSQUITO MEASURES IN CANTONMENTS WITH SPECIAL REFERENCE TO 'DRY DAY' INSTITUTED IN 1927

By F. F. STROTHER-SMITH

COLONEL, I.M.S.

Offg. A. D. M. S., Rawalpindi District, Murree

THE term 'dry day' is a misnomer because it is only necessary that a period of three hours from 6 a.m. to 9 a.m. on one day a week should be dry. During this period of three hours all receptacles for water in cantonments must be

Summary

(1) Examination of prawns from the Delta districts on two occasions revealed the presence of typical cholera vibrios, the agglutination and cultural reactions of which would have led to the diagnosis of cholera had they been isolated from the excreta of a suspected case of cholera. The isolation of one of these vibrios occurred just before the report of a case of cholera in Pyapon District which had previously been free from cholera for nearly nine months.

(2) As prawns are a favourite article of diet in Burma, the above finding would appear to call for further extensive investigation.

(3) Investigations are also needed to see if typical cholera vibrios can be regularly found in prawns prior to the outbreaks of cholera which occurs annually in the Delta districts.

(4) A further communication will be submitted in connection with those vibrios which were isolated from prawns got from the Delta areas and were found to be non-agglutinating with high-titre anti-cholera serum.

empty. These include water troughs for animals, garden tanks and *nullahs* in gardens, all small pits and bullock runs from wells, etc. Fire buckets are allowed to be emptied and immediately refilled or if this is not possible, for example in grass farms, a small amount of cresol solution is added to each bucket to prevent breeding of mosquitoes. If all units and bungalow owners in cantonments co-operate and see that every possible breeding place in their unit lines or bungalows are 'dry' during this period, mosquitoes will be unable to mature. From the time the female mosquito lays her eggs in the water until the mature mosquito flies away is more than eight full days. This explains the object of the 'dry day' scheme.

In some cantonments there are large areas of water which cannot be emptied. It will generally be found that very little breeding takes place in these areas unless they are in the shade. The edges of these areas must be kept clean of grass and all forms of undergrowth. Hoof marks around the sides are carefully watched and sprayed with oil if necessary. In Meerut where we have a number of these large borrow-pits under the direct rays of the sun I have never been able to discover mosquito larvæ, except in hoof marks and in drains leading into the pit. These drains should be filled in. Areas where water has been noticed to lie during the monsoon should be marked with pegs and gradually filled up as soon as possible. A garrison engineer who is willing to be helpful can supply a lot of material from old buildings during demolition and the contractor will dump it in a place for the unit to spread.

The scheme is organized as follows :—

An anti-malarial medical officer is appointed in each cantonment to work under the orders of the senior medical officer. In large cantonments such as at Meerut, Rawalpindi, Lucknow, this should be a whole-time job from 1st February to 1st November.

On 1st February each year—that is in Northern India—each unit will appoint an officer as unit anti-malarial officer, and a squad of one N. C. O. and two to four men according to the size of the unit. All these officers and other ranks, whether British or Indian, will be given a course of lectures on the scheme and on anti-malarial work. They will be taken round their own lines by a medical officer and all danger areas shown to them and anti-malarial methods described in relation to their own lines. The first 'dry day' should be in the first week of February—this may appear a little early but I have found that it is necessary to have at least two 'dry days' before all units and bungalow owners get into the working of the scheme.

Outside unit areas

A squad of one British N. C. O. and from two to five other ranks, according to the size of station, is appointed at the same time as unit squads.

It is the duty of this squad to carry out anti-malarial work on the British troops' side of the station. A similar squad of Indians is appointed for the Indian troops' side of the station.

Taking Meerut as an example—we have one British N. C. O. and five other ranks for the British troops' side and the same number of Indians for the Indian troops' side. Taking the British side—the whole area outside unit lines is divided up into five parts and allotted to the five men. Each man's area is again subdivided into five areas—one area for each day of the week except Thursdays. Reports on these areas are taken daily at 10-30 a.m. by the anti-malarial officer and the cantonment map flagged to show breeding areas. On Thursdays—that is 'dry day'—each man inspects his whole area to see that 'dry day' is being observed, and in case of non-observance a report is furnished to the anti-malarial officer who prepares two lists of defaulters, one of military personnel for the Station Commander and one of private individuals, shop owners, etc., for the executive officer. In the case of the latter prosecutions are ordered after the third offence—they having previously been warned on each occasion.

Each member of this inspecting squad carries a book of duplicate cards and in case of non-observance he gives a card to the owner or a servant and shows him where the fault lies, i.e., a tank full of water or *ghurra* full of water and breeding mosquitoes. He obtains the signature of the owner or the servant on his duplicate card. This is important later, in case a prosecution is ordered. The same scheme applies to the Indian troops' side of the station.

It will be seen at once that the success of the scheme largely depends on the support given to the medical authorities by the Station Commander. Personally I have never had any difficulty in this respect.

A brigade or station order should be published in the beginning of February. The following is a copy of that published in Meerut :—

Anti-malarial measures, 1936

With effect from 13th February, 1936, anti-malarial inspection will take place every Thursday from 6 a.m. to 9 a.m.

2. Every Thursday, all water tanks, channels and every depression where water is lying will be cleaned out and left dry from 6 a.m. to 9 a.m. during which hours they will be inspected by anti-malarial squads. Any tanks, channels, etc., not required should be filled in with earth. This applies to officers' bungalows as well as unit lines.

3. Officers Commanding Units will make a thorough inspection of their barracks and lines, paying particular attention to places where detached men live and spend much of their time, e.g., married quarters, stores, etc., and to places such as horse jumps, obstacle courses, and field works, where water is likely to lie.

4. Bungalow residents should make a thorough inspection of their houses, outhouses, stables and compounds. They are requested to fit their wells early every morning to destroy mosquitoes and their larvæ. The cost of doing so is small.

The following is a copy of the circular letter sent to units in Meerut in 1934 and might serve a useful purpose if published in orders in every cantonment in India :—

Subject:—*Anti-malarial measures, 1934-35.*

The attention of all concerned is drawn to Brigade Order No. dated.

I am directed by the Brigade Commander to say that all cases of non-observance of 'dry day' reported by the S. M. O. to this Headquarters will be investigated by this office and that after the 10th March, 1934, all officers not observing 'dry day' will be seen by the Brigade Commander and required to explain personally the reasons why Brigade Orders have not been carried out.

In each cantonment the cantonment board usually gives a grant for anti-malarial work. I think a better plan is to ask for coolies—the number according to the size of the cantonment. In Meerut we have 10 to 12 men during the malarial season. This batch of coolies works under the orders of the anti-malarial officer and is available for work in both British and Indian areas. They fill in pits, carry the oil under the direction of the N. C. O., keep down overgrowth of weeds and grass and clean the edges of all large areas of water.

The use of oil for water lying in small isolated depressions in lines and riding schools is to be deprecated. These pits and depressions should be filled in by the unit concerned.

Besides the above scheme for prevention of breeding of mosquitoes, other means of preventing malaria are :—

(1) We have in each unit lines a child-welfare centre—in reality a dispensary for the families—with a nurse in charge. It is the duty of the nurse under the direction of the lady sub-assistant surgeon to examine all children for enlarged spleen at the beginning of each hot weather and a list of those discovered is kept in the centre. These children are given quinine and treated in the usual manner.

(2) Mosquito nets are used except in the very hot dry period from 15th May to 25th June roughly. During this period there are no mosquitoes and all troops are very grateful for this respite during the very hot period. In Meerut since 1932 this has been done with the exception of this year when the rains started at the end of May. No increase in the number of malaria cases can possibly result from this.

It may be mentioned here that the above scheme was so successful in Sialkot in 1927, 1928, 1929 and 1930, that nets were not necessary at any period throughout the year and the number of malaria cases fell from several hundreds to almost *nil*. This success was in a large measure due to the fact that we had a regiment of Sikh Pioneers under a commanding officer who was himself an anti-malarial expert. This regiment carried out most of the anti-malarial drainage, etc., in Sialkot.

The application of the above scheme will naturally be more difficult in cities and towns

CINCHONA FEBRIFUGE IN THE TREATMENT OF MALARIA

By RAMKRISHNA N. GORE, L.M. & S.

For twenty years (1905 to 1925) I used quinine for the treatment of malaria, either by mouth or hypodermically, in doses smaller than

(Continued from previous column)

outside cantonments. The collector and municipal and district boards have not got the same powers to see that these orders and recommendations are carried out, as the Station Commander has in cantonments.

Still if this scheme, in so far as it can be carried out in civil areas, is explained to the public by posters and leaflets in the language of the people and by a notice in the local cinema the day before the selected dry day, I feel that the attention of the people will be drawn to the value of the scheme.

The local health officer, with the assistance of a number of trained *jemadars*, should go round the cities and towns and advise the people, and on dry day make a thorough inspection of the areas allotted to them, and where necessary deal with breeding areas or empty troughs, *ghurras*, tins, etc., where mosquitoes are breeding. All private practitioners can help by giving their patients instructions about the scheme and telling them how it works, and very soon the simplicity and the value of the scheme will be instilled into the minds of the people.

I am at present carrying out tests in Rawalpindi with a new spraying machine for barracks and houses called the 'phantomyst'. The solution used in this machine—Lethane in 3 per cent solution in kerosene oil—is most effective against mosquitoes, flies, etc.

This machine produces a fine mist in the room and penetrates to all parts of the room. Other solutions such as 'pyefly' and pyrethrum can be used but I have found 'lethane' most lethal. This machine is most economical—a large model D.1 will only use one ounce in 5 minutes. If this is taken into consideration in comparison with the use of the usual hand and foot pumps—in both the latter the spray is in the form of droplets and large quantities are used—great economy will be effected.

In the malarial season cinema houses harbour large numbers of mosquitoes and spread malaria. A machine such as the above used for half an hour or less before the performance will kill off all mosquitoes and other insects and also purify the air.

This machine can be purchased in various sizes from Messrs. Andre (Components), Ltd., 38, Felsham Road, Putney, S.W.15, London, to whom I am indebted for the use of a D.1 'phantomyst' to test in Rawalpindi.

The 'lethane' can be obtained from Messrs. Charles Lennig & Co., Ltd., 177, West Street, Erith, Kent, England.

are ordinarily recommended. I found the treatment effective in relieving patients of fever, but not in preventing relapses or enlargement of the spleen. In respect of these two manifestations of malaria, I wished for a better drug, and the change from quinine to cinchona febrifuge I was led to adopt after reading the convincing contribution 'On a Standard Treatment for Malaria' by Acton and Knowles (1924). In spite of this article this treatment has enjoyed little popularity in this country. It is now being realized that quinine has not been able to fulfil the expectation of an ideal cure for malaria.

Believing that few patients would like the cinchona mixture, it occurred to me to try the febrifuge and test its efficacy in the form of tablets. The first case on which I tried the febrifuge was one of my servants who every year suffered from malarial fever with severe rigors and bilious vomiting. His spleen was enlarged and by 1925 it had reached the umbilicus. Until then he was being treated with quinine hypodermically. It used to relieve him of the fever but had no influence on his spleen.

After the last injection 4-grain tablets of cinchona febrifuge (Java) were given, three tablets a day, morning, noon and night, to be swallowed with water, for seven days, then twice a day for a fortnight and once a day for a week more.

The servant himself having noticed a definite reduction in his spleen, asked me to confirm it. On examination I was greatly struck with the marked reduction in the size of his spleen. The response to cinchona was spectacular, the spleen was now less than half, there being improvement in his general health, and the pallor in his face was replaced by some redness.

This case so greatly impressed me that I commenced the use of cinchona febrifuge tablets in my practice in place of quinine, and I found it to be a success not only in ridding the patients of fever but in preventing relapses and definitely reducing enlarged spleens. One effect, which does not appear to have been alluded to in the literature, is the laxative effect of the febrifuge. In fact this effect was brought to my notice first by my servant and then by the patients, by their enquiring if I had added anything to the tablets to move the bowels.

Fever and hypertrophy of the spleen, the most prominent symptoms of malaria, develop with the disease and disappear as it is cured. The therapeutic value of cinchona febrifuge in malaria has long been accepted. From 1925 to 1932 when I had to retire from practice on account of ill health, I used cinchona febrifuge almost with uniform success for nearly seven years in place of quinine.

Among rural populations suffering from malaria, my experience suggests that cinchona febrifuge powder should be the drug of choice. Honey is a good vehicle for making pills or

(Continued at foot of next column)

PRELIMINARY REPORT ON AN EXPERIMENT IN COOLIE-LINE SANITATION

By K. P. HARE, M.B., B.S. (Lond.), L.M.S.S.A.
Medical Officer, Tingri Medical Association, Assam

The problem presented

FROM a public health point of view the three major scourges of the Assam Valley tea estates are malaria, dysentery and hookworm disease. The two latter are, essentially, diseases of faulty sanitation since, in both, infection is spread by badly disposed faeces. The management have done a great deal towards improvement of coolie-line sanitation by their enthusiastic adoption of the tube-well system of water supply which avoids the danger of contaminated surface water. This measure has, undoubtedly, reduced the incidence of dysentery and other bowel diseases but has, of course, had no effect on hookworm infection and has left untouched the problem of fly-spread of bowel infections. The coolies, at present, defæcate on the ground in any convenient situation round about their lines, very frequently among the tea bushes themselves. Conditions are, therefore, ideal for contamination of food by flies and for infection and re-infection by hookworm of the coolies working among the tea bushes. Moreover, the intolerable smell pervading certain areas can be easily imagined. The provision of some type of latrine is the only solution to the problem,

(Continued from previous column)

paste and since honey is available in villages, 4-grain pills can be made with it for adults, and for children a proportionate quantity can be made into a paste with honey. This method of administering cinchona febrifuge has been found very suitable.

As cinchona febrifuge is efficacious and cheap it will ensure the greatest benefit to the greatest number for the money available. According to Acton: 'A most important point in the treatment of malaria is that it shall be continuous'. It must also be realized that the method of administration and the doses which have varied within wide limits count in the successful treatment of the malaria sick.

Since 1916 I began giving as a routine a 3-grain dose of quinine hydrochloride just at the commencement of the rigor or of fever if without a rigor, with the idea that fresh parasites in the plasma before entering erythrocytes would be killed in greater numbers, as quinine is absorbed very rapidly and a small quantity of it is inimical to the freshly liberated parasites. This single preliminary additional dose of quinine gave better results than cinchona febrifuge without it.

REFERENCE

Acton, H. W., and Knowles, R. (1924). *Indian Med. Gaz.*, Vol. LIX, p. 177.

but many types have been installed in this district in the past and they have been universally unpopular with the coolies. They have been installed in the compounds of tea estate factories and hospitals and the coolies have objected to their communal aspect and refused to use them except under compulsion. The management have, therefore, not been encouraged to experiment with communal latrines in the lines. The question whether some form of latrine, which the coolies would be willing to use, could be provided at an economic cost was, therefore, taken up with the Superintendent of the Tingri Tea Co., Ltd. The Balimara line of Dirial Tea Estate was selected for the experiment, as it is a fairly isolated line of a reasonable size (the total population is 130 souls) and compactly planned. I was unfortunately prevented from making a stool survey of this line, before a mass treatment of oil of chenopodium (m. xxx) was given, by a tornado which swept the district and made heavy inroads on my time. The results of other surveys are given in tables I, II and III :—

TABLE I

Stool survey of a random sample of 255 coolies, resident in this district, of all ages and in good health

Infection		Number infected	Percentage incidence
All helminths	208	81.5
Hookworm	165	64.7
Ascaris	113	44.3

TABLE II

Stool survey of 112 persons, being the total population of an isolated line on another estate

Infection		Number infected	Percentage incidence
All helminths	103	91.9
Hookworm	97	86.6
Ascaris	54	48.2
Trichuris	61	54.4

TABLE III

Stool survey of 56 persons, being a random sample of coolies living on Dirial Tea Estate, excluding the Balimara line

Infection		Number infected	Percentage incidence
All helminths	49	87.5
Hookworm	40	71.4
Ascaris	33	58.9
Trichuris	29	51.8

In all these surveys a saline concentration method was used to eliminate errors in diagnosis as far as possible*.

The percentage incidence rates for dysentery in the Balimara line and in the other lines of Dirial Tea Estate are given in table IV :—

TABLE IV
Dysentery on Dirial Tea Estate

Line	Period of observation	Number of cases	Percentage incidence
Balimara	June 1936 to May 1937.	9	6.9
Other lines	Do.	38	3.7
Balimara	June 1937 to February 1938.	3	2.3
Other lines	Do.	27	2.6

Note.—Tube wells were sunk in 'other lines' in May 1936 but not in Balimara line until May 1937. The effect was to reduce the dysentery incidence of that line to that of the remainder of the estate. The latrine system was installed in Balimara line during February 1938.

Type of latrine provided

Enquiry among the coolies living in the Balimara line elicited the information that they would willingly use latrines if a separate one could be provided for each family and that, under such circumstances, they would themselves be responsible for the cleanliness of the latrines. Doubts as to smell and danger of contamination of the tube well were raised but were easily disposed of. The only type of latrine providing effective sanitation consistent with economy, considering the number needed, is the 'bored-hole'. The next problem was the design of a suitable housing which must be cheap, clean, easily erected and reasonably durable. Tales of difficulty regarding doors had also come to our ears. Sun-dried bricks, made on the estate with a Kapax machine, came to the rescue and made possible the design of a cheap and effective shelter. Doors were dispensed with and wing walls substituted and roofs were omitted for several reasons. Firstly, many coolies object to a roofed latrine on the grounds that 'it is wrong to defæcate in a house', secondly, the open construction allows of natural cleansing of the squatting plate by rain and, thirdly, cost was enormously reduced. The houses in this particular line are double, that is to say, each

* Approximately 0.5 c.cm. of stool was shaken up vigorously with 10 c.cm. of saturated common salt solution and the mixture transferred to a tube $\frac{5}{8}$ -inch in diameter holding 10 c.cm. A $\frac{3}{8}$ -inch cover slip was placed on the top, in contact with the upper surface of the mixture, and allowed to remain so for thirty minutes. It was then removed and examined under a $\frac{3}{8}$ -inch objective.

house has a central partition making it suitable for two families so that the latrines also were built in pairs. Scale drawings are appended (figures 1 and 2). A general plan of the lines is given in figure 3.

The general construction is as follows :—

The bored-holes are made in the usual way with a fourteen-inch augur and vary in depth from fourteen to twenty feet according to the

level of the water table. They are covered by the squatting plates (set on cement) around which the shelter is built. Low foundation walls, one foot high, and two corner pillars are

of pucca bricks. The main body of the walls is of Kapax bricks topped by two courses of pucca bricks to withstand direct heavy rain.

The full height of the walls from the ground is five feet six inches. The space between the squatting plate and the walls is filled in with concrete sloped up to the walls. The whole structure is made weather-proof by painting the Kapax bricks with two liberal coats of a mixture of tar and crude oil.

The estate manager has very kindly supplied me with the following specification and bill of costs for making one pair of latrines :—

Quantity	Material	Price		
		Rs.	As.	P.
200	.. Pucca bricks ..	5	0	0
500	.. Kapax ..	1	0	0
10 seers	.. Lime ..	0	4	0
2 bags	.. Sand ..	0	4	0
5 seers	.. Cement ..	0	7	0
15 "	.. Tar ..	3	12	0
2 gallons	.. Crude oil ..	0	11	0
2	Squatting plates	3	8	0
	Labour for boring	2	0	0
	" " building	7	0	0
	" " painting	0	4	0
TOTAL Rs. ..		24	2	0

He informs me that these costs are greater than they should be and that by employing labour directly instead of through a contractor they could be reduced by about Rs. 4, giving an all-in cost of about Rs. 10 per latrine (or family).

Practical experience.—From the very first these latrines have been completely popular. There has never been any hesitation on the part of any of the coolies in using them and they do, in fact, take a pride in keeping them clean. Within a very short time of their completion coolies from the other lines on the estate were asking to be similarly equipped. The management hope to equip one other line, at least, during the ensuing winter. The oil and tar coating appears to be effective in protecting the Kapax bricks from the effects of heavy rain and the bored-holes show no tendency so far to subside although no bamboo lining has been used. Aesthetically, there is some satisfaction in being able to walk anywhere round about this line without one's nostrils being assailed at every step. Regarding the effect on incidence of dysentery and hookworm infection, I hope to present a further communication at a later date.

Summary.—An account of the difficulties involved in securing adequate sanitation in Assam tea estates is given and a successful solution is described.

Acknowledgments.—My thanks are due to Mr. F. Woolley Smith, Superintendent, Tingri Tea Co., Ltd., for his permission to carry out this experiment, his interest in its progress and for permission to publish this account. I am also indebted to Mr. J. R. Morris, Manager, Dirial Tea Estate, for carrying the idea into effect, for his part in the design of the housings and for the specification accompanying this account.

AN APPARATUS FOR CONTINUOUS OILING OF STREAMS

By E. G. MICHELSON, M.B., Ch.B. (Aberdeen)
Kalighat, South Sylhet, Assam.

THE use of oil screens on small slow-running streams as a means of controlling mosquito breeding on tea estates is practically universal, and its advantages are well known. It has also certain disadvantages and defects, and it is to remedy these that the following modification is suggested.

The greatest enemy of the oil screen is the sudden storm which comes along and sweeps away all the oil leaving that stretch of stream full of the larvæ from the stretch further up, and unless immediate oiling is carried out a large number of these hatch out in a few days and up goes the malarial rate. To do away with this defect in some measure the little addition described here has been tried out and found to work well.

The materials required for each screen are simple—two tins and two pieces of wick.

The tin should be of quart size or a little bigger, and it is fixed top and bottom by means

of wire, just above high-water level to the supporting upright of the screen—one tin to each upright.

The wick used and found most efficient is two and a half inches wide and double thickness. To one end is attached a weight, or else some measure adopted whereby the wick cannot be blown out of the tin. This end is placed in the tin which has been filled with oil, and the other end of the wick is stitched to the canvas or gunny of the screen. The gunny of the screen should be wide enough to allow for rising water, and the stitching of the wick should be just on the level of the usual width of the stream.

A piece of wire twisted round the tin and allowed to project out for about six inches will prevent the wick resting against the tin and so wasting oil. Over each tin a small shade may be constructed to prevent undue evaporation.

Experience has shown that with this size of wick one quart of oil will last for eight days and

THE BACTERIOLOGICAL EXAMINATION AND THE HYDROGEN-ION CONCENTRATION OF THE URINE OF A SERIES OF 122 CHOLERA PATIENTS

By D. N. CHATTERJEE

and

K. S. MALIK

(From the Cholera Bacteriological Enquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)

GREIG (1913) in a preliminary note recorded the isolation of cholera vibrios from the urine of 8 out of 55 cholera patients. From this observation he concluded that in a certain number of cholera patients the vibrio is carried by the blood stream to the kidneys and that in these cases the disease is a septicæmia. In this paper, Greig also drew attention to the importance of this finding in the prevention of cholera. In two of Greig's cases vibrios were recovered from the urine during the stage of convalescence when the patients were working. Although these observations have been accepted by all subsequent writers on cholera we are not aware of any further work on the presence of vibrios in the urine of cholera patients and have failed to find any reference to a full account of Greig's work on these lines. During the course of an investigation into the reaction of the urine of cholera patients it was thought desirable to examine each sample for the presence of vibrios. The methods employed are summarized below:—

(A) *The bacteriological examination of urine.*
—The urine was collected by a sterile catheter under aseptic conditions. Approximately 10

(Continued from previous column)

give a continuous coating to the stream for that time. It has also been found that the ideal distance apart for screens to give the maximum effect to the oil is about 130 yards, but that distance will naturally vary with the configuration of the stream, i.e., bends, variations in width and so on. This works out at fourteen screens to the mile with an expenditure in oil of seven gallons per mile weekly.

The even flow of the oil has been found to be unaffected by spates and it is an advantage that when the water resumes its normal level, the oil which had previously been carried to the spate level is left deposited on the bank of the stream. If it is desired to have the oil spread over the whole width of the stream (it has only been applied to the sides here) a few bamboo pegs driven into the bed of the stream in a diagonal line will have the desired effect.

It may be mentioned that the device has not been tried out with Malariol but only with crude oil. The evaporation of the former would render the rate of consumption somewhat higher.

c.cm. of the urine was added to a tube containing 2 c.cm. of 10 per cent peptone water and the reaction, if acid, made alkaline by the addition of 4 per cent caustic soda; bromothymol blue was used as an indicator. In a certain number of patients the quantity of urine obtained was less than 10 c.cm. when it was added to 1 per cent peptone water. The peptone water tubes after incubation were plated on bile-salt-agar plates. A few drops of urine from the bottom of the tube were plated direct on a bile-salt-agar plate.

(B) *The determination of the hydrogen-ion concentration.*—The pH of the urine was determined by the colorimetric method (Hellige's comparator) soon after the collection of the sample.

Results.—Catheter specimens of urine from 122 patients suffering clinically from cholera were examined. The urines were collected on various days of the disease, from the 1st to 7th day. Vibrios were not isolated from any of the samples of the urines examined.

The hydrogen-ion concentration of the urine from 50 bacteriologically-proven cases of cholera was determined. The urines of 27 apparently normal individuals of the same class as the cholera patients were examined as a control series. It was found that the reaction of the urine during the acute stage of the disease was

markedly acid and became normal on about the seventh day.

The average hydrogen-ion concentration of the urines collected on different days of the disease is shown below :—

Day of disease	1	2	3	4	5	6	7	Urine of 27 healthy individuals
Average pH of urine.	4.9	5.0	5.4	5.5	5.6	5.6	5.9	6.0

Summary.—(1) Samples of urine collected by catheter from a series of 122 cholera patients were examined for the presence of *V. cholerae*. Vibrios were not isolated from any of the samples.

(2) The hydrogen-ion concentration of samples of urine of a series of 50 bacteriologically-proven cholera patients was estimated. It was found that the urine during the acute stage of the disease was markedly acid (pH 4.4 to 5.4) and became normal as the acute symptoms subsided.

A Mirror of Hospital Practice

ECTOPIC KIDNEY SIMULATING OVARIAN TUMOUR

(WITH REPORT OF A CASE)

By P. C. ROY, M.B., L.M. (Dublin)

Lecturer in Obstetrics and Gynaecology, Orissa Medical School, Cuttack

Ectopic kidney in the sacral region is a rare condition. It is not only an interesting condition but its recognition may prove of importance and present difficulties in the differential diagnosis of tumours of the genital organs and adnexa in women.

A case recently occurred in the Cuttack General Hospital of which an account is given.

Mrs. X, married, aged 24, was admitted to the Cuttack General Hospital in January 1938, complaining of colicky pains of the lower part of the abdomen, particularly in the flanks and on the right side, sometimes transmitted to the thigh and into the right subcostal region. She also noticed a lump (duration two years) situated just above the right side of the pubis, which, she stated, was constantly changing with movement, intra-abdominal pressure and the periodical filling and emptying of the bladder and rectum.

Menstruation began at the age of 15 years and recurred every three weeks for three days; there was scanty flow with pains at the beginning. Urination was difficult and sometimes painful. She was habitually constipated. She had been married when 20 years of age. Her present complaint had lasted for two years

during which time she had several attacks of generalized colicky pain in the abdomen and right loin, aggravated during defaecation and urination. She never suffered from fainting during the attack. She was well nourished and her heart and lungs were normal.

Urine—normal.

Stool—negative except for scanty hookworm infection.

Blood—nothing abnormal.

The temperature and pulse rate were normal. The abdomen was soft with slight tenderness over the tumour in the suprapubic area. A lump could be felt above the pubis, it was about the size of a man's fist and could be displaced outside and to the right from the pelvic region.

On bimanual examination the cervix of the uterus was felt to be directed slightly backwards. The body of the uterus was anteverted and anteflexed, of normal consistence and mobile. Behind the uterus there was felt a tumour about the size of a man's fist, solid in consistence and fairly mobile, oval in shape with smooth surface, not tender even on deep pressure. The right ovary could not be palpated. On the left side both the left ovary and fallopian tube were palpated and found to be normal. The case was thought to be a solid right ovarian tumour with a lengthy pedicle, which became twisted at times, producing the characteristic symptoms of occasional pain of colicky nature. On the 21st January, an operation was performed, under general anaesthesia. The abdomen was opened in the middle line (sub-umbilical incision). The uterus, fallopian tubes and both ovaries were found to be normal. But behind the uterus and on the right side there was a kidney-shaped tumour with a long mesentery, attached to the right side of the sacrum. An incision into the capsule of the tumour revealed

kidney substance. It had its hilum pointing towards the pubis. From this the ureter could be traced and on the poles of the kidney there were multiple long arteries from the middle sacral and iliac arteries. The left kidney was found to be normal and in its normal position.

Nephrectomy would be the usual procedure but owing to the fact that the kidney was found to be normal in appearance and had a long mesentery, which could be lifted up to the right lumbar region, nephrectomy was not done. The kidney and its mesentery was lifted up to the lumbar region, its capsule being opened and fixed to the right posterior abdominal wall by some mattress sutures. The abdomen was closed in the usual manner. The patient made an uneventful recovery. She has had no attack of colicky pain since then.

Comments

1. Anomalous development of the kidney in the sacral region due to a rest of nephrogenic element is not common.

2. When it occurs, specially in women, the greatest difficulty is found in diagnosing the condition and in differentiating it from adnexal tumours, specially ovarian tumours.

3. Paroxysmal pain of colicky type which the patient experienced for a long time was due to twisting of the mesentery simulating the chronic axial rotation of the pedicle of an ovarian tumour.

A CASE NOTE ON CANCRUM ORIS FOLLOWING PNEUMONIA TREATED BY PRONTOSIL*

By D. C. MAJUMDER, L.M.P. (Assam)

Daimukhia Tea Estate, Doom Dooma, Upper Assam

Introduction.—Cancrum oris following pneumonia is a rare condition. I have seen two other cases of cancrum oris in this practice, one following dysentery and the other idiopathic. Both died in spite of all treatment.

D. G., a female, aged 26 years, was admitted to hospital on 11th July, 1937, with definite signs of pneumonia of the left lung. Later on the right lung was also affected. Temperature, pulse and respiration returned to normal on the eleventh day of the disease, though she had coarse râles persisting in the lungs. On 11th August, i.e., a month after, she was running a low temperature in the evening and on the 22nd she complained of severe pain and burning sensation in the right cheek.

On examination the cheek was found to be inflamed and a hard lump was felt. A horic compress was given. The next morning a white patch was noticed inside the cheek. The breath was foul. She was given a warm potassium chlorate gargle and (1 in 10) hydrogen peroxide, alternately along with the compress. The condition became progressively worse till a cancrum oris developed. On 30th August, the ulcer was cauterized as recommended by Rose and Carless (1924) but this had no effect. Her general condition became worse and the temperature ranged from 99° to 102°F., hæmoglobin went down to 35 per cent and the patient became toxæmic. It was decided to give a trial to Prontosil album oral (Bayer) and six tablets a day were administered. On the eleventh day of prontosil treatment the temperature touched the normal line and remained normal for five days but went

up again for three more days and then dropped to normal till the patient was discharged from hospital. Prontosil was continued altogether for three weeks. Signs of toxæmia lessened from the third day of the treatment. Along with the decrease of temperature and toxæmia, the ulcer also began to heal up, and was completely cured after the completion of the treatment.

My thanks are due to Dr. H. Flack for his valuable help.

A CASE OF ASCARIS LUMBRICOIDES INFECTION SIMULATING CEREBRAL TYPE OF MALARIA

By A. K. GHOSE, L.M.F., L.T.M.

Medical Officer, Ambari Tea Estate, Carron, Jalpaiguri District

ON the 15th March, 1938, at about 5 p.m., a coolie girl about 8 years of age, while playing in front of her hut suddenly fell down unconscious. I was called at 7 p.m. and found her in the following condition :—

Completely unconscious. Violent spasms all over the body. Great struggling. Lock-jaw and sometimes tongue was caught between the teeth. Spleen not palpable. Temperature normal. Respiration and pulse normal.

From my previous experience I clinically diagnosed the condition to be due to subtertian malaria. I have seen cases of cerebral malaria even when the temperature is almost normal. I at once injected 7½ gr. of quinine bi-hydrochloride intramuscularly after taking a few blood films, both thick and thin. Next morning it was reported to me that the girl had vomited two live round worms at night; after which the symptoms of excitement much abated and she enjoyed some sleep. I examined the blood films but no parasites could be found even after prolonged search. I went to see her next morning at 7 a.m. and found her in a normal state. I asked her relatives to send her stool for examination when she passed one. Stool examination showed ova of *Ascaris lumbricoides* and hookworm in good numbers.

The sudden onset and sudden disappearance of the symptoms after vomiting two worms are the points of interest in this case.

Discussion

A. lumbricoides has been held responsible for various manifestations, for example, volvulus, intestinal obstruction, obstruction of the pancreatic or bile duct and diarrhoea with cholera-like symptoms.

It may also give rise to many nervous symptoms.

A CASE OF LOWER SEGMENT CÆSAREAN SECTION

By D. R. LEWIS, M.B., F.R.C.S.Ed.

Civil Surgeon, Maubin

OPPORTUNITIES for delivery of a child by Cæsarean section occur in *mofussil* hospitals only extremely rarely and for that reason I consider the following case worth publication :—

* Read in a meeting of the Doom Dooma and Associated Tea Company's Medical Society held on 25th November, 1937.

My assistant was called to see a deformed Hindu woman, aged 28, who was at full term of her first pregnancy and was said to have been in labour for the previous four days. On examining the woman he found that she had a contracted pelvis and he therefore advised her husband to take the patient to the hospital immediately, for delivery by operation. There is a great deal of reluctance on the part of Hindu women to seek treatment at the hospital and in this particular case the old *dai* who was in attendance on her, gave her the assurance that she would deliver her normally before that night and thus my assistant's advice was not acted upon by the patient's husband with the result that the next day she reached a critical state and had to be brought to the hospital.

When the patient arrived in hospital it was 5-20 p.m. on 5th March, 1938. Although she had been in labour for the past five days the os was dilated only to the extent of admitting two fingers. The child's head was found engaged. Foetal heart sounds were heard, and were 168 per minute. The woman had a temperature of 101°F. and her pulse was 120 per minute.

An immediate Caesarean section was decided upon and the patient was removed to the theatre. The abdomen was opened up by a left paramedian incision under spinal stovain and the uterus exposed. A transverse incision was made across the uterus at its lower segment after incising and stripping of the peritoneum and pushing up the bladder, the child was delivered by its head. The placenta was removed manually; but some part of the membranes was found adherent to the uterine wall and would not come off easily. The adherent membranes were scraped out with the fingers and the uterine cavity mopped out with gauze soaked in a 2 per cent solution of iodine in glycerine. The uterus was sutured with catgut and the abdominal wound closed in layers. As the uterus showed signs of sepsis an injection of 5 c.cm. of a 5 per cent solution of prontosil 'Bayer' was given intramuscularly.

The child was asphyxiated and had to be given artificial respiration for a period of 20 minutes before it started crying. Both the mother and child made uninterrupted progress.

A CASE OF TABES DORSALIS IN A HINDU

By MOHAN LAL PATHAK, M.B., B.S.
In charge, Police and Sub-Jail Hospitals,
Lower Dharmasala, District Kangra

TABES DORSALIS is a rare disease in India. So it seems worth while to record this case.

In January 1936 the patient, S. R., 30, Hindu male, soda-water hawker by occupation, came to the surgical out-patients department of the Jubilee Hospital, Amritsar, complaining of painless swelling of the right ankle joint of two years' duration. From there he was referred to the medical out-patients department, where he was seen by me. He was admitted in the second surgical ward where a detailed examination was conducted.

Family history and personal history.—Nothing particular.

Past history.—In 1920, when only 14, he got three sores outside his prepuce after exposure, as the result of

which he developed temporary phimosis. Some indigenous treatment was adopted which relieved him.

In 1928 he again developed two sores without any exposure which lasted for 15 days and subsided apparently without any treatment. Except this, there is no history of secondary or tertiary lues.

In 1933 he suffered from frequency of stools with marked tenesmus without any blood or mucus. He was given two courses of 12 injections each, of some medicine (emetine?) without any relief. The disorder subsided by itself after about three months. Possibly the attacks were rectal crises.

Then he noticed swelling of his right ankle for which, after trying various indigenous practitioners, he came to the hospital.

Examination of the nervous system. *Motor functions.*—Muscular power normal. Co-ordination perfect in the upper limbs, but defective in the lower limbs.

While sitting the head can be easily brought in between the extended legs, either leg can be made to form an acute angle with the trunk while the other leg is kept extended, fingers can be hyper-extended back to a right angle, indicating marked hypotonia.

Sensory functions. *Superficial senses.*—Dorsum of the toes, soles of the feet, perianal region, penis and scrotum are anaesthetic to touch, pain, heat and cold. Lateral border of the left foot, a band about 2½ inches in width on the left side and 1 inch on the right side at the level of the nipples extending right across the front and back of the chest and a small area on the medial aspect of right arm are partially anaesthetic. Cold is interpreted as heat on the lower abdomen, medial aspect of the arms and sometimes on the scrotum. Cotton-wool touch is interpreted as pin prick on the lower abdomen.

Deep senses.—Sense of position absent in the toes and ankles, impaired in the knees and normal in all other joints. Romberg's sign marked. Algometer sense absent on the feet, impaired on the legs and normal in other regions. Sense of vibration absent from toes and fingers, impaired in ankles, and normal in other parts. Asthesiometer sense is impaired on the legs and cannot be tested on the feet.

Reflex functions.—*Deep reflexes.*—Wrist extensor jerk is sluggish on both sides. Otherwise all the deep reflexes of upper and lower limbs are totally absent.

Superficial reflexes.—Plantar, bulbocavernosus and anal reflexes absent. Cremasteric reflex sluggish. Abdominal reflexes abnormally brisk. Epigastric reflexes normal.

Organic reflexes.—There is hesitancy of micturition. Sometimes urinary flow stops, to start again after a minute or so (vesical crisis). Sometimes there is incontinence of stools. Breathing normal except temporary attacks of dyspnoea (bronchial crisis?).

Pupillary reflexes.—Typical Argyll Robertson pupil.

Cranial nerve functions.—Sometimes the patient gets macropsia. Field of vision as tested by finger movements restricted on all sides.

Trophic changes.—There is a hard area about a picc in diameter on the soles.

Locomotor system.—Right ankle joint is swollen but not tender. The joint is flail-like. X-ray examination shows disorganization of the joint, destruction of bone ends and formation of new bone round about. Joint cavity cannot be differentiated.

Other systems normal on ordinary examination.

Blood—Wassermann + + -.

Cerebro-spinal fluid—Wassermann + + +.

Undoubtedly the patient was a typical case of tabes dorsalis.

The patient was given a full course of neosalvarsan with iodide and mercury by mouth, with no improvement. Then he was given 10 injections of sulfosin on alternate days. He got marked febrile reaction (temperature 103°F. or so) after every injection but without any improvement in his condition. If anything he was steadily growing worse. After about five months' stay in the hospital he was discharged with a plaster-of-Paris splint on his right ankle.

I thank Lieut.-Colonel P. A. Dargan, I.M.S., the hospital superintendent, for permission to publish this case and Dr. Ganesh Sahai, the surgeon in charge of the case, for providing facilities to study it.

A CASE OF REPEATED ABORTION TREATED WITH VITAMIN E AND PROLUTON

By I. G. K. MENON, M.B., B.S.

Honorary Assistant Physician, British Cochín

The patient was a girl aged 24.

Previous history.—Subject always to severe dysmenorrhœa, worse before and on the first day of the period—loss of blood always profuse.

First pregnancy in 1934, three months after marriage. In the 11th week of pregnancy, bleeding started. Examination *per vaginam* showed a retroverted uterus, mobile. The retroversion was corrected and a pessary introduced but despite that and sedative treatment with calcium, viburnum, liquor sedans, etc., and perfect rest, complete abortion occurred, exactly one week after bleeding started. Loss of blood was alarming in its quantity. This occurred at about the time due for the periods.

Subsequently a pessary was worn for several months. She became pregnant again in 1935. Examination showed the uterus mobile and retroverted; so it was corrected and a pessary was worn early. Despite that and prophylactic calcium, liquor sedans, adexolin, etc., with rest, bleeding appeared in the 11th week of pregnancy as before, continued for one week and terminated in abortion. This time also, loss of blood was marked. The dysmenorrhœa was slightly less after these abortions, but still very marked. The pessary was not being used. In May 1936, about a year after the second abortion, vaginal examination showed the uterus mobile, retroverted and with a certain amount of retroflexion. A ventral fixation of the uterus was suggested but refused.

In August 1936 she commenced taking vitamin E, one capsule a day. Crooke's Collosol wheat germ oil capsules and Glaxo Laboratory wheat germ oil extract were used. It was noticed very soon that the dysmenorrhœa completely disappeared, the loss of blood at the periods lessened and, though no other tonics were being taken, her weight, which used to be very steady at 112 lb., increased in three months to 126 lb.

History of present pregnancy.—She had her last period in January 1937. After vitamin E the inter-menstrual period was occasionally prolonged and so until 42 days of amenorrhœa pregnancy was considered doubtful. A vaginal examination on the 45th day revealed a uterus in the correct position with no retroversion or retroflexion and signs suggestive of pregnancy. Brownish stains occasionally taking deep red tinge were noticed at this time, even though the vitamin E was being continued. On the 55th day, fresh blood stains and backache were noticed and so next morning, 4 units of Proluton (Sehering) were given intramuscularly. After that, no bleeding or even brownish stains occurred.

Bi-weekly injections of Proluton (2 units at a time) were continued till the 6th month of pregnancy while vitamin E was continued till the 8th month, in addition to adexolin and caleinol. Weak pains started at 7 p.m. on 27th day and an easy normal delivery took place at 2-30 p.m., on the 27th day of pregnancy. The baby was a female child weighing 6 lb. Loss of blood was less than the average and the puerperium was uneventful.

The baby was noted to be quick in its development in all respects. She has been fed entirely on breast milk so far and has progressed from 6 lb. at birth to 17 lb. in her 5th month.

The interesting points in this case are :—

1. The correction of the retroversion without any reposition or pessary, after vitamin E. It would seem as if deposition of fat in the broad ligament and increased tone of the supporting ligaments resulted after vitamin E in this natural correction.

2. The complete cessation of bleeding with Proluton treatment in spite of the failure of all other usual methods in the previous two abortions and even of vitamin E in this instance.

[*Note.*—Whilst the possibility cannot be denied, the evidence of the specific action of vitamin E in this case seems to be lacking.—EDITOR, I. M. G.]

A CASE OF PELLAGRA SUCCESSFULLY TREATED WITH INTRAVENOUS INJECTIONS OF SODIUM THIOSULPHATE

By D. R. LEWIS, M.B., F.R.C.S.ED.

Civil Surgeon, Maubin, Burma

S., a Hindu male, aged 20, a native of Fyzabad district, sought my advice on 1st May, 1938, for raised symmetrical patches of discoloration on the dorsal aspect of his hands, forearms, legs and feet. He gave the history that two months ago he noticed dark patches, about the size of a rupee, on the dorsal surface of both wrists and ankles. The former spread upwards towards the elbows and the latter towards the toes. A fortnight later new patches appeared just below the neck, on the outer surface of both knees and behind the elbows. The patches on the knees began to spread upwards and medially.

At the time of examination the patches on the feet, wrists, knees and elbows appeared black and the skin was dry and coarse. There was no pain except itching sensations on exposure to sunlight. There were also discrete patches on the forehead and cheeks, and two on the chest, one on the manubrium sterni and the other at the root of the neck on the left side. These patches were smooth, but deeply-pigmented dark brown. The central area was less pigmented than the periphery. They appeared ring-shaped.

He had small areas of leukoplakia at the angles of the mouth, the one on the right side being more marked.

The nails were normal.

He stated that for the past month he had lost his appetite, did not taste his food and was not able to digest it.

The bowels were regular. The urine was scanty and high coloured, and there was a burning sensation during micturition.

The patient has been in this country for the last four months. His usual diet in India was rice and *dāl* and he takes the same diet here too. He is a vegetarian, belonging to the *durwan* class, with low resisting power.

Treatment.—For this particular patient I chose intravenous injection of sodium thiosulphate as recommended by Sabry; no other treatment, medicinal or dietetic, was given.

He was admitted into the hospital on 2nd May and was asked to continue his old diet of rice and *dāl* obtained from the same source. He was given 10 c.cm. of a 10 per cent solution of sodium thiosulphate twice weekly. The first effect noticed was that the patches began to change colour. What was originally black now became brown and what was brown became erythematous. A few days later all signs of pigmentation and erythema passed off. There was a sense of well-being. His appetite returned as well as his powers of digestion. The sites of the original patches on the feet, elbows and ankles are still rough to the feel. Those on the knees and wrists are less rough. The more recent ones on the chest, face and back of the neck have completely disappeared.

The patient gained 9 lb. during his treatment.

Indian Medical Gazette

OCTOBER

THE TREATMENT OF LOBAR PNEUMONIA

A QUARTER of a century ago the general attitude towards pneumonia was a fatalistic one and is reflected in the saying of Sir William Osler that pneumonia is the 'old man's friend', the implication being that this disease removes him rapidly from the world when his life is becoming a burden to himself, as well as to others responsible for him. The treatment for the disease was 'expectant' and consisted of little more than nursing and the judicious—and also unfortunately injudicious—use of alcohol and digitalis.

It may have been just the steady advance of medical science in which the investigation of this disease took its turn, or perhaps it was the terrible toll of life amongst people of all ages taken by pneumonia in the great influenza epidemic of 1918 that stimulated us; whatever was the cause for this change, there has been a very decided change of attitude and the treatment of lobar pneumonia has been engaging the serious attention of the medical profession in many western countries during the last decade or so, but it is in the United States that there has been the greatest concentration of effort. This is very easily understood, for the mortality rate seems to be higher in North America than in any other part of the world where the conditions can be said to be comparable. At the beginning of the century the death rate, for all ages considered together, was in the thirty per cents in large American hospitals and in the twenties in the corresponding London hospitals. Then, again in America not only have the large research organizations put pneumonia second only to cancer in order of importance as a subject for research, but the large hospitals, the universities, and the federal and state health authorities have undertaken extensive enquiries; and most significant of all even insurance companies have considered it a sound commercial proposition to undertake or to assist financially schemes of research aimed at placing the treatment of this disease on a sound footing.

An essential prelude to the introduction of serum in the treatment of pneumonia was the recognition of the different serological types by Lister in South Africa, and by Dochez and Gillespie in the United States. This knowledge was essential even for the preparation of a polyvalent serum, but time has shown that it is only by the use of homologous sera that any significant reduction in the death rate can be effected.

Experience of the last three years has established beyond any doubt the value of anti-pneumococcal serum. The death rate from

lobar pneumonia shows very considerable variation in different circumstances: it varies from almost *nil* in the child to almost 100 per cent in the aged, and in any one age group it will show marked variation from place to place and from time to time, but in the healthy adult male between 20 and 50, economically the most important group, it can probably be said that where efficient serum treatment has been given the death rate has been nearly halved.

The success of the treatment depends on the time of administration of the serum and on the number of units of homologous antitoxin that the serum contains; unless it is given within the first few days and in adequate amounts it is of little value. There is a close association between these two facts. In order that a sufficient number of units may be given in a reasonable bulk of serum it is important that a univalent serum should be used, and this necessitates the ascertaining of the type of infecting pneumococcus, which in its turn means delay.

If the serum is not given within the first three days the chances of success are considerably reduced. There is often some delay before a patient comes under medical observation and if to this has to be added about twenty-four hours that the standard methods of typing usually take, the number of patients receiving the full benefit of the serum will be few. Armstrong's method of direct 'typing' with the pneumococci-laden sputum of the patient and high-titre type sera can be done in a few minutes, but even in these circumstances the requisitioning of the services of an expert bacteriologist and the collection of the necessary materials will take some time. To overcome this difficulty, in some American states, they have organized a state pneumonia treatment service on which any doctor can call for assistance in ascertaining the type and for the provision of anti-pneumococcal serum. No such elaborate organization exists even in England and it could not be contemplated in this country.

In the past the horse has been used for the preparation of anti-pneumococcal serum but recently the rabbit, which was used only for the production of high-titre serum for typing, has been shown to be capable of producing a serum that is therapeutically very active. The rabbit serum was used at first only in patients known to be sensitive to horse serum, but recently it has been claimed that rabbit serum is far more effective than horse serum, and in a series of sixty-nine adults, Loughlin, Bennett and Spitz of Brooklyn claim a mortality rate of only 7.4 per cent, and say that no patient who received the serum within 96 hours died.

A very serious drawback to the serum treatment of pneumonia is the high cost of the serum. There is no reason to suppose that this cost is an artificial one and capable of reduction to any important extent; the production of serum of sufficient potency may take as long as two years and horses sometimes die in the process. One

hundred thousand units may be looked upon as almost the minimum effective dose and in many cases 200,000 units, 300,000 units, and even larger dosages are given. The retail cost of 100,000 units is about 45 dollars in America and it is certainly not less in India.

Another serious complication is the multiplicity of types; these number well over thirty now. Admittedly, in England and America between a half and two-thirds of the cases will be type I or II and the large majority of the rest fall into about four 'higher' types. This not only adds to the difficulty of identifying the types but means the stocking of a large variety of homologous sera. In India, matters are made worse by the fact that types I and II are not the common types, and in a recent investigation only in about one-quarter of the cases of pneumonia were type I or II pneumococci found to be the infecting organisms, and in yet another series the proportion was as low as 12 per cent.

All these facts taken together seem to us to rule out anti-pneumococcal serum altogether as a practical solution to the problem of the treatment of pneumonia in India.

A paper recently appeared in these columns which suggested that the early use of vaccines might be of some value, and in the milder forms of the disease—which are undoubtedly the rule in India—the writer reported considerable success in a small series. As this method of treatment is not generally looked upon with favour outside India, we hesitate to recommend it at present. It is in any case essential that this vaccine should be made from virulent cultures of the types most prevalent in the neighbourhood. It is hoped that further reports of this method will shortly be forthcoming, and that they will be equally favourable, but meanwhile we must control our optimism.

Are we then to be thrown back on the old expectant methods 'with the judicious use of alcohol and digitalis', to which is now added intravenous glucose and the liberal use of oxygen? The present trend of opinion is that the most judicious use of alcohol and digitalis is to keep these two substances in their respective bottles. The American opinion seems to be almost unanimous that the results have been much better since alcohol was given up altogether, and in Great Britain even those who do not take this extreme view usually consider that the psychological and sleep-producing effects of alcohol are its main recommendations. Similarly, the giving of digitalis is looked upon by the majority as adding another poison to the already poisoned heart, but opinion on this point is not unanimous.

The opinion about oxygen has also undergone a change; but in a reverse direction, and from being divided and sceptical, it is now unanimous and definite. The previous unsatisfactory position of oxygen therapy was due entirely to the totally inadequate methods by which it was given, and these methods are still used widely

in India, though in some of the larger hospitals better methods are now being introduced. No benefit whatsoever is obtained from the oxygen if a funnel, attached directly to the oxygen cylinder—so that the rate of oxygen delivery is unknown, is waved nonchalantly and occasionally by a nurse or attendant some few inches from the patient's face. It is seldom given until the patient is moribund and beyond the help of any oxygen, and it is therefore not surprising that in Indian hospitals and households the ordering of the oxygen cylinder is tantamount to ordering the undertaker. Any momentary improvement that is observed can probably be accounted for by the stimulating effect of the air movement. The psychological effect on the patient and his relatives is the very reverse of stimulating and the only person benefited is the physician who appears to be able to go home with a feeling of satisfaction—to which he has incidentally no right—that all that is humanly possible has been done.

Oxygen tents should certainly be available in the larger hospitals in India, but their use will be limited to the cooler months of the year unless they can be combined with some system of cooling the air and maintaining air movements. The mask is unsatisfactory and not well tolerated, but the nasal catheter is usually well tolerated by patients, particularly when they have once experienced the relief that is given by this measure, and it has in addition the great advantages of simplicity and low cost.

A no. 10 or smaller catheter is used, additional holes should be cut so that the stream of oxygen does not play on one spot in the mucous membrane; the catheter should be passed well into the naso-pharynx: and the supply of oxygen should be liberal, about 2 litres a minute. If no special apparatus is available the oxygen can be bubbled through water in a flask or Wouff's bottle. The statement that the rate of bubbling should be a little faster than one can count is most misleading and liable to end in an inadequate amount being given. (The rate can be tested by noting how long it takes to empty a 500 c.cm. flask—or other receptacle of known capacity—filled and inverted over a bowl of water when oxygen from the catheter is passed into it: it should take 15 seconds in the case of the 500 c.cm. flask.) *In all cases oxygen should be started early and should be given continuously.*

The introduction of sulphanilamide in the treatment of hæmolytic streptococcal and allied infections opened up a new vista in chemotherapy, and drugs of this group were naturally tried in pneumonia. Britton, Buttle, Gray and Stephenson, and others in Britain, and Cooper, Gross and Mellon, and others in America testing sulphanilamide experimentally and clinically against pneumococcal infections obtained inconclusive, but suggestive, results. The experiments were extended to other allied compounds and early this year Whitby found that a compound,

2-(*p*-aminobenzene-sulphon-amido) pyridine, had much more marked protecting action in mice injected with 10,000 lethal doses of different types of pneumococci than other compounds hitherto tested. More recently this drug, now known as 'M and B 693', has been used clinically in pneumonia with some very promising results.

It is too soon to be jubilant about this particular compound, but we are certainly entitled to be optimistic regarding the future of chemotherapy in this disease. The very great advantage of the drugs of this group is that they are not expensive and it seems possible that herein lies the solution to the problem of the treatment of lobar pneumonia in this country.

MENTAL HYGIENE AND ITS SIGNIFICANCE

By R. M. KASLIWAL, M.D. (Luck.), M.R.C.P. (Lond.),
D.T.M. & H. (Eng.)

CAPTAIN, I.M.S.

Officer Commanding Post Hospital, Comilla

EACH and every one of us lives in two different worlds, one which is common to us all and another which is entirely of one's own creation. In fact, this latter world is more important and dearer to us than the common world. We cling to our ideas and ideals, our thoughts and notions almost as tenaciously as if ours were the only right and just world. It sometimes hinders and sometimes helps us in understanding each other's point of view. It often prejudices us to such an extent that we are unable to visualize things in their true perspective. It even modifies our impression about the common world. It is, in fact, as responsible for our happiness as for our unhappiness, and yet if we face the facts squarely, we can safely say that practically no hygienic measures have been introduced into this country to stop the accumulation of the so-called misconceptions, inner conflicts and repressions in order to prevent future misery and mental disease.

During the last two or three decades much attention has been paid to the eradication of disease by laying stress on the preventive side of medicine, but little has been done or is being done for the prevention of mental diseases proper and the so-called neuroses which are increasing rapidly as life becomes more complex, and for some of which society is as responsible as for the germs of physical disease.

Society is at present shirking its responsibility with regard to these social diseases and it is now high time that the medical profession in India, with the mutual co-operation of public bodies, should take a lead in the preventive side of this branch of medicine, just as they did when the modern hygienic measures were introduced for the prevention of infectious diseases.

It is only by the development of this aspect of hygiene that so much misery, unhappiness and disease, which is to such a great extent the result of clogged mentality, can successfully be dealt with. On it will depend the development in the future of well-balanced normal minds, fully equipped to meet the trying exigencies of our lives.

We are the product of our breeding and environment. The question of breed, which is of such great importance, will not be dealt with here. It comes under the purview of eugenics.

Although seed is of prime importance the external influences, home surroundings and other environment are of equally great importance for the proper development of human mentality, and therefore it is difficult to say which of the two deserves the first place.

The mind starts developing from the time that the foetus is in the womb. Excessive worry, malnutrition or other untoward effects to the mother have all been known to be reflected in the child in the form of certain aberrant traits appearing when the child is born and grows up; thus for the proper development of the baby the mother ought to be in perfect physical and mental equilibrium.

The most important duty of the parents begins when the child is born. The mind undergoes a rapid development during the infantile period, and in order to give full scope for its development no undue hindrances and obstacles should be imposed upon it. It should be recognized that the child is only a young animal and that impressions created at this stage may modify his whole future life. Two opposite powerful forces are dominant in the mind at this period; one is the sense of dependence and the other is that of independence. They are both biological and primary and the so-called adult 'misfits' are a result of the failure of parents to recognize the ruling power of these primary impulses. When a baby cuddles in his mother's arms he is relishing the sense of dependence and automatically maintains a feeling of satisfaction and comfort and recognizes protection in his parent.

If at this period the parent hurts the feelings of the child unduly, as is commonly done by careless mothers in beating their babies or neglecting them, the image of worship formed in the child's mind falls to pieces. The loss of this impulse creates a burst of negative independence. Such a conflict or event may prove to be the starting point of the future neurotic adult individual who views everything with distrust and who finds it difficult to adapt himself to his surroundings. Similarly, an overbearing attitude of the parents to their children collides with their sense of independence and interferes with their proper maturity; thus these children on reaching adult age are still living in the infantile

period of protection and dependence, and are unable unaided to meet the problems and exigencies of adult life. It should therefore be clearly understood by all parents that their relationship with their children is of vital importance and it should be of such a nature as not to interfere with the primary forces and impulses of the child, which should be given proper scope for development. The irrational behaviour of parents, both in the domain of permission and prohibition, should be censured and there must not be too much of either. That excess of everything is bad is an obvious truth, and this should be the guiding principle of the parents in their relationship with their children.

As the child grows, the surroundings domestic, social, economical, psychical and spiritual exert a good deal of power in moulding his mentality. Recent advances in psychology teach us that when there is perfect harmony between the individual and his environment the development of mentality takes the proper channel resulting in future happiness and peace of mind. On the other hand if there are destructive stimuli operating on the individual, he is unable to adapt himself to his environment, which ultimately results in mental conflicts and confusion, and subsequently misery follows.

This has been very aptly emphasized by David Seabury who writes that, 'A right relation of the self to surroundings is a primary factor in the direction of inherited impulses and the release and guidance of inner powers'. One so very often sees the results of the suitability and unsuitability of such surroundings among children of happy and unhappy families.

In the light of modern research also it is now known that it is not necessary for the environment to be a good one but it should be such as is suitable to the individual. What may be good for one individual need not necessarily be good for another. Personal needs and requirements vary according to one's inherent tendencies and, in order to give the inborn elements the fullest opportunity for growth, one's surroundings must be suitable. The influence of home surroundings and other environment on an individual, especially in the formative period of his life, is therefore of great importance, and the parents should realize the importance of the presence of primary impulses within their children which, instead of being repressed, should be given the fullest opportunity for normal expansion.

As the child grows into a man the importance of a healthy environment still holds good. Happiness, present and future, proper mental development and correct perspective about things develop only if the environments through which the person has gone were healthy. Many a genius has been allowed to rot and sane-minded persons turned cynical owing to the unhealthy mental atmosphere through which they have passed.

What constitutes a healthy mental atmosphere is another important question. It probably

differs with different individuals but approximately it should be made up of peaceful, pleasant and comfortable home surroundings combined with sufficient suitable work and a congenial social environment. In no stage of the life should the undue dominating influence of anybody be allowed to continue. Every one of us is familiar with the domineering influence of a parent or a friend and the results thereof. Such an individual is not given an opportunity to develop his own personality, with the result that when he goes out into the world, he finds it difficult to make a start and is always looking for assistance. All of us have at times sensed that a particular atmosphere is stimulating or undermining us, and for the sake of avoiding the detrimental effect of an undermining or a dominating atmosphere one must get away from such a situation.

Besides this factor of environment, which plays a great part in the moulding of mentality, there are certain internal feelings which also exert an equally important influence. Worry and pessimism always keep us alive to our troubles. They have a very maiming effect on our mental processes. Though it is easier said than done, as far as possible every effort should be made to avoid this pernicious habit of worrying. A cheerful and optimistic attitude towards a troublesome situation helps matters to a very large extent, whereas worry and pessimism only put extra hindrances in the way and clog the whole mentality. One cannot see all the points of a particular issue nearly as well when one is worried as when one is calm. An inveterate worrier gradually becomes very introspective and ultimately becomes a neurotic or a hypochondriac. It is natural to worry about certain important problems. To worry to a certain extent is normal but when a person worries too much and worries about trifles he transgresses the normal limits, and it is then that it begins to tell on his mental faculties. Individuals should therefore be shown the evils of this habit, and should be instructed how to avoid it as far as possible.

Brooding over past unhappy events is another bad habit which has a very detrimental effect on our mental faculties, particularly memory. Continuous mental repetition of past unhappy incidents and fighting imaginary battles takes away not only the peace of mind at that moment, but makes the person apathetic and bad tempered for the rest of the day. It is as if the incident has occurred again the same day. Such mental rumination ruins the happiness and peace of mind which is a very important factor in keeping the mental processes in good order.

'Inferiority complex' is familiar to all of us, and it would therefore be interesting to know how it breeds and what ravages it produces in the mental atmosphere. It is more often relative than absolute, meaning thereby that it may be noticed in an individual under certain circumstances only, and not always. It is a matter

of common observation to notice it in an individual in the presence of a particular person or society, whereas nothing of the kind is manifested by him in different company. It is to a certain extent normal, and becomes apparent only when a person feels himself a little strange and unadapted to a situation, and as soon as he is removed from that situation to a more congenial one he once again assumes a normal attitude. It is only when the complex takes a severe turn and operates in all situations, that is, when it becomes a part and parcel of the individual, that it becomes a psychological problem. In almost all these cases it is the result of some underlying repression which may be either in the form of some unfulfilled wish or an organic inferiority due to some physical defect.

It is also commonly observed that in order to conceal or avoid their inferiority these individuals sometimes develop the 'superiority complex' which may be manifested in one of several ways. The bully, the swashbuckling and boasting type of individual, the person who talks too much of his physical powers and attainments, the so-called ascetic and various other

individuals in different aspects of life sometimes adopt this characteristic superior attitude just to hide their sense of inferiority. This is an outcome of some form of unhealthy condition of the mental atmosphere which, by proper mental hygienic measures adopted in early childhood, could to a certain extent be prevented from appearing in the adult, and thus save a great deal of mental unhappiness to the individual in particular and humanity in general.

Similarly, there are many problems occurring in everyday life which are chiefly the outcome of clogged mentality and which keep us unhappy in our already so-called unhappy world, and if, by proper care and mental hygienic measures, these problems could be prevented and removed what an immense amount of misery would be lifted from our shoulders.

It is therefore necessary that, with the modern advances already made in this branch of medicine, steps should be taken to introduce them for the general welfare and utility of the people, and psychological clinics and other places where regular mental hygienic work can be carried out should be started in India.

Medical News

CALCIUM LACTATE AS A MILK SUBSTITUTE

EXPERIMENTS carried out by the Nutrition Research Laboratories, Coonoor, on a group of south Indian school children, who were given a daily dose of calcium lactate instead of milk for a period of three to four months, show that the children increased in height and weight as compared to other groups which received no calcium lactate. It was found that the calcium lactate groups put on more weight, and showed also a slight increase in stature.

The calcium lactate had a good effect on the general condition of the children although the calcium salt does not, as might be expected, equal milk in value as a supplement. It does however help to make good one serious deficiency, and is a *partial* milk substitute.

What it costs

To supply a child with a daily drink of 8 oz. of liquid skimmed milk reconstituted from powder costs about 12 annas per month. The supply of such milk in schools on a large scale would mean considerable expense. Children who need milk most are those whose parents can least afford it.

In the experiments with calcium lactate half of one gramme of calcium lactate was given daily, at a cost of about half to one anna per child per month. This is by no means a large expenditure and the regular administration of a calcium salt might be feasible even in the poorest schools. Milk is best, but in present circumstances, calcium lactate is better than nothing. Its provision may be recommended to Educational Departments and other organizations concerned with the care of children. The calcium salt could be dispensed rapidly and easily from a tin with a spoon of suitable size.

A daily dose of calcium lactate may benefit children in other countries besides India. It would probably make a very useful dietary supplement for children in Africa and many other parts of the world, for whom milk is not available, and whose staple diet is rice or some other food deficient in calcium.

The Coonoor experiments suggest a new approach to the problem of malnutrition among such children.

MEDICAL SUPPLIES BY AIR. RAPID AID IN EMERGENCY CASES

THE air transport of serums and vaccines has recently shown a remarkable increase, according to a traffic census made by Imperial Airways.

Practically every day great manufacturing houses in London send medical supplies by air not only to European countries but to the remotest parts of the world, frequently right into the heart of the bush.

Not the least interesting aspect of this traffic is the humanitarian part played in the saving of life, as, for instance, when serums are needed to combat diphtheria or scarlet fever epidemics away from civilized centres.

Without air transport it would be impossible to cope with sudden epidemics or accidents that occur in remote districts. To-day, with regular air services available, doctors ask confidently for the rarest serum, knowing that it will be in their hands in a few hours.

It is not practicable to keep many of these preparations in stock. Apart from being 'short-dated', they are also extremely expensive. One bulb often costs as much as £4.

An example of these emergency calls was provided only last week, when distemper broke out in a kennel of very valuable dogs in the Straits Settlements. By the next available flying-boat from Southampton there was rushed out a supply of virus. As the virus must be alive and fully active at the time of injection, there is a vital need to expedite delivery. When taken by air, the journey time is cut down from weeks to days, and from days to hours.

In Cyprus some time ago there was an epidemic of meningitis, and Imperial Airways flying-boats carried out considerable quantities of meningococcus serum.

Supplies of gas gangrene anti-toxin have recently been sent to Spain; and every week typhoid and cholera vaccines and serums are despatched by air, both for prophylactic and treatment purposes.

[Oct., 1938]

Not all these preparations, of course, are intended for a sudden emergency, which shows that air transport is being used in a routine manner for restocking and normal usage.

The large medical supply houses are specially organized to deal with air consignments. Cables from abroad are immediately telephoned by the cable company, prior to the delivery of the cable.

An instance of the speed of working was seen when a London firm of manufacturing chemists received an urgent call from Stockholm for a certain serum. The serum left the premises in exactly 13 minutes, and was in Stockholm a few hours later.

A few weeks ago surgeons in a hospital in Africa were in urgent need of a certain type of anæsthetic which could only be procured from a certain laboratory in the United States. In response to an urgent cable, a supply of the anæsthetic was sent immediately by train to the nearest air-port, flown to New York, and carried across the North Atlantic by ocean-liner, and reaching England an Imperial Airways air-liner continued the journey by flying the preparation to an air-port in Africa. The final stage to the hospital was completed by fast car.

To take another aspect of the use of air transport for medical purposes, doctors have found that patients whose condition would make a surface journey dangerous, are able to travel by air without suffering any ill-effects. There have been many recent incidents of patients coming to England by flying-boat to undergo operations or certain forms of treatment.

Special accommodation can be provided for patients in these big flying-boats, and an air journey from abroad is made so quickly and with such absence of fatigue, that patients arrive in London without having suffered any discomfort whatever.

A case in point was that of a diver who, as a result of being brought to the surface too quickly, contracted caisson disease. He had to be rushed back to England by air for treatment at a London hospital.

It is quite a normal procedure to-day for London medical men to make use of specially-chartered ambulance 'planes for sending patients over to receive treatment at continental clinics. Taken by motor-car from a nursing home to Croydon air-port, and transferred immediately to a waiting ambulance 'plane, a patient can reach in a few hours' flying some destination on the other side of the channel. The experienced pilots who fly these air ambulances take them up to heights where smooth, swift journeys are assured.

One of the most interesting services in the world is the special air ambulance service operated in Australia by the famous Inland Mission. Not only does this mission employ fast aircraft to carry doctors and nurses to urgent cases, and ambulance aircraft for the transport of patients requiring urgent hospital treatment, but it now has at its disposal larger aircraft fitted up as complete operating theatres.

This means that when a patient is hundreds of miles from the nearest hospital, and his condition so grave that he cannot be moved, an aerial operating theatre can be flown to the spot and an urgent emergency operation performed without the need to do more than carry the patient into the aircraft.

SUMMARY OF TUBERCULOSIS NEWS FOR THE MONTH OF AUGUST 1938

THE executive committee of the International Union against Tuberculosis, Paris, offered a biennial prize of the value of 2,500 French francs (in memory of the late Professor Leon Bernard, who was the founder and for fourteen years the secretary-general of the Union) for an original essay in English or French on the 'Social aspects of tuberculosis'. Thirteen entries were submitted from India through the King George Thanksgiving (Anti-Tuberculosis) Fund. The executive committee of the International Union has decided to award the prize to Dr. Karl Fischel (United States), Dr. E. Arnould (France) and Dr. J. B. McDougall (Great Britain).

2. H. E. the Marchioness of Linlithgow's Appeal for the King-Emperor's Anti-Tuberculosis Fund

The Bombay Field Club has organized an exhibition of photographs of places of historical and archaeological interest throughout India, Burma and Ceylon. The proceeds of the exhibition will be given to the King-Emperor's Anti-Tuberculosis Fund.

His Highness the Nawab of Junagadh has sanctioned a scheme for a lucky bag in aid of the King-Emperor's Anti-Tuberculosis Fund.

The 16th list of subscriptions issued by the Honorary Treasurer of the Fund shows that the amount actually received by him up to 31st July, 1938, was Rs. 51,16,968-9-9.

THE SAIDAPET HEALTH ASSOCIATION

THE Saidapet Health Association realized in 1933 that if a group once becomes involved in caring for the severely afflicted it becomes almost impossible to divert time and effort to discovering and removing the causes that brought the affliction to the people. The Saidapet Health Project has therefore steered itself against expending its efforts upon present effects. For five years it has concentrated upon a detailed study of Saidapet and causes that might prevent healthy living.

The material presented in their report describes the work of what has come to be known as the Saidapet Health Project. This is a joint enterprise of several medical and social service agencies which have pooled their resources and workers in an effort to discover ways and means of raising the level of the social and health life of a small town in South India. The report is issued in the hope that it may be of use to others working along similar lines.

The basis for the study

This preliminary health study of Saidapet is not offered as a survey that has discovered conditions, and emphasized or remedied them; it is published because the doctors and social service workers undertaking it are searching for a technique which may be useful here and elsewhere, in helping the residents to make better homes, and therefore a better town.

Saidapet appears to be, in its religious, social and economic framework, a typical small town in South India. The residents work hard for their living. There is a general air of friendliness and goodwill. There are former municipal difficulties the rate of taxation is high. The sanitary and health level is low, though the difference may be only apparent, not real.

In conducting our survey we have kept these questions in mind:

(i) The Government Dispensary in Saidapet is a busy place. Nearby in Madras are the famous hospitals of the Presidency. Yet people use them only in emergencies. The dispensary is clean, yet up to its walls crowds the bazaar, insanitary, uninfluenced and unchanged. What can be done to carry the influence of the dispensary beyond its walls? How may fear of hospitals be overcome?

(ii) A vigorous campaign is yearly carried on by the municipality against cholera, smallpox and enteric fever. Co-operation is indifferent; hence the epidemics are controlled, not eradicated. What can be done to arouse interest in preventive measures?

(iii) Leprosy is a fairly common affliction in Saidapet. Is the incidence higher than elsewhere, or would similar surveys reveal similar conditions? Heretofore the control method has been isolation. To isolate the large number of wage-earners concerned in Saidapet would be an economic catastrophe even if funds were available to make it possible. Can Saidapet be used as a research laboratory for the study of leprosy in the situation in which it arises?

(iv) Filariasis is very common in Saidapet. The cause is known, but at present the cure is not known. Is it possible to use Saidapet as a laboratory for research which will bring the knowledge required?

(v) Can constructive use be made of the handicaps under which Saidapet struggles? Health measures undertaken to date, though sound, have not aroused interest or the co-operation of the public. But everyone in Saidapet is interested in the control and cure of leprosy. This is clear from the keen interest shown and the co-operation given in the first house-to-house survey conducted by the Saidapet Skin and Leprosy Relief Association, now the Saidapet Health Association. This interest and co-operation grows steadily.

(vi) One final question may be formulated in the light of the foregoing:—Is it possible to use the concern for leprosy as a lever to lift the health level of the entire community? The measures necessary to control it will benefit everyone, and will, if adopted, make Saidapet a cleaner and a healthier town in which to live. But to achieve success all sides of community life must be approached, with emphasis upon all the healthy aspects, and an attempt to change all the unhealthy details.

MEDICAL REVIEW FOR INDIA

AN Indian Medical Review, the first attempt of its kind in the history of modern medicine in India, containing information on all matters of interest to the medical, nursing, pharmaceutical and allied professions, will shortly be published by the Director-General, Indian Medical Service.

Hitherto the various provinces and the Indian States have been publishing annual records of the activities of their respective medical and public health departments. The Public Health Commissioner with the Government of India has also been publishing annual reports dealing with the incidence of diseases, and vital and health statistics, but a review of the type now to be published is a new departure, and hopes are entertained that the publication will fulfil a great need.

The subjects, which it is proposed to include, cover a wide field from administrative organizations in the provinces and at the centre to statistics relating to medical colleges, hospitals and dispensaries in British India and to those under the control of the Political and External Affairs Departments of the Government of India and Mission Medical Institutions.

All about the medical world

Detailed information, it is understood, will be given in the publication about the medical profession and medical services of India, hospitals, dispensaries and nursing homes, with special reference to facilities for rural medical relief, a subject of vital interest; medical inspection of school children, post-graduate training of medical officers; x-ray and radium facilities available in India; mental hospitals and psychiatric clinics; scales of fees received from patients at the various Government hospitals; legislation for the control of practitioners of the Indian systems of medicine; Provincial and Central legislation regarding the registration and control of practitioners of the modern western system of medicine and surgery; medical education of men and women in India; history and activities of the various medical colleges and schools; the system of training of nurses, their examination, registration and conditions of service; facilities available for maternity cases and training of the midwife and the *dai*; history and activities of the important research institutions and of the Imperial Serological Department; control of pharmacy and drugs; and the work, methods and organization of the numerous medical and cognate societies.

THE JOURNAL OF INVESTIGATIVE DERMATOLOGY

ACCORDING to the 'announcement' this journal is the outcome of several years' consideration of American dermatologists on the formation of a new society and journal to be confined to dermatological research.

It is claimed that both society and journal cover a new field. This seems not strictly correct for it is

rather the splitting off from the subject of dermatology a section that up to the present appears to us to have been adequately dealt with at the ordinary meetings of dermatologists and in ordinary journals on dermatology.

However, American dermatologists probably know better than anyone else what are their needs so it is not for a foreigner to criticize this new venture. But it means that most workers outside the United States will be debarred from knowing what advances are being made in that country, for few will be prepared to increase their already heavy annual bill on standard journals of dermatology by another 6 dollars a year.

The first number contains five articles, two from abroad and three from the pen of American writers; as a sign of the present trend in dermatological research four of the articles are on the subject of allergy in one or other of its aspects.

The first number is printed and produced in the well-known and pleasing style of the Williams and Wilkins Company who print so many American scientific journals, and to anyone with a long purse and plenty of library accommodation we recommend this new journal.

MYCOPATHOLOGIA

THIS is a new journal which is apparently to be devoted to papers dealing with mycology only.

As the paper will be published in the language of the contributor, and as it is edited by two Italians and published in Holland, one will need to be an accomplished linguist to be able to use the journal efficiently. However, there are summaries in English and other languages of many of the papers.

Whilst the criticism applicable in the case of all specialist journals, namely, that they encourage the segregation of the special subject, is applicable in this case, we have little doubt that it will serve a useful purpose as a repository for highly technical papers on medical mycology. It is a great help to the specialist to have such papers collected in a high-class journal of the kind this one promises to be.

RECEPTION COMMITTEE OF THE XV ALL-INDIA MEDICAL CONFERENCE, MEERUT

Organizing Secretary: Captain R. N. Bose, M.B., Garvie Medical Library, Town Hall, Meerut, U. P.

THE next All-India Medical Conference is holding its 15th session in Meerut during Christmas week.

Besides the General Section and the Exhibition, there will be a Scientific Section where original papers will be read and discussed thus affording an excellent opportunity for members to exchange opinions with members of the profession working in different parts of India.

The scale of fees is as follows:—

	Rs.
1. Membership of Reception Committee ..	10
2. Delegate from a Branch of the Indian Medical Association ..	5
3. Other member of the Indian Medical Association attending the Conference ..	5
4. Non-member of the Indian Medical Association attending the Conference ..	8

Any medical man or other scientist can also take part only in Scientific Section on payment of a fee of Rs. 5 only.

If anyone intends to contribute a paper, a typed copy of the same with an abstract of not more than 200 words and membership fee may be sent to the organizing secretary and the title of the paper sent in as soon as possible. There will also be sub-sections of the different branches of medical science. Anyone wishing special arrangements to be made in connection with their papers should let the secretary know in good time.

The papers will be the property of the Indian Medical Association and will be published in the *Journal of the Indian Medical Association* at the discretion of the Editor.

BENGAL COUNCIL OF MEDICAL REGISTRATION

1. The Council of Medical Registration, Bengal, submitted to Government in October 1934, their recommendations for a re-allocation of its constitution under section 4 of the Act, and for the removal of some working defects by amending the Bengal Medical Act of 1914. The recommendations were repeated in their resolution of July 1936 and February 1937.

2. The Council in their resolution of January 1937 and July 1938 recommended to Government an amendment of section 19 of the Act so as to make it clear that the Council has the power to recognize or withdraw recognition of medical schools.

3. The Council's proposal for raising the fee for entry of additional medical qualifications from Rs. 5 to Rs. 25 was sanctioned by Government in February 1936.

4. The Council by a resolution in February 1937 decided upon a scheme of improving the standard of training for the Licentiates, proposing *inter alia* for raising the preliminary qualification to I.Sc. with physics and chemistry, and extending the period of the medical course from four to five years. The recommendation was repeated by a further resolution in January 1938 when it also proposed that a deputation should wait upon the Hon'ble Minister in charge to explain the urgency of the question.

5. In their resolutions of July 1937 and July 1938 emphasized the need of separate teachers for separate subjects and of improvements in other directions in several medical schools. The recognition was extended by two years and in two cases by one year within which they were required to remove the defects.

6. A standard form of inspection of medical schools and hospitals where the students received their training was adopted by the Council by a resolution in July 1938, with a view to securing uniformity and also in order to indicate to the institutions what requirements they are to fulfil.

7. At their meetings of January 1938 the Council expressed their grave anxiety regarding the financial position, and adopted resolutions that the grant from Government should be increased. The ordinary half-yearly meeting due in July 1937 had to be stopped for want of funds.

8. The Council at their meeting of July 1936 adopted a resolution that representatives from them should inspect the licentiate examinations held by the State Medical Faculty.

ABSTRACT OF THE PROCEEDINGS OF ASSAM MEDICAL COUNCIL

THE ordinary general meeting of the Assam Medical Council was held at Shillong at 10-30 a.m. on Thursday, the 8th October, 1936,* in the office of the Inspector-General of Civil Hospitals, Assam, Shillong.

Proceedings

Resolved that the Calcutta University be approached with a view to ascertaining on what terms and conditions they would be prepared to reopen the admission of selected L. M. Ps. for degree qualifications by examination.

Resolved that in the interests of efficiency opportunities be given to all compounders serving in Government, local and municipal boards other than those serving in the headquarters hospitals to attend periodical refresher courses in district headquarters hospitals.

Resolved that a strong recommendation be made to all appointing authorities that in future no individual should be appointed as a compounder unless he is in possession of a recognized compounder's certificate.

Resolved that, while appreciating the desirability of extending the curriculum of the Berry-White Medical School from four to five years, this council realized

that this cannot be done until the present four years' curriculum is brought up to a proper standard.

Resolved that the principle of registration of compounders be approved and the question now be taken up with the Government of Assam and with the governments of other provinces.

Resolved that the following reply be sent to the Secretary, Medical Council of India:—

(i) In the opinion of this Council Indian Nationals who have obtained Medical Degrees of repute in foreign countries with which there is no reciprocity should be granted recognition of these Degrees in India.

The definition of 'Degrees of repute' should be determined by the Indian Medical Council and communicated to Registrars of the Provincial Medical Councils.

(ii) The Council is of opinion that Nationals of foreign countries with which there is no reciprocity should not be recognized when they come to India until such time as reciprocity is established.

THE OPERATIONS IN WAZIRISTAN

AMONG honours conferred for services rendered in connection with the operations in Waziristan from September to December last year are the following:—

C.B.E. (Military).—Colonel R. E. U. Newman, D.B.E., M.C., M.B. (Edin.), R.A.M.C. (now retired).

D.S.O.—Lieutenant-Colonel Stanley Arnott, M.D. (Edin.), R.A.M.C.

M.B.E. (Military).—Captain V. M. Albuquerque, F.R.C.S. (Eng.), I.M.S.

Military Medal.—Lieutenant (late assistant surgeon) M. C. Condillac, M.R.C.S. (Eng.), Auxiliary Force Medical Corps, India.

Current Topics

120 Cases of Tuberculosis in Children at Batavia in 1935 and 1936*

By J. H. DE HAAS

TE BEK SIANG

and

INJO BENG LIONG

(From the Children's Department of the Central Civil Hospital and Medical College at Batavia)

(An English Translation from *Geneesk. Tijdschr. Nederl.-Indië*, Vol. LXXVII, p. 2945)

'VERY little is known regarding tuberculous infection and disease in infancy and childhood in India' (Ukil, 1937).

When, scarcely a decade ago, pediatrics in this country developed into an independent branch of medicine, it still was governed by prejudice to an extent that exceeded its dependence upon objective research. One of the stories kept current—for reasons more readily to be understood a little further on—was to the effect that tuberculosis amongst children in this country did not occur at all, or at any rate very rarely.

After a previous effort made in this direction, it is now possible finally to dispose of this notion on the strength of investigations based upon actual observation.

In 1933 an article was published dealing with 26 cases of tuberculosis in Chinese children that a year previously had been admitted into this department (de Haas,

* A paper read at Samarang before the Second Netherlands Indian Tuberculosis Congress, on 31st July, 1937; rendered into English by E. E. Power.

[This translation was accepted for publication in the Special Tuberculosis number, but had to be held over on account of shortage of space.—Editor, I. M. G.]

* Report received 11th July, 1938.

1933), in which connection the supposition was advanced—contrary to the conceptions that generally prevailed at the time—that a *systematic* investigation would readily prove that also amongst native children tuberculosis was not by any means rare; since which period there have been a few communications in the Netherlands Indies on tuberculosis in infants and children.

In addition to the demonstrations at various meetings, of children suffering from tuberculosis, as, for example, by Liem Ghik Djiang (1936) and Van Joost (1936) at Malang, by Luyke Roskott at Sourabaya (1936), Miss Bonnet at Samarang (1936), and also of children from our Batavia Clinic (de Haas, 1936, 1937; Injo Beng Liong, 1936; Te Bek Siang, 1937) more specific reference must be made to the data on tuberculosis in children in the papers read by Müller of Sourabaya (1936) and Reddingius of Batavia (1936) at the preceding Tuberculosis Day.

Between 1930 and 1936 there were brought in for post-mortem examination at Sourabaya 199 children between the ages of six months and 16 years, 25 or 12½ per cent of whom had died of tuberculosis, a mortality figure that will prove to be the same as that prevailing amongst the children in our Batavia hospital.

In the course of eight years (1928 to 1936) Reddingius observed in the Surgical Clinic at Batavia spondylitis in 33 children below the age of 15, and coxitis tuberculosa in 29 such children; that is to say, an annual average of eight cases of bone tuberculosis in children that previously must have had a primary affection.

The clinical observations made in our children's department these past several years, and the tuberculin survey amongst school-going children at Batavia published last year (Injo Beng Liong and de Haas, 1936) caused us to anticipate that tuberculosis in children could not be very rare in this country. This actually had already been determined *a priori* by the fact that pulmonary tuberculosis in adults here is quite frequent, and analogous to conditions in Europe at a former period; there is bound to be also in the tropics a considerable frequency of tuberculosis in children, in interaction with food, housing, and other social conditions.

This is borne out by the data in the subjoined table. This table contains only those cases of tuberculosis in children of which the diagnosis had been definitely determined after clinical observation. If there remained any doubt at the time that the case records were subjected to a further scrutiny, the case in point was not included amongst these observations, even though previously the diagnosis had been tuberculosis. Thus it was that the 120 cases, now to be discussed, represent the minimum number of cases which during 1935 and 1936 were given clinical treatment in our department. Actually the number undoubtedly was greater, seeing that also cases of tuberculosis must have occurred amongst the more or less doubtful instances.

In addition it occurs constantly in our department that children are admitted that die within a few hours, in which cases, provided no *post mortem* takes place, it is sometimes impossible to establish a diagnosis. Amongst these there undoubtedly also will be children with tuberculosis, as was obvious from the autopsies performed in several instances.

Furthermore the already considerable number obtained would have been still larger if it were not that pulmonary tuberculosis in children is difficult to recognize by the family physician: the stages leading from infection to illness are so broad and are marked by such very gradual transitions that the disease, indicated by symptoms that are anything but definite, in many instances is difficult to be determined, always provided that tuberculin reactions are not being made systematically. Thus it is a very rare occurrence that a child is referred to our department by the family doctor after his having diagnosed tuberculosis.

Last, but not the least, the significance of the number indicated must also be viewed in the light of the fact—already pointed out (de Haas, 1933)—that bovine

tuberculosis is practically unknown here amongst human beings; at any rate, it has not as yet been found to occur. This could not very well be otherwise amongst a population not drinking any milk, and therefore *a fortiori* any unboiled milk; and to this must still be added that it is the opinion of veterinarians here that tuberculosis of cattle in this country is of rare occurrence (Lobel *et al.*, 1936).

These same investigators, however, found human strains in pigs. They pointed out with justice that most likely these pigs had been infected through human beings, but that in their turn they again would be likely to spread human tubercle bacilli; that is to say, they would be dangerous to human beings.

As regards England and Scotland Griffith (1931) and Griffith and Smith (1935) give bovine infection in children as amounting to 17 per cent, and for the Province of Zuid-Holland Boer (1933) found 25 per cent (15 cases out of 65). Boer (1936) in Zuid-Holland found amongst adults 3 per cent of bovine infections.

It is hardly possible to represent schematically the method according to which our diagnosis was determined. The tuberculin reaction—no tuberculosis in children without a positive tuberculin reaction—was taken as its basis, to be amplified by clinical observation, roentgen photographs, bacteriological cultures and animal tests of the gastric juice or other material, and where possible also *post-mortem* particulars. With reference thereto the bacteriological examination exercises an ever-increasing importance, whilst it is impossible to pursue the course of a tuberculous pulmonary process in children without repeatedly making roentgen photographs.

Through these modern methods of research the study of tuberculosis in children for several years past has developed so rapidly, whilst the notions connected therewith have undergone such swift changes, that as yet it is impossible to contemplate the results objectively, the more so since the process referred to is still in course of rapid development.

Thus it is not likely to have been a mere coincidence that Huet, the Netherlands physician with the greatest experience with reference to tuberculosis in children, transmitted his study on the clinical course and the treatment of pulmonary tuberculosis in children (Huet, 1932) to a younger colleague with the admonition: 'Be careful about accepting what is contained herein'; a symptom of modesty that indicates an amount of experience which, in addition to caution, more specifically inspires respect.

It is self-evident, however, that one of the first surveys concerning tuberculosis in children in the Netherlands Indies will have to be envisaged upon the basis of the above-quoted saying, whilst also the data having reference thereto, the most important of which have been comprised within the subjoined table, may prove to be not altogether devoid of significance.

This table permits of the following conclusions being drawn:—

1. Of the 120 tuberculous children observed, 30 were infants less than one year of age.
2. Both in infants and in children above one year of age the fatality rate is not less than about 40 per cent.
3. Of the infants admitted in the course of these two years approximately 2½ per cent suffered from tuberculosis.
4. Of the children above one year of age admitted within these two years 7 per cent suffered from tuberculosis.
5. Of the infants that died in our department in the course of this period 3 per cent died of tuberculosis.
6. Of the children above one year of age no less than 13 per cent died of tuberculosis; this being a striking correspondence in mortality with the above-mentioned *post-mortem* rate of 12½ per cent, published by Müller of Sourabaya.

The fatality rate can be unfavourably effected through only serious cases having been sent for treatment, though this is hardly likely to have been the case with reference to infants, seeing that of 48 infants

TABLE

Age and racial classification in 120 cases of tuberculosis in children at Batavia in 1935 and 1936

Classification	INFANTS		CHILDREN		TOTAL		MORBIDITY, PERCENTAGE (a)		MORTALITY, PERCENTAGE (b)	
	Total	+	Total	+	Total	+	Infants	Children	Infants	Children

Fatality ..	50 ± 9.1		39 ± 5.1		42 ± 4.5					

(a) With reference to the total number of children admitted to the department during 1935-36.

(b) With reference to the total number of deaths in the department during 1935-36.

(c) Of which 67 were children between the ages of one and four years.

(d) Of which 25 were children between the ages of one and four years.

(e) Not including three children taken away in dying condition by their parents.

with tuberculosis that were admitted to the Amsterdam Children's Clinic between 1928 and 1934 (and with reference to which it is very likely that the diagnosis could have been formulated earlier), also one-half died (De Lange and De Bruin, 1935).

But even if it were true that the number of children sent for treatment to our department, and that die there, would hardly represent proportionately the amount of children's disease and child mortality within this city, at any rate, it cannot be denied that the picture presented by our department in this respect leaves an approximate impression of the suffering of infants and children in the native and Chinese quarters of Batavia.

Subject to the above-mentioned restriction this would signify that of the approximately 5,000 infants less than one year of age that annually die in Batavia (de Haas, 1936) 150 succumb to tuberculosis; whilst of the approximately 2,500 children over one year of age that annually die in our capital, fully 300 will have died of tuberculosis.

According to this estimate, which actually is far less unsupported by evidence than one would like to believe, about 500 children annually die of tuberculosis in Batavia, whilst at a fatality rate of 40 per cent. 1,000 to 1,500 children would be suffering from tuberculosis as a disease. Once again it must be pointed out with emphasis that the figures here adduced do not pretend to represent the exact frequency. If the fatality rate within the city is less, because it is possible that in our department the relatively severer cases are submitted for treatment, then the total number of children suffering from tuberculosis will be still greater than the figure here calculated.

Even those to whom the affliction of parents and of children at Batavia remains *terra incognita* will hardly fail to realize that tuberculosis in children here, far from being rare, is particularly frequent, both amongst the native and the Chinese population, even though the figures given are only approximately correct, and even though it be fully realized that the havoc wrought by tuberculosis amongst children here represents but a minor part of the high mortality amongst infants and children, principally determined by entirely different factors.

In 27 out of the 120 cases observed the contact person could be indicated, whilst in practically all instances there must have been infection through a person with open phthisis. Blacklock (1932) some years ago pointed out how difficult it was in Europe to discover such contact persons. It need hardly be

emphasized that in the more primitive tropics such difficulties are still greater, in fact insurmountable sometimes.

It is probable that some improvement can be made in this respect by systematic house visiting, whilst on the other hand again, through the systematic tuberculin survey and general examination of children in whose surroundings a tuberculous adult has been discovered, the early infection of children can readily be established.

Upon admission to our department, it is true, the tuberculin reaction is systematically applied, but in 18 out of the 120 cases this could not be done because of the death of the child ensuing within a few days after its having been admitted. Of the 102 von Pirquet reactions applied, 75 were found to be positive, 73 ± 4.4 per cent. Von Pirquet (1907) himself already knew that children with a serious form of tuberculosis may exhibit a negative cutaneous reaction.

From the end of 1935 onward it became customary with us to apply, besides the von Pirquet reaction, also that of Mantoux, usually in a 1 in 5,000 dilution, but also sometimes, if previously tuberculosis diagnosis was considered to be likely, with a 1 in 100,000 dilution, so as to prevent a too severe reaction. In this way the Mantoux reaction was applied to 67 out of 120 tuberculous children: of these 49 (73 per cent) reacted positively, which is approximately as many as reacted in this way upon the application of the von Pirquet reaction.

In 14 negative cases upon applying Mantoux (1 : 5,000) the tuberculin reaction could be repeated after three or four days with Mantoux (1 : 100), whilst in two instances Mantoux (1 : 100) was applied immediately. In 13 of these cases the reaction resulted positively.

Thus with the Mantoux reaction in 69 children the total positive cases in tuberculosis was 62 = 90 ± 3.6 per cent. A negative Mantoux reaction occurred only in succumbing (cachectic) conditions, one or two weeks prior to the child's demise. The difference with the von Pirquet reaction, which provided a percentage of positive cases amounting to 73 ± 4.4 per cent, is devoid of statistical significance, and would probably have been smaller had the von Pirquet reaction been repeated.

The negative tuberculin reactions, sometimes even where Mantoux (1 : 100) was applied, in some children with tuberculosis shortly before their demise, are apparently opposed to the rule above laid down: no tuberculosis in infants or children without a positive

tuberculin reaction. But in the nature of things this rule applies to children that are ill, and not to such as are already dying. Even in children that are on the point of succumbing to tuberculosis a negative Mantoux reaction is rare.

Only in 12 out of the 120 children no active pulmonary divergences were found, but the symptoms indicated spondylitis 3, coxitis 2, lymphomata 3, tuberculosis of the kidney 2, and scrofula 1. Practically all (108 children), therefore, suffered from pulmonary tuberculosis with or without its relative complications.

This short synopsis does not allow of a detailed discussion of the nature of the pulmonary divergences that were observed in connection with these children. Their differentiation, with reference to which the physical examination plays but a minor part—and it is this which enables us to understand why formerly it was believed that tuberculosis in infants and children was but a rare occurrence in this country—even with roentgen control is so difficult that it is impossible to sketch in brief these difficulties which even at the dissection table may still present themselves. Definite correspondence of clinical with roentgenological, and of roentgenological with *post-mortem* results, is quite rare.

Here it is simply pointed out that in 67 out of the 120 children pulmonary infiltrations were observed roentgenologically, nine of these were combined with pleuritis. Of the five primary complexes three were found upon *post-mortem* examination. The so-called pulmonary hilus divergences represent those roentgenological phenomena that are most difficult to interpret. Less hesitation is sometimes shown in diagnosing swollen tracheo-bronchial glands.

Of the 50 that died, 36 children died of meningitis and/or miliary tuberculosis, and 14 of other tuberculous deviations. Of these latter, four children had a generalized tuberculosis (two with tuberculosis of the brain, without meningitis), eight a progressive pulmonary tuberculosis with or without cavitation, whilst in the case of one child that had succumbed, the tuberculosis had been complicated by paratyphoid A, and in another by bacillary dysentery.

All these forms of tuberculosis in children and infants occurred both amongst native and Chinese children, they having been described already in the latter in 1933. The surmise then expressed, to the effect that native children in Batavia, after their infection with tubercle bacilli, could pass through the *identical* forms of tuberculosis and were threatened with the *identical* complications (tuberculous meningitis, general dissemination, infiltration, cavitation, etc.) as were children in Europe, is now being confirmed most convincingly.

The considerable frequency of miliary disseminations represents the most striking proof thereof. Thus amongst the 53 native children, tuberculous meningitis was observed in nine instances, amongst the 63 Chinese in 19 instances, and amongst the four European children in two instances; that is to say, in no less than 30 cases (12 of which were infants) of tuberculous meningitis in a total of 120.

In nine of these 30 children with meningitis a general miliary tuberculosis was found to exist, whilst in the case of nine other children a miliary dissemination was diagnosed (roentgenologically or *post mortem*) without meningitis accompanying it.

Seeing that only three out of the 16 native children, and only 12 out of the 32 Chinese children that had died could be subjected to a *post-mortem* examination—this small number of autopsies represents a very serious hiatus in this investigation—it is quite possible that cases of miliary tuberculosis without meningitis were not recognized as such, because even in the roentgen photograph the miliary dissemination may be difficult of interpretation.

The number of cases of meningitis (30) and of miliary dissemination without meningitis (9) together, therefore, amount to at least 39, or three-fourths of the 50 deceased, and this does not include three children with meningitis or with miliary tuberculosis that were removed in dying condition by their families.

As is the case in Europe, and therefore also amongst native and Chinese children, miliary dissemination and meningitis represent the complications most to be feared in pulmonary tuberculosis, and this the more so as the child is younger. Wallgren (1935) has very correctly pointed out that the treatment of tuberculosis in infants and children must mainly be directed, therefore, to the prevention of miliary dissemination, and that this can be attained by means of prolonged rest under adequate hygienic conditions.

For the Netherlands Indies this signifies (in so far as this need still be argued after what has been said above with reference to the frequent occurrence of tuberculosis in children) that here also children's sanatoria, where the little patients in the first instance must be regarded as children and not as pocket editions of adult tuberculous patients, are indispensable if in the treatment of tuberculosis in children one does not wish to fall back upon an amateurishness that is as costly as it is harmful. It may be pointed out with considerable satisfaction that in the course of the current year the first children's sanatorium is being opened in the Netherlands Indies at Batoe in East Java. It is to be hoped that it can be managed on a pediatric basis, and that this laudable example may soon find emulation.

In combating tuberculosis in children any sanatorium, to be established in the Netherlands Indies, can but play a minor part, for the main point in this connection is the improvement in social and hygienic conditions, a proposition which Dinger (1936) has maintained also with reference to the campaign against tuberculosis amongst adults in this country and which, on the basis of very wide European experience, cannot possibly be contradicted. As Varrier Jones (1937) put it: 'The result would be cheaper than hospitalization, in cash and moral'.

Together with this, however, the significance of the isolation of adults with open tuberculosis—the source of infection of children—must not be underestimated.

Some years ago it would appear as if not only adult sufferers from open tuberculosis represented a source of infection for children, but also that children could easily infect each other. Armand Delille and Vibert in 1927 re-called that as early as in 1898 Meunier had already proven the existence of tubercle bacilli in the stomach contents, removed before food had been taken, of children that had swallowed the coughed-up mucus.

This method, practically forgotten, not only proved to be a very satisfactory one, but at the same time caused the problem of so-called open tuberculosis in children to assume within a very short space of time an entirely different aspect (whilst also in the case of adults it becomes of even greater significance). A summary of the literature thereon was published by de Haas (1932), in the course of which it was explained why, though it may not be neglected, the mutual infection of young children need not be given too wide a significance.

Since then this method has been applied regularly in our department, in the manner indicated by Jensen (Poulsen, 1932), to children with a positive tuberculin reaction, even though clinically and/or roentgenologically no divergences were found. The bacteriological examination—culture or animal test—was performed in the medical laboratory at Batavia.

In 88 out of the 120 children the gastric juice could be examined in this manner. The culture and/or animal test in the case of no less than 50 children was found to be positive: a result which sufficiently indicates the significance of the bacteriological examination also in the tropics, without it being necessary to enter more deeply into the subject.

It is nevertheless probable that the number of positive bacteriological examinations could have been still greater, in view of the fact that in some instances where there were extensive pulmonary divergences, though the tuberculin reaction was positive, the bacteriological outcome proved to be negative.

With this the bacteriological examination of the spinal fluid turned out positive 22, of which 18 with

gastric juice that was negative or had been left unexamined. In addition in the case of seven children tubercle bacilli were found in other material bacteriologically examined (urine 3, pus from lymphomas 3, a streak preparation from an ulcer of the cornea 1) of which four had negative or untested gastric juice.

All in all, therefore, in $50 + 18 + 4 = 72$ out of the 120 children tubercle bacilli, in every instance of human origin, were found to be present in one of the body fluids indicated.

To the two common children's diseases of which the diagnosis has long since been based upon bacteriological examination, i.e., typhoid and bacillary dysentery, a third has been added in recent years, namely, tuberculosis. The significance of bacteriology in pediatrics in the tropics, where these three diseases are of daily occurrence, can hardly be exaggerated, quite apart from the indispensable assistance which is afforded by the bacteriological examination in specific infections, and by accidental affections that are of less frequent occurrence.

The support of other so-called accessory sciences is of no less importance, whilst epidemiological orientation has become indispensable. If, therefore, one desires to obtain a correct insight into the considerable significance of tuberculosis in infants and children in these countries, instead of relying too greatly upon mere impressions, then it will be necessary that, side by side with the physical and pathological anatomical examination, the study of tuberculosis in infants and children must become based upon a *systematic* tuberculin examination, a *systematic* roentgenological examination, and a *systematic* bacteriological examination.

This research was carried out with the aid of the Queen Wilhelmina Jubileum Foundation at Batavia.

Summary

1. In the children's department of the Central Civil Hospital and Medical College at Batavia there have been observed, in the course of the two years 1935 and 1936, at least 120 cases of tuberculosis in 53 native, 63 Chinese, and four European children.

2. Of the 120 cases one-quarter were infants and three-quarters were children over one year of age.

The fatality rate averaged about 40 per cent. The hospital morbidity in infants and older children was 2.6 per cent and 7 per cent, respectively, with reference to the total number of patients admitted, whilst the mortality was 3 per cent and 13 per cent, respectively, with reference to the total number of deaths in the hospital.

3. In Batavia, and probably also in the whole of the Netherlands Indies, tuberculosis frequently occurs amongst native and Chinese children, and must be regarded as a serious disease.

In spite of opinions to the contrary, previously expressed, the undeniable relation existing between tuberculosis in adults and in children appears to hold good also for the Netherlands Indies, as was to be expected.

4. The native and Chinese children in Batavia, after having been infected with tubercle bacilli, pass through the identical forms of tuberculosis and are subject to the same complications as are children in Europe similarly affected.

In addition to sanatoria for adults, and not merely as an annex thereto, children's sanatoria should be established on a pediatric basis in the Netherlands Indies.

5. The diagnosis of child tuberculosis in this country is based upon the tuberculin test, there being no child tuberculosis without a positive tuberculin reaction.

The few negative tuberculin reactions in children with tuberculosis just prior to their demise do not constitute actual exceptions to this rule.

6. In the case of 102 children the von Pirquet reaction was applied (without being repeated) and was found to be positive in 75 cases, or 73 ± 4.4 per cent.

In the case of 69 children the Mantoux reaction was applied (1/100 after 1/5,000); this proved to be positive in 64 cases, or 92 ± 3.3 per cent.

7. Of the 120 children 12 were without active pulmonary process (3 spondylitis, 2 coxitis, 3 lymphomata, 1 tuberculosis of the kidney, and 3 scrofula).

8. In the case of 16 out of the 120 children military tuberculosis was diagnosed, seven without meningitis. The total number of meningitis cases was 30 in 50 of those diseased.

Also here military diffusion, with or without meningitis, is the complication most to be feared (39 cases out of 50 deaths) in connection with child tuberculosis.

9. In 88 cases the gastric juice was bacteriologically examined, and in 50 instances tubercle bacilli were found.

10. Of the 22 children with tubercle bacilli in the spinal fluid there were 18 whose gastric juice either had been negative or had not been examined.

From other material (pus, urine, etc.) tubercle bacilli were cultivated seven times, out of which the gastric juice had been found to be negative or had not been examined four times.

In the case of 72 out of the 120 children, therefore, the diagnosis of tuberculosis was confirmed bacteriologically (animal and culture experiments in the Central Medical Laboratory at Batavia).

11. In addition to the physical and the pathological examination, in the tropics the study of tuberculosis in children should be based upon a *systematic* tuberculin examination, a *systematic* roentgenological examination, and a *systematic* bacteriological examination.

Communities are still to be found where ignorance and prejudice prevail to such an extent that any measure of control appears almost impossible of application. The first point to consider is whether tuberculosis exists to any great extent in such a community. The hospital records are not always to be depended upon to furnish very accurate returns; in the first place, the rapidly fatal case common in primitive communities never enters hospital; secondly, with a busy out-patient department and crowded wards differential diagnosis is not easy and the diagnosis of bronchitis not infrequently conceals the damage which should be laid to the credit of tuberculosis. The only certain methods of ascertaining, with some degree of accuracy, the amount of tuberculosis present are the tuberculin test and post mortems. Local prejudice is less easy of solution, but as long as schools, police forces and jails exist, material will be found for investigation. Where an aversion to the introduction of medicines under the skin is met with, Craig's test is especially useful, as the extra O. T. is wiped off and the puncture does not appear to the untrained observer to introduce the material into the body. Actually, in most parts of the tropics, injections are largely demanded by the inhabitants who see in this method of administering medicaments a great improvement on

the old-fashioned way of merely swallowing them, so that intradermal tests should not arouse any great antipathy.

The acquisition of information through the medium of post mortems is sadly hampered in many parts, especially where the population is of the Mohammedan faith. Routine autopsies are out of the question, but the keen medical officer will always be on the look out for opportunities furnished by post mortems required to be done in the interests of the law. The records of these can furnish a good deal of information if they are performed with an eye to general interest as well as to the ascertainment of the actual cause of death. Again, a considerable amount of information may be acquired by the use of the x-ray. It is true there are still areas where no x-ray apparatus is available, but these are becoming fewer in number, and time spent on carrying out as large a series of screenings as possible would yield a great deal of valuable information. The correct assessment of the presence or absence of thoracic disease requires practice but experience soon brings a reasonably high standard of proficiency. Nowadays, there are screens on the market which give as clear a picture as one could possibly desire.

Once information has been acquired regarding the amount and type of tuberculosis present measures have to be considered in relation to the control of the disease if it is, or threatens to be, a public health problem of any magnitude. In work of this nature there is only one royal road to success and that is concentration on the family as a unit, not on the infected individual alone.

This is especially necessary in communities where the people live in rural or semi-rural conditions. As soon as an open case is detected, every effort should be made to carry out as efficient isolation as may be obtained. Conditions vary so much that it would be foolish to lay down any specified methods, there are places where the disease is regarded with so much horror that the unfortunate sufferer is practically left to care for himself; elsewhere no notice is taken of the condition and the whole family is exposed to intense infection. As far as possible two measures should be enforced, namely, the cleanly disposal of sputum and the placing of the patient in the open air for as many hours of the day as possible, but guarded from the direct rays of the sun. In some cases an ordinary calabash filled with wood ash forms an excellent receptacle for sputum or an issue of old tins containing a small amount of liquid disinfectant will suffice. Where feasible the contacts should be tuberculin tested and screened and the regular issue of a little medicine, especially cod-liver oil, to the children, often suffices to ensure their regular attendance at a hospital out-patient department for a considerable period, thus enabling them to be kept under observation.

In a community such as outlined here, the tuberculosis dispensary can serve no good purpose, its place as a clearing centre can be filled to better purpose by the district hospital. To set up a dispensary before its proper function is appreciated by the population it is intended to serve would merely be a waste of time and money. It resolves itself into keeping up another out-patient department, as those with all and every ailment would go to it for treatment. Once simple anti-tuberculosis measures are set going over a wide area and the inhabitants begin to appreciate their significance then the time is ripe for the first step in organized work, the erection of the tuberculosis dispensary. Nor does this entail considerable expense: the erection of a simple structure with room for expansion is much more desirable than the usual type where limited waiting accommodation aids the spread of infection; here patients, healthy adults and children may have to crowd in together and the dispensary unwittingly becomes the centre for further dissemination of infection. The best type of building is that built well off the ground so that shelter from rain or sun may be obtained under the structure with no restriction on ventilation. It should be in a central

position, easy of access, though not on too commanding a site in order to avoid attracting undesirable publicity. On the other hand, to site such a dispensary in some remote corner on the farther edge of town or village, encourages people to be secretive, and the idea that tuberculosis is something to be ashamed of gains ground.

In the early stages any attempt at introducing treatment requiring regular attendance is likely to meet with failure; the unsophisticated native is at a loss to understand either the nature of the treatment or the need for its repetition. A judicious selection of cases with minimal progressive lesions for treatment by phrenic evulsion is recommended, it only requires a few successes to induce others to come forward. Even in these more backward communities there is always one section that will respond to intelligent propaganda and seek treatment, namely, the clerical and administrative subordinate staff and school teachers. If a start can be made by detecting early cases amongst this class and active collapse instituted, the results will attract widespread attention. Patients drawn from this class ensure better results, they are capable of understanding the principles of treatment and their circumstances are such as to permit of rest for a prolonged period and a reasonable standard of nourishment. Such cases amply repay the trouble and care expended on them if they are carefully selected and their progress attentively watched. One demonstration of the efficacy of artificial pneumothorax is worth a score of hygiene talks. Hitherto, in many parts even amongst the educated natives, their attitude has been that tuberculosis is one hundred per cent fatal and while they may seek advice it is only in the last stages when despair drives them to try medicines, in which they have no real faith. The infiltration of the news amongst the better educated portions of the populace soon extends even to the most ignorant.

Once the desire for treatment is aroused in the minds of the people the question is how to carry out such treatment in circumstances that will make the patient feel at ease and yet will enable the medical man to administer it under optimum conditions. The answer appears to be the setting up of small communities where sufferers may live under conditions resembling their habitual environment and yet permitting of reasonable isolation and continued attention. Cummins describes the work of Swiss missionaries in Portuguese East Africa who have developed a 'tuberculosis village' in which the patients are cared for and fed by their own relatives, and yet treated and supervised by medical men who understand them and can fathom their prejudices and anxieties, instilling confidence in them by this appreciation of their mental processes. The huts are inexpensive to construct, and when vacated on account of death or removal can be burnt down.

Stones, discussing the problem of tuberculosis in Uganda, suggests that sanatorium treatment will not suit African needs, but village settlements appear to be the solution. The patient, once treatment is successfully under way, could carry on trades as is done in settlements at home, especially such employment as is suited to his needs and training. He quotes the suitability of experimental small-holding schemes of the Uganda Department of Agriculture for such settlements. He puts the matter very aptly when he says 'segregation with contentment should be our watchword'. The excellent work done by missions in connection with the maintenance and treatment of lepers might well be extended to village settlements for the tuberculous.

The above measures, elementary though they appear, if energetically carried out should have a decisive effect in checking the extension of the active disease. In no part of the world, save, perhaps, amongst a few primitive hill tribes or remote jungle dwellers, will tuberculosis ever sweep through the community as it did among the North American Indians; infection is now too general. Kleine commenting on anti-tuberculosis work carried on in Africa, with especial

reference to that of Wilcocks, asserts that any fear of the disease assuming epidemic proportions, even in remote regions of East Africa, is groundless. The slow gradual infection of whole populations that is taking place is a sufficient guarantee against the repetition of the disasters seen in the past.

Control of tuberculosis in developing communities

As these communities develop and present possibilities of gain to the pioneers of commerce and industry, the problems of defence against tuberculosis become more difficult. One of the most important sources of infection from outside is the entrance of the petty trader, so often one of the oriental races, who carries with him the organisms of disease readily enough but fails to bestow along with these unwelcome gifts those elements necessary for rapid and effective immunization. This invasion, mainly by Indian and Arab traders, is general throughout Africa. Rodhain was of the opinion that the disease was spread in Belgian Congo by Arabs and Baluchi traders as well as by Europeans. Elsewhere the same process has been observed. The writer has had clear evidence of the spread of tuberculosis through an area in British North Borneo, densely populated by a primitive tribe, following the setting up of shops by Chinese traders. In areas where traders are already established in large numbers little can be done in the way of special prevention by forbidding their entry, but in sheltered communities any infiltration by such traders ought to be more strictly controlled by the medical department.

The part that should be played by Government control during this evolutionary process is admirably set out by Young who, as the result of his experience in West Africa, affirms the theory that equality cannot be present as between immune and non-immune peoples. This lack of resistance clearly renders rapid urbanization a most undesirable process for native races. Young would reverse the usual process of bringing the native to the city by erecting townships in outlying districts. In planning for these, the density of the population would be limited by restricting the number of buildings to be erected on any given area. Moreover, he would place upon industry the burden of housing its workers in decent manner. These two measures would lead to the setting up of small townships extending out into the bush instead of becoming grossly overcrowded at the centre. No industrial concern would be allowed to commence operations until it owned, or obtained an option on, land in its immediate vicinity to supply sufficient accommodation for houses for all its workers and their families. This measure would prevent the setting up of new works in the heart of an already overcrowded town and the enticement of rural dwellers to flock to the town and enter the unhealthy environment associated with urban employment. If groups of industries were established along these lines small townships, limited in size, could be set up which would be sufficiently near the agricultural areas to enable workers to obtain their natural foodstuffs cheaply and further would not estrange them entirely from their old methods of living.

It is in these gradually evolving communities that survey methods are so necessary; by tuberculin test and fluoroscopy it should be possible to watch the progress of infection and to circumscribe the more dangerous foci of disease. The establishment of a tuberculosis dispensary would be a measure of great practical value; the community has now outgrown the limited resources of the district hospital and its individual members have attained the stage where they may be expected to make intelligent use of such a centre. Along with the erection of a dispensary there arises the problem of providing a specialized medical staff. Once again we are faced with the question of the relative importance of tuberculosis compared with other diseases and the necessity for deciding whether the additional expense of the appointment of a phthisiologist is justified. In the more backward communities the best person to handle the problem is the district medical officer; he has a sound all-round

knowledge and if necessary should be encouraged to take study leave to make himself *au fait* with the more technical aspects of tuberculosis treatment. In communities where development is proceeding, the health officer, in co-operation with the staff of the district hospital, should be made responsible for anti-tuberculosis measures. One cannot recommend the appointment of specialist officers at this stage; the extra expense is not justifiable; further, most tropical countries have in their service men with post-graduate experience of tuberculosis work. An experienced officer of this kind could be seconded for a time to formulate a plan of campaign and to assist in dealing with special aspects of the task.

There is also the question of a subordinate staff and the problem of obtaining an efficient personnel for such a staff from among the local inhabitants. To expect to be able to produce a highly trained and certificated staff from a community slowly evolving out of a primitive state would be foolish. On the other hand, to import such a staff from Europe would be beyond the means of most communities if it were to be devoted entirely to tuberculosis work. It is not necessary to demand a high standard of training for such health visitors; in the first place, a course of training in the local hospital of sufficient duration to enable them to understand the elementary facts about the treatment and prevention of disease should be arranged. To undergo this training women should be selected, who have had a reasonable degree of education, and are possessed of common sense and a good moral standard. The mission or religious body that cannot produce such women nowadays from amongst its adherents is rare indeed. They need not be capable of solving difficult nursing problems, but they must be able to do hard work, face rebuffs with quiet patience and show a quick sympathy and understanding and unquestioned loyalty. Given these qualities the development of such a woman, of whatever race, into a first-class social worker is a matter of time and largely dependent on the ability of the medical officers to mould her into the desired pattern.

The presence of a dispensary raises the question of hospitalization, and it should be met at this stage by granting accommodation in the general wards of the district hospital to cases fit for collapse therapy, and if possible the erection of a separate ward for advanced cases requiring isolation. The gradual introduction of artificial pneumothorax treatment would probably meet with a reasonable degree of success, since in a community developing along normal lines there is a greater tendency for the population to become fixed and a lessened desire on the part of the individuals to bolt into the bush when they encounter something they do not understand.

The control of tuberculosis in municipalities and townships

In an established and long urbanized community the interested medical officer need search no longer for the existence of tuberculosis, but it is more necessary for him to study the trend of the disease in relation to economic and racial factors. Crockett emphasizes this fact when he says that despite the exposure of many successive generations and the improvement in the standard of living in the United Kingdom the incidence of the disease is no less. What has altered is the character of the malady since the rapidly progressive case is less often encountered, but much of the disease is of the concealed or latent variety. The need for careful surveys and examination of all available pathological evidence still continues and should not be neglected, if time is available, simply because routine methods of treatment have been organized along recognized lines and it is felt that there are no new fields to conquer.

In any urban area the establishment of a tuberculosis dispensary should be an accomplished fact, whether the local authorities or Government are responsible for its upkeep. The number of large towns throughout the tropics without any tuberculosis centres is surprising,

especially as many are quite capable of undertaking the financial responsibility for such a project. It is more often due rather to fear of heavy financial commitments than to actual apathy; few realize that a dispensary can be run without any exaggerated expenditure. In urban communities where there is a responsible and well-to-do section, every effort should be made to encourage these better-class people to take a share in the work by providing financial aid and by working on committees in connection with the dispensary. Nor should the dispensary physician be content to work only at the dispensary; other preventive measures should be encouraged. The routine examination of school-children might well include monthly weighings and those who have lost weight should be examined clinically and by fluoroscopy. Hetherington states that latent apical tuberculosis of adolescents causes moderate loss of weight in some but not in all cases. As a rule, however, the writer has found that the scales form a good guide, and indicate the necessity or otherwise for further examination. Another method of prevention should be the fluoroscopic examination of school teachers at regular intervals; not only will this aid detection of cases, but it also has definite value as propaganda and interests the teachers in the question of tuberculosis.

In the smaller township, if such a one is available, a health officer who has held a resident appointment in an up-to-date sanatorium at home should be responsible for the tuberculosis work in addition to his other duties. In many of the large tropical towns the prevention of tuberculosis is rapidly becoming the most important health problem and the appointment of a full-time tuberculosis officer is no longer a luxury, but a necessity. In such areas the required standards for health visitors may well be raised and the posts filled by fully trained local nurses, especially those in possession of a health visitor's certificate.

Nor is the simple tuberculosis village alone able to meet the demands of a sophisticated community; the provision of more orthodox institutional treatment has to be considered.

There is no doubt in the minds of most tropical workers that the results of treatment are sufficiently good to justify the provision of tuberculosis institutions. To view the question solely in the light of direct results of active treatment is a mistaken policy. The propaganda effect of modern therapeutic methods is far more important than the end results alone. Nor must we forget the public health aspect of successful treatment lessening the number of infectious cases at large. Especially is this evident in ambulatory A. P. treatment, as by these means we are enabled to deal with those who refuse any but the minimum institutional treatment. Frimodt-Møller claims that of 807 patients traced after their discharge from his sanatorium in India after five years 54.5 per cent were still alive. Results such as these indicate that it is wrong to adopt the hopeless attitude so common in the past. If institutional treatment is to be carried out and the necessary resources are available, the erection of a hospital for all types of cases is indicated and not just a sanatorium for early cases.

Crocket advocates the establishment of a sanatorium to deal with all stages of the disease, from the hospital for its advanced cases to the labour colony for the convalescent ones. Those are exactly the lines that should be followed in the tropics. To build in one corner a lazaret for the dying and to erect on a different site a sanatorium for those who improve means that the advanced case will never seek hospitalization, unless he is absolutely forced by legal or economic requirements. But if within the same compounds we have all the necessary accommodation for each stage of the disease the sufferer will readily seek admission; even if he is assigned to the advanced wards, he sees about him those who have improved and the hope that it will not be long before he is able to cross the compound into the convalescent wards is ever present with him.

The hospital should be as near to the town as is consistent with ample accommodation and grounds; distance means transport and few natives are sufficiently well off to pay even the few cents required for their regular conveyance to and fro. This means that visits by friends and relatives are limited and furnishes an additional reason for not entering hospital. Even in tropical countries where sites are available in the hills, it appears inadvisable to make use of such sites on account of their distance, except for those able to afford the cost of transport. Suitable accommodation for those able to pay must be provided. Paneth as a result of his experiences in Java urges the necessity of establishing the principle of patients contributing whatever they can afford.

No tuberculosis hospital is going to get the best results if it can only obtain its cases when they have reached an advanced stage. The best way of obtaining cases in a reasonably early stage, apart from contact work, is by continuous propaganda. The tuberculosis officer must be prepared to speak in season and out of season; to-day in the tropics there are springing up innumerable societies for young men and women and these always welcome health talks. Propaganda amongst school teachers is one that brings the best returns; the teacher holds a very definite position amongst his or her neighbours and his advice is more often sought than may be the case in this country. Pictorial propaganda should be employed extensively; posters, magic lantern slides, cinematograph shows have all a great appeal. One thing they require, however, is local colour, as far as possible they should be prepared on the spot, those from abroad often fail to impress natives because they portray surroundings unfamiliar to them.

In view of the fact that early and energetic treatment is producing good results, even amongst the less resistant races, it is necessary to consider the question of after-care. Carter who had a wide experience of tuberculosis among the negroes of the U. S. A. said that tuberculosis is curable in the negro, but that he is so prone to return to his careless habits and to enter unsuitable occupations that the mortality after leaving the sanatorium is frightfully high. Frimodt-Møller at the Union Mission Sanatorium in the Madras Presidency has set up the nucleus of a tuberculosis colony to provide a living for poorer patients who leave the sanatorium in sufficiently good health not to require further treatment, but as yet not fit to earn their living by ordinary means. A small silk farm has been established and the product enables eight patients to earn a sum of money equivalent to what they would gain in ordinary manual employment elsewhere. In order, therefore, to give patients time to be completely restored to health, every effort should be made to establish after-care centres where remunerative and useful employment may be obtained.

The use of B. C. G. has not been stressed in view of the controversy still raging. It has been employed in Mauritius, but no results are available as yet. B. C. G. has been used in the French colonies since 1925 with apparently very satisfactory results. Toullec furnishes results from Dakar where the mortality among the vaccinated infants has fallen from 25 per cent to 10 per cent, whereas no appreciable decline has been noted in the unvaccinated groups.

The place of legislation in the anti-tuberculosis scheme requires careful consideration and Matthews has summed it up in a sentence that every tuberculosis worker would do well to commit to memory 'When a native thinks his disease can be cured or materially eased by medical aid, no law will be required to make him seek it'. The writer adheres to his view that it is a useful weapon to have in reserve, but it should be employed only as a last resource.

There are still many parts of the tropics where the native denied the treatment necessary for the arrest of tuberculosis would, if he but knew them, echo in his heartfelt manner those well-known sentences of Trudeau who recounts in his autobiography something of his feelings on being told that he had pulmonary

tuberculosis. 'Black despair filled my heart; I think I know something of the feelings of the man at the bar who is told he is to be hanged on a given date, for in those days pulmonary consumption was considered as absolutely fatal.'

To-day much is being done to remove that feeling of hopelessness still present in less fortunate lands. Blanchard outlining the measures employed in French West Africa says that expansion of facilities for hospitalization and treatment is being actively pursued in all the French colonies.

Much more has yet to be accomplished; de Langen and Lichtenstein write 'Tuberculosis must come to form the most important problem of all tropical countries before very long. It is amazing to see with what degree of apathy the increase of tuberculosis is being regarded in East Asia. Millions are being spent annually for the eradication of leprosy, while for the fight against tuberculosis a few paltry thousands have with difficulty been raised. The mortality statistics of the Philippine Islands over the ten years ending

1930 show the relative importance of these two diseases to the community in a most striking way; out of every thousand inhabitants 54.1 died in the course of ten years from tuberculosis; 0.27 died of leprosy. The mortality from tuberculosis was, therefore, just over 200 times as high as that from leprosy; the difference in morbidity may well be left to the imagination! The time will come, and that right soon, when this ostrich-like policy will have to be set aside, and the terrible scourge that is threatening the East be met face to face'.

British Guiana is a small country situated right in the tropical belt, it has scanty financial resources despite its potentialities and is largely populated by a race peculiarly susceptible to tuberculosis. Yet to-day it can boast of having an active and efficient organization to deal with the menace of tuberculosis and a mortality rate from that disease (0.8 per 1,000) which many a greater and richer tropical region might well envy. What has been done there may be accomplished elsewhere.

Reviews

LEPROSY: DIAGNOSIS, TREATMENT AND PREVENTION.—By E. Muir, C.I.E., M.D., F.R.C.S. (Edn.). Sixth Edition. Published by the Indian Council of the British Empire Leprosy Relief Association, New Delhi. 192 pages. 85 illustrations

This is called the sixth edition of this book but actually it is a completely new book. The old edition had only 73 pages and a few illustrations, while for this edition the text has been entirely re-written and is nearly three times as long, while the illustrations are better and much more numerous. In the work of revision the author has been fortunate in obtaining the active co-operation of Dr. J. Lowe, his successor in Calcutta. As the author states in the preface, the book is issued primarily for the use of doctors in India, but it is hoped that workers in other countries also will find it useful.

The book is divided into three sections. The first and longest section deals with the history, epidemiology, bacteriology, clinical and histological features and diagnosis of leprosy. A feature of this section is the linking together of clinical and histological findings. Thus, for example, the histology of normal skin is described and then the clinical and pathological changes produced in it by the different forms of leprosy. The same plan is followed for nerve lesions. It is clearly brought out that the difference between the two main types of leprosy (here called 'neural' and 'cutaneous' according to the 'Manila' classification) is not primarily a difference in the site of the lesions but a difference in the nature of the tissue response to infection. This idea—that the varying types and degrees of tissue response to the invasion by the bacilli are the underlying cause of the widely varying clinical manifestations of leprosy—is constantly expressed throughout the book. These varying clinical manifestations are thoroughly discussed and excellently illustrated by photographs.

The section on treatment and prognosis occupies thirty-five pages and contains full and clear descriptions of the methods of preparation and administration of the various forms of chaulmoogra oil, but it also emphasizes strongly the importance of general treatment and hygiene. Various other useful medical and surgical procedures are described.

The third section deals with prevention and it stresses the limitations of treatment and the importance of isolation of infectious cases in the control of leprosy. The work of institutions is discussed, but the opinion is expressed that, in India and other such countries, isolation in institutions is possible for only a small

proportion of infectious patients. The development of various forms of village isolation is therefore strongly urged. The formation of leper villages, the isolation of groups of patients outside ordinary villages and isolation of individual patients inside villages are discussed, the first two measures being favoured. The work of the leprosy clinic is described with emphasis on the importance of linking-up treatment work in the clinic with preventive work in villages.

This book is a most excellent one and should appeal to a very wide public. The clinical and practical aspects of leprosy are clearly explained, so that the book should appeal to the clinician and the general practitioner; the sections on epidemiology and control should certainly be read by every public health worker in India; some of the more technical aspects of leprosy are dealt with thoroughly and the book should therefore be of use to the specialist worker in leprosy.

The book is excellently printed and bound and is most excellent value for its low price.

THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE INCLUDING MEDICINE, SURGERY, OBSTETRICS, GYNÆCOLOGY AND OTHER SPECIAL SUBJECTS. Under the General Editorship of Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., M.D., D.Sc., D.C.L., LL.D. 1938. Butterworth and Company, Limited, London. (To be completed in 11 volumes. Sold in complete sets only. Cash price, Rs. 25 per volume. Also available on the instalment system at Rs. 10 per month. Price, Rs. 26-8 per volume. Only available from Messrs. Butterworth and Company (India), Limited, Calcutta. Volume III. Pp. xxv plus 681 plus 54

This volume commences with 'cataract' and ends with 'diaphragm diseases'. Of special interest to readers in this country are the chapters on 'cholera' by Sir Leonard Rogers, and on dengue by Sir John Megaw. In each case the subject is one of which the writer has made a special study during his service in India and in which he has maintained his interest since his retirement from this country. In its essentials the treatment of cholera has undergone very little change from the position in which it was placed by Sir Leonard thirty years ago; the intravenous injection of alkaline and hypertonic saline is still the mainstay of the treatment. More recent introductions such as bacteriophage, in both prophylaxis and treatment, have been considered in detail and their importance judiciously weighed. On the other hand, the reader is given no encouragement to use the essential-oils mixture

which must be looked upon as little more than a placebo—a placebo to the conscience of the physician. The chapter on colitis is written by Sir Arthur Hurst, not a tropical worker, but a great authority on this condition, which, though more common in the tropics, is a cosmopolitan disease; the importance of tropical intestinal infections in the causation is not overlooked. The chapter on clonorchiasis, a tropical infection but one that does not occur in this country, is written by Dr. P. A. Mapleston who gives a short but concise account of the condition.

There are three useful chapters on certain eye diseases which happen to fall in the C's—cataract, and diseases of the cornea and conjunctiva; each of these is illustrated by an excellent coloured plate. The chapter on cataract is by Sir Stewart Duke-Elder.

Contraception is given about twenty pages: this chapter is written by Dr. Blacker, Hony. Secretary, Birth Control Investigation Committee, and Dr. Joan Malleson, Medical Officer of the North Kensington Birth Control Clinic. Different methods are described and discussed. The sheath, if properly used, should have a 100 per cent success. They place the failure rate with the Dutch cap at only 1 in 5,000 occasions.

Other important chapters in this volume are on cerebro-spinal fever by Dr. Lethaby Tidy, on diabetes by Dr. Wilfred Oakley, and on dental sepsis in relation to systemic disease by Sir Norman Bennett.

This volume is distinguished by the large number of colour plates, all relevant and beautifully executed both as original paintings and in their reproduction; the picture of a child with cerebro-spinal fever is of Royal Academy standard. In other respects, the volume is quite up to the high standard of its predecessors.

SULFANILAMIDE THERAPY OF BACTERIAL INFECTIONS—WITH SPECIAL REFERENCE TO DISEASES CAUSED BY HÆMOLYTIC STREPTOCOCCI, PNEUMOCOCCI, MENINGOCOCCI AND GONOCOCCI.—By R. R. Mollon, M.D., Dr.P.H., D.Sc. (Hon.), P. Gross, M.D., and F. B. Cooper, M.S. 1938. Charles C. Thomas, Publisher, Springfield, Illinois (220, East Monroe Street). Pp. xiii plus 398. Illustrated. Price, \$4.00, post paid

It is barely two years since the sulphanilamide flood burst on medical practice. The introduction of this series of drugs is not an advance to which one can truly apply the word 'revolutionary'; its effect has been much better than a revolution—in which the destruction of the old order is often a much more prominent feature than the construction of the new. But, if it has frustrated us in the use of one medical literary cliché, it has fully justified another, and we can say without fear of contradiction that it has added a whole battery to the 'armamentarium of the physician', and, incidentally, of the surgeon and of the obstetrician.

The physician or surgeon who has no originality in thought or experience, or who is fully preoccupied, or naturally indolent, usually rationalizes his lack of literary achievements, assumes an air of feigned modesty, and scoffs at his colleagues for 'rushing into print'. The enterprise of the authors and publishers of this book must, however, gain the admiration of all, even of the owners of completely silent pens; to produce a book of 400 pages on the sulphanilamides well within two years of their first clinical application is no mean achievement.

The first section of the book is a review of the literature on the chemistry and pharmacology of the sulphanilamide compounds, and on the early *in vitro* and *in vivo* experiments on their bactericidal properties. The last chapters in this section are on the chemotherapeutic results achieved in streptococcal and in other infections, respectively, in man.

The second section deals with the authors' own experimental work on the bacteriostatic properties of these compounds, with the therapeutic properties in streptococcal infections in laboratory animals, and in pneumonia and streptococcal meningitis in man.

In the third section they discuss the mode of the action and the part played by the host's defensive mechanism, and in the last the criteria of efficiency for sulphanilamide compounds.

There is a bibliography of three hundred references, an addendum in which the most recent work is reported, an authors' index, and a subject index.

Altogether it is a very valuable contribution on an important topical subject, and the authors and publishers are to be congratulated, not only on their enterprise and expedition but on their mastery of all aspects of the subject and on their method of presenting it.

DISEASES OF THE SKIN: FOR PRACTITIONERS AND STUDENTS.—By G. C. Andrews, A.B., M.D. Second Edition. 1938. W. B. Saunders Company, Philadelphia and London. Pp. 899 with 938 illustrations. Price, 45s.

We are unacquainted with the first edition of this book which apparently was published eight years ago.

According to the preface a great many additions have been made both to the text and the figures. There are one or two statements in it with which we cannot altogether agree. For instance, the author says 'The pathology of each disease is now fully discussed . . .' would, in our opinion, be more correctly rendered 'the histological appearance of the principal diseases is briefly described'; nor could we find any special discussion on allergy as we were led to expect.

A new chapter has been added on virus diseases, as well as one on vitamin deficiencies, and another on infiltrations of metabolic products. This is a good move because the ætiological influence of all three factors is now well recognized in dermatology and they make three distinct and handy groups. At the same time we hardly think it right to consider aphthous fever as a skin disease, and the inclusion of seborrhœic warts and senile keratosis in virus diseases is not in accord with accepted opinion of their cause.

We were also surprised to find a brief and inadequate description of hookworm disease in a book on dermatology. It is here apparently for two reasons. The first because of the local reaction and subsequent secondary infection commonly seen at the site of entry of the larvæ, and the second because 'After the disease is developed ulceration of the legs is common'. The first may possibly be accepted but the second is based on the fact that in communities where hookworm infection is practically universal leg ulcers are as a rule not uncommon, so the two conditions are bound to co-exist fairly frequently. To infer an ætiological connection between them seems unjustifiable.

The above are only minor criticisms that have appealed to us as we have gone through the book, but if one regards it from the general rather than the particular point of view it is an excellent complete summary of diseases of the skin. This will be readily understood when it is noted that the total number of pages, including the index, is only 899 and there are 938 figures.

The illustrations deserve special commendation because without exception they are clear and informative. Judging from the acknowledgments the author has collected his illustrations from all over the world, which in a large measure explains their excellence.

The book is bound with the new familiar flexible back which is a feature of the publishing house of Saunders. It allows free handling of a heavy volume without fear of damage to the binding.

As a reference book on dermatology for the general practitioner we think this publication should be of special value, largely because the numerous and characteristic photographic reproductions will greatly assist the tyro in making a diagnosis.

P. A. M.

TUBERCULOSIS AMONG CHILDREN AND ADULTS.

—By J. A. Myers, Ph.D., M.D., F.A.C.P. Second Edition. 1938. Published by Charles C. Thomas, Illinois and Baltimore. Pp. xviii plus 401. Illustrated. Price, \$4.50

THE first edition of the book was published in 1930 under the title of 'Tuberculosis among children', with an admirable introduction from Allen K. Krause. This, the second edition, is completely re-written; it is divided into three parts—part I deals with the pathology, diagnosis, prognosis and treatment of tuberculosis in infancy, part II with tuberculosis in childhood and part III with tuberculosis among young adults. The preventive aspects of the disease have been amply emphasized.

The author, who is in charge of tuberculosis work at the Lymanhurst school of tuberculous children, Minnesota, points out that a very close relationship exists between the benign first infection type of tuberculosis in children and the clinical re-infection type of disease in adult life. The childhood type of infection prepares the way for the adult type of tuberculosis, in which re-infections from exogenous sources play a large part in a fair proportion of cases. He thinks that in infancy and childhood lies the fountain head of tuberculosis and that through careful study of children in schools and homes, large numbers of unsuspected spreaders of bacilli can be detected, while the detected children can be surveyed and guided throughout successive epochs of life, particularly through young adult life. As an argument in support he brings out the fact that, although tuberculosis had declined in the west, there has been very little reduction in death rate in young adults from 15 to 24 years. He, therefore, pleads for continuous supervision from childhood up to adult age. Dr. Allen K. Krause has admirably summed up the position in the following paragraph of the introduction written by him: 'That "the child is father to the man" is never truer than in the domain of human tuberculosis. Seeds strike root in childhood; roots take firm or weak hold as the immature body wrestles with the stresses of growth and development poorly or well; fruition, pulmonary phthisis, bane of a cooped-up civilization, bursts as life's powers unfold to the full with the coming of adult years. This is the story of the common run of tuberculosis patients; they reap what indifferent circumstance has sown in them in long-forgotten bygone years: touched by tubercle bacilli, they are the unlucky heirs of accident and ignorance, of which ignorance is perhaps the more prolific breeder.'

The addition of chapters on sensitization and immunity, of two chapters on tuberculous meningitis and chronic non-tuberculous basal pulmonary diseases in childhood by C. A. Stewart and of a chapter on tuberculous disease of the bones and joints have enhanced the usefulness of the book. The scientific facts are accurately and well presented. The book will be found to be useful to students and practitioners, as well as to sanitarians.

The printing and get-up reflect credit on the publishers.

A. C. U.

TREATMENT IN GENERAL PRACTICE: THE MANAGEMENT OF SOME MAJOR MEDICAL DISORDERS. Volume II. Articles republished from the *British Medical Journal* Second Edition. 1938. H. K. Lewis and Company, Limited, London. Pp. xli plus 436. Price, 10s. 6d.

A REVIEW of the second edition of the first series of these reprinted papers on treatment appeared in the last number of the *Gazette*; we refer our readers to this. We are glad to see another edition of the second series. As in the case of the first edition, many of the articles are reprinted in their original state, others have been touched up, but we believe we are right in saying that none has been re-written. Why indeed should they be? It is only two years since the first edition was published and in that time advances have been made but no revolutions have taken place.

In this volume diseases of the nervous system, diseases of the blood, metabolic and kidney diseases, and rheumatic diseases are dealt with. The writers are representative of the British School, and L. J. Witts, J. F. Wilkinson and L. S. P. Davidson are amongst the writers on blood diseases.

The most important advance in the last two years has been the introduction of sulphanilamide. In the chapter on migraine, ergotamine tartrate has been mentioned. It is a drug that has as yet scarcely found its proper place in the treatment of this difficult condition, but it is a promising recruit. Special reference to individual articles would be out of place; however, the same high standard, set in the first series, is maintained throughout the second. These two volumes really should find a place on every practitioner's desk.

ELECTRO-THERAPY AND LIGHT-THERAPY.—By

RICHARD KOVACS, M.D. Third Edition. 1938. Henry Kimpton, London. Pp. 744. Illustrated with 307 engravings and a colour plate. Price, 35s.

THE second edition of this excellent work appeared in 1935 when it was duly noticed in these columns. The third and latest edition has been considerably enlarged by the author. The very excellent chapter on the physics of electro-therapy has been completely revised and should make very easy reading for medical men with the minimum of equipment in physics. An entirely new chapter has been written on the relation of physiology and electro-therapy. The chapter on general electro-therapy has been considerably enlarged. The section on galvanism has been entirely re-written. The recently introduced methods of vaso-dilatation by ionization with histamine or mecholyl are ably discussed. The chapter on electro-diagnosis including condenser testing and the chronaxie has been enlarged.

One of the most remarkable portions in the book is that on short-wave diathermy. Two entirely new chapters have been added giving clinical indications and contra-indications and the technique of this method in great detail. Electro-pyrexia is the subject of a new chapter.

The subject of light-therapy has also been elaborated.

The book is provided with a very useful glossary and an adequate index. It is the standard work on the subject in America.

Dr. Kovacs is a man of international reputation and a distinguished authority in his sphere.

Physicians who are apt to raise their eyebrows at the mention of electro-medical methods of treatment will find much food for thought here. The practitioner in electro-therapy will find it an invaluable addition to the volumes on his consulting-room table where it will always form a reliable work of reference. We would specially commend it to aspirants for the D.M.R.E.

G. G.

THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE BLOOD.—By T. Ordway, M.D., and L. W. Gorham, M.D. Revised by R. Isaacs, M.D.

(Reprinted from Oxford Monographs on 'Diagnosis and Treatment'.) 1937. Oxford University Press, London and New York. Pp. xi plus 605. Illustrated. Price, 32s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

HEMATOLOGY has made very great advances during the last decade and many new books on the subject have appeared. We cannot therefore support the action of the publishers in re-issuing this 8-year-old volume in which a few, a very few, pages have been interpolated in an attempt to bring it up to date. The failure is no fault of the new editor: it just cannot be done this way.

There is much to be said for the book if one can carry oneself back eight years. The arrangement is good and the descriptions clear. There are some valuable plates which are not in any way out-dated. There are references at the end of each section, but in many instances the most recent reference is 1926.

These well-known publishers have recently been responsible for two excellent books on this subject, Castle and Minot's and Janet Vaughan's, and we cannot understand why they have now attempted to revive this one.

L. E. N.

SALTS AND THEIR REACTIONS: A CLASS BOOK OF PRACTICAL CHEMISTRY.—By L. Dobbin, Ph.D., and J. E. Mackenzie, D.Sc. Sixth Edition. 1936. E. and S. Livingstone, Edinburgh. Pp. ix plus 246. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 4-8

THIS is a class book of practical inorganic chemistry meant for students going up for 'First Science', 'Preliminary Scientific', 'First Professional' and other examinations of the universities and of the Royal Colleges of Physicians, Surgeons and Veterinary Surgeons of Great Britain.

In the first section, dealing with the nature and properties of the salts, the theoretical aspects have been explained and in the second section some general methods of preparing salts have been introduced. The third section is divided into two parts, one dealing with the reactions due to the metallic radicals and the other dealing with reactions due to the acidic radicals. All these reactions have been carefully explained with the help of equations. The next section deals with the dry-way reactions and finally there is a section dealing with some typical volumetric analyses. There is an appendix describing experiments with some common organic substances such as carbohydrates, alcohols, oils, milk, albumin, etc.

This handy volume has already passed through several editions and written as it is by authors having wide experience among students, it would prove valuable for the I.Sc., B.Sc., or medical students of the Indian universities and faculties.

S. G.

THE FOOT.—By Norman C. Lake, M.D., M.S., D.Sc. (Lond.), F.R.C.S. (Eng.). Second Edition. 1938. Baillière, Tindall and Cox, London. Pp. viii plus 366, with 113 illustrations

THE appearance of a second edition of this book within the brief space of three years may be taken as adequate testimony to its utility and popularity. The value of the present edition has been greatly increased by the addition of new chapters on congenital club foot and foot problems. Although a great deal of fresh matter has been incorporated in addition to numerous illustrations, the body of the book has been kept within reasonable limits, on which the author may be complimented. The inclusion of a bibliography and a glossary of the New English Nomenclature will be useful to the reader.

We hope that this edition will prove to be at least as welcome as its predecessor. It would be a useful addition to the library of the general practitioner. The printing, get-up and illustrations are excellent.

P. N. R.

THE AMERICAN POCKET MEDICAL DICTIONARY.—Edited by W. A. Newman Dorland, A.M., M.D. Sixteenth Edition. 1938. W. B. Saunders Company, Philadelphia and London. Pp. 973. Price, 8s. 6d. (plain). 10s. 6d. with Thumb Index

THIS dictionary first appeared in 1898 so that with the present volume 16 editions have appeared in forty-one years, which is sufficient evidence of the steady demand it must enjoy.

Unfortunately the term 'pocket' is becoming rather misleading for it now measures about 1½ inches in thickness. This is not the fault of the publishers because to keep it up to date many new words have to be constantly added, and old ones cannot be discarded; in the present instance it has been increased by over 2,500 new words bringing the total to over 50,000. When this aspect is considered it is remarkable

that the book has been kept as small as it is, and if it would make an unsightly bulge in the pocket of a fashionably dressed practitioner it is small enough to be quite unobtrusive on the consulting-room desk.

P. A. M.

A TEXTBOOK OF MEDICINE FOR NURSES.—By E. Noble Chamberlain, M.D., M.Sc., F.R.C.P. Third Edition. 1938. Oxford University Press, London, New York and Toronto. Pp. xviii plus 460. Illustrated. Price, 20s. Obtainable from Oxford University Press, Bombay and Calcutta

THIS book has long been recognized by nurses for its usefulness. The third edition will be welcomed. The arrangement, which is based on the syllabus of the General Nursing Council of England and Wales, is a help to those studying for examinations. As this syllabus forms the basis of some of those laid down by registration councils in India, the book will be as valuable to nurses in this country as in England.

Tropical diseases are included, and the appendix of tests and summaries is most helpful. Although no new chapters have been added many of them have been enlarged and the number of illustrations has been increased.

It is a book every nurse should endeavour to have in her possession, not only for the purpose of passing examinations, but for reference during her career. No library in a nurse-training school should be without a copy of this valuable contribution of the education of the nurse.

M. D. W.

A MANUAL OF SURGERY FOR NURSES.—By C. Wells, M.B., F.R.C.S. 1938. E. and S. Livingstone, Edinburgh. Pp. viii plus 409. With 159 illustrations. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 7

WITH the rapid advances which are being made in the technique of modern surgery, the competent and reliable nurse is becoming more and more of a necessity. She is expected, not only to follow intelligently all recent advances in pre- and post-operative treatment, but also to handle and maintain in use intricate apparatus.

This book, consisting of 396 pages and 33 chapters, is of a handy size and successfully embodies the two main objects of the author, namely, to introduce the student nurse to the science and craft of surgery in a clear and straightforward manner, and to present the subject-matter in the form most likely to prove helpful. 'Pathological processes are described as fully as is necessary to clarify the clinical picture, and symptoms and signs are stressed whenever they are of especial importance from the nursing point of view.' There are numerous well-set-out diagrams and also a comprehensive anatomical plate for frontispiece.

We have much pleasure in recommending this useful little book not only to those for whom it is intended, but also to members of the medical profession. The printing and get-up are of good standard, and there is a useful index.

P. N. R.

MENTAL NURSING IN OBSERVATION WARD.—By I. M. Sclaire, L.R.C.P.S. (Edin.). 1938. E. and S. Livingstone, Edinburgh. Pp. xii plus 259. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 4-8

THIS very readable book is presented in 13 chapters, and in its preparation the aim has been to present clear pictures of the common types of psychoses and psycho-neuroses which are to be met in any observation ward. All the chapters are well written, and are so correlated as to give the reader a sound idea of the care required by mental patients of the various types. The author tries to do justice to the psycho-analytic school of thought, but his own experience in the treatment of a dipsomaniac by psycho-analysis—the duration

of the treatment was over two years—illustrates the limitations of this method of treatment in hospitals. The chapters on normal psychology and anatomy and physiology are well written, with emphasis upon certain aspects which are important from the nursing point of view. The last two chapters deal with the practical side, and though designed for the nursing profession, the student and physician will likewise find them refreshing and informing.

It is a thoughtful and useful book written by a well-experienced psycho-therapist. Concise, yet not sacrificing detail, the book may be read alike by general practitioners, nurses, and all who are charged with the responsibility of the care of the mentally ill. It is unfortunate that the author has not added a chapter on occupational therapy, otherwise the book covers the complete ground required by the nurse who is desirous of obtaining the Certificate of Proficiency in Mental Nursing, granted by the Royal Medico-Psychological Association. It may not be generally known that the examinations for this diploma are periodically held in India at the Ranchi European Mental Hospital.

A METHOD OF ANATOMY: DESCRIPTIVE AND DEDUCTIVE.—By J. C. Boileau Grant, M.C., M.B., Ch.B., F.R.C.S.E. 1937. Baillière, Tindall and Cox, London. Pp. xx plus 650, with 564 figures. Price, 27s.

IN this book the author has presented a new method of approach for the study of human anatomy. No doubt many excellent textbooks are available, but many of these are much too big for the purpose of medical students.

Professor Grant's departure from the traditional lines of writing textbooks will be welcomed by students and teachers alike, for this method of presentation has not only made the subject more interesting, but has made the matter simpler, rational, and easily understood. He has laid stress upon the underlying principles involved and shown a new way to get at the anatomical facts by a process of deduction. The formidable and unpleasant task of memorizing anatomical relations has thereby been reduced to a minimum.

In every region a predominating structure has been considered first, and the parts have been constructed around it; such a structure, whether a muscle, bone, nerve, or vessel, has been very aptly named a 'key structure' which when grasped will undoubtedly enable the reader to unlock the intricacies of various relations. The significance and bearings of the relations on the clinical studies have been kept constantly in view.

The book has been treated on a regional basis. The abdomen, thorax, extremities, and head and neck have been allotted one chapter each. The pelvis has been considered in a separate chapter. The seventh chapter is miscellaneous and contains considerations of individual cranial and vertebral bones, and a general outline of joints into three types which appear to be simple and at the same time very practical.

All chapters have been uniformly treated and, whenever clear understanding of relations or of the real nature of the structures demanded, the morphological and embryological elucidation has been incorporated, especially in the chapter on the abdomen. The text has been fully illustrated; a special feature of the illustrations is their simplicity—all being line drawings—and accuracy.

No special section has been allotted to osteology but in every region important bones have been discussed with special reference to their relations to the soft structures. The general principle underlying the study of the long bones has been lucidly presented and the conventions in the terminology explained in the schematic figures, 48 and 50. Muscular actions and movements of the joints have been explained when necessary by diagrams; figures 93, 94 and 95 illustrate the various movements of the shoulder girdle in a way which should be readily understood and easily remembered by students. The illustrations are mostly original and fully explanatory to the context.

We have found the book to be pleasant throughout and full of sound information which is not mere condensation of facts but a clear and precise exposition of various relationships and their full clinical bearings. Every section is equally interesting. If the aim of the study of anatomy in the medical schools be chiefly to enable students to understand the medical and surgical problems of the human body, Professor Grant has succeeded remarkably well in achieving this end; for he has shown very creditably through a limited space of 600 pages how not only the subject can be read with interest and learnt, but also what is more important, how such lessons can be retained.

We have no doubt that the book will appeal to all students and teachers during their pre-clinical and clinical studies alike, and it fully deserves a place in every medical library.

S. C. S.

AIDS TO HISTOLOGY.—By A. Goodall, M.D., F.R.C.P.E. Fourth Edition. 1938. Baillière, Tindall and Cox, London. Pp. viii plus 151. Illustrated. Price, 3s. 6d.

THAT this little book has been useful to many, will be borne out by the fact that it is passing through its fourth edition. The present volume has been revised, and some new sections are added, *e.g.*, ossification, hæmatology, and ductless glands. An account of all kinds of tissues is included, a few of which are illustrated.

To us it seems that the book will more meet the purpose of the advanced student, than serve as a guide to the beginner. To those who have already done work in the laboratory and are in the need of a small compendium having all essential facts of histology, for which they cannot devote the time necessary to go through larger textbooks, it will bring relief by helping them to marshal the facts observed during their class work, for revision before their examinations.

S. C. S.

AIDS TO EMBRYOLOGY.—By R. H. Hunter, M.D., M.Ch., Ph.D., M.I.R.A. Third Edition. 1938. Baillière, Tindall and Cox, London. Pp. viii plus 178. Illustrated. Price, 3s. 6d.

As one of the 'Aid Series' this book needs little introduction and the fact that it is passing through the third edition speaks of the popularity it has gained already.

The present edition, though it maintains its old form, has some sections revised and entirely rewritten. Chapter II is new and contains a compact but lucid account of modern conceptions on 'the transmission of hereditary characters'.

The recent idea of the relations of the oestrus-producing substances to the changes in the uterine mucosa has been incorporated, and the actions of prolactin A and B and the factors X and Z are well illustrated in an original schematic diagram. Every chapter has been brought in line with modern views. The book has been further enriched by providing a summary at the end of all important sections and also by inclusion of a list of common anomalies that are usually met with in the dissecting room or obstetrical wards.

The book is a succinct exposition of all the embryological problems, sorted out from the vast mass of the present-day literature.

Complicated problems have been illustrated by suitable sketches, which will help the reader to visualize the process involved. The book fully covers the syllabus under the new regulations of the General Medical Council.

We are sure in the present volume will be found all relevant matter in a nutshell suitable for revision purposes which all students before their ordeal look for.

S. C. S.

Abstracts from Reports

REPORT OF THE INTERGOVERNMENTAL CONFERENCE OF FAR EASTERN COUNTRIES ON RURAL HYGIENE HELD AT BANDOENG (JAVA), 3RD TO 13TH AUGUST, 1937. LEAGUE OF NATIONS HEALTH ORGANIZATION, GENEVA

THIS is a very important publication and it is difficult to abstract satisfactorily as we feel that none of it should be omitted. We give below the resolutions and recommendations of the various sections of the Conference, as they sum up the opinions of the large body of experts who attended the meetings.

HEALTH AND MEDICAL SERVICES

Resolutions

In Eastern countries more than anywhere else, preventive medicine is the cheapest means of improving the health conditions of the population in the rural areas, and it is along preventive lines that the effort should be principally directed.

2. The system suitable for a given area may be that in which curative and preventive work are combined in one organization, or that in which the two are carried out by separate organizations. Where economic conditions have allowed the adoption of the latter system, care should be taken that neither organization should develop disproportionately to the other and that where this disproportion exists, it should be corrected.

Where the former system has been adopted and the same personnel are responsible for both curative and preventive work, it is important that the preventive work should not be neglected. The time and effort which auxiliary personnel devote to curative and preventive work respectively should be determined by the superior staff.

3. As ultimately the preventive and curative work must be organized on a basis of accurate knowledge of the diseases and disabilities in an area, the importance of collecting accurate vital statistics cannot be over-emphasized. Our knowledge of morbidity in wide rural areas is very insufficient and it is therefore essential that every effort should be made to increase and improve it.

4. It is absolutely necessary to bring medical and health services as near to the population as possible, but the decentralization of activities should be guided and supervised by a central body in order to maintain efficiency and ensure a uniform policy.

5. While it is believed that decentralized preventive effort brings, comparatively, the greatest benefit to the health of the rural population at relatively the smallest cost, the means of applying this principle must necessarily vary with different local conditions and resources. No single type of organization can be recommended for general adoption, but it is essential that, whatever the means may be, they should be applied with sufficient thoroughness to make the beneficial effect of preventive work clear to the rural population and that the area of operations should be defined accordingly. The likelihood of attaining results which are permanent is increased if the size of the field of operation is determined in accordance with the capacity of the staff.

Progress will depend on gaining the confidence of the people by demonstrating to them the benefits of preventive work, so that they will voluntarily take a share in the work by contributing to it in money or in labour.

A preliminary study of local conditions and requirements in the villages themselves should serve as a basis upon which details of the local services can be organized.

The kind of organization employed for curative and preventive work by different countries has been described in detail in the respective national reports.

6. As regards the question of the training of medical men, it has happened in many Eastern countries, as elsewhere, that medical education has evolved from a simple beginning to a modern Western standard. This historical process of evolution should be accelerated as much as possible.

7. The Conference considers that, commensurately with its resources and its level of general education, every country should, in the sphere of medical education, attain the highest scientific level of theoretical and practical training, which should include facilities and opportunities for research. The spirit of preventive and social medicine should permeate more and more the whole programme of medical studies.

8. The Conference emphasizes the importance of adequately training a large body of auxiliary personnel in order that the connecting link between the rural inhabitant and the medical men may be as efficient as possible.

It also considers that the following views expressed in the report of the Preparatory Committee should be accepted as sound and followed as closely as possible, *viz*, that—

(a) their training should be as simple and practical as possible;

(b) care should be taken to ensure that their training does not make them lose touch with the people;

(c) remuneration should be adjusted to the economic conditions prevailing in the country districts;

(d) they should not take up their practice at too early an age;

(e) more importance should be attached to character (sense of duty, self-reliance) than to superficial erudition; and the Conference would add

(f) that instruction at least in hygiene of traditional or indigenous midwives during a transitional period may be required in some regions.

9. Emphasis is laid on the necessity for ensuring that all members of the auxiliary staff receive adequate training in hygiene and preventive medicine. The composition of the auxiliary staff relative to the kind of work they are called upon to do will vary in different areas.

10. At present it is not possible to state what should be the *per capita* expenditure or the percentage of the general budget which should be allocated to medical and health services.

11. It is essential that all Governments be convinced of the importance of public health and be prepared to finance it liberally. They must be imbued with the view that public health expenditure is a wise and profitable investment of public funds, and should adopt a more generous policy in this respect.

12. It is essential all Governments should realize that, while difficult to express in terms of money, the economic loss caused throughout the Far East by ill health is a vital factor in determining the ultimate welfare of a country. No administration claiming to have the well-being of its people at heart can afford to overlook this.

13. Funds may be either central or local. It is advisable that the principle of local support be inculcated whenever possible and that the proportion contributed by local bodies should gradually increase. But to meet cases where local bodies with the responsibility for public health have not the means fully to finance it, the Central Health Department must provide annually in its budget adequate funds to supplement the deficiency, so that the necessary services may be supplied under proper supervision.

14. Approved voluntary agencies and associations should be encouraged to contribute to health activities.

15. It is essential to the proper functioning of a health service that the emoluments offered be fully adequate so that the right type of man with proper training may be attracted and retained, and enabled to devote his full time to the service.

16. It is recommended that Administrations, when considering budgets for health purposes, bear in mind the following points:—

(a) The financial saving and the economic advantages which result from employing the local people of the country and from using local materials, wherever practicable, in construction and maintenance of works in rural areas;

(b) The value in times of financial prosperity of forming a reserve fund to be set aside for health and medical services in times of economic depression so that the necessary continuity of work may be safeguarded.

RURAL RECONSTRUCTION AND COLLABORATION OF THE POPULATION

1. The Conference strongly emphasizes the importance and urgency of rural reconstruction as a primary responsibility of every Government.

2. The Conference is of the opinion that one of the first steps in rural reconstruction that each Government should undertake is the co-ordination of the activities of its various agencies, both in planning and execution, so that the Government services to the population may be integrated, comprehensive and effective.

3. In the opinion of this Conference, it is necessary that every village or group of villages, as the case may be, should have an organization of its own, namely, a committee for conducting its affairs and promoting its welfare in all directions.

4. There should be an organization of control—namely, a committee of management consisting of Government experts, representatives of villages and other non-officials—to advise village committees as to the programme to be undertaken and to see that the programme is carried out, due consideration being given to the psychology of the peasant.

5. The village committees may be entrusted with duties relating to—

(a) water supply;

(b) sanitation, house improvement and village-planning;

(c) construction and maintenance of village roads and waterways;

(d) social and recreational activities including playgrounds;

(e) education of adults, both men and women.

6. Every village or group of villages should have, as far as possible—

(a) a health centre or unit;

(b) a school and library;

(c) co-operative societies;

(d) demonstrations of improved agricultural practices;

(e) facilities for improved animal husbandry, including the provision of preventive veterinary services;

(f) home gardens;

(g) home industries.

7. The Conference calls the attention of the Governments to the success achieved by the establishment in strategic points of rural welfare centres with adequate extension facilities. The welfare centre experiments with methods of approach, introduces improvements, enables the experts to collaborate and affords facilities for the field training of workers.

8. The Conference realizes that any success in rural reconstruction is dependent on the presence of properly trained personnel and that it is therefore necessary that adequate facilities should be provided for the formation of technical personnel needed in all branches of work. The selection and training of suitable personnel, both men and women, is all-important. The training must be of a practical nature, including actual participation in rural work.

9. The Conference, realizing the increasing importance of the rôle which must be played by women in rural reconstruction, urges that everything be done to ensure that women shall be given all opportunity to develop their activities in this important field.

10. The Conference desires to emphasize the important part to be played by the village school in

the work of rural reconstruction. It is essential that rural schools have a curriculum of study specially suited to prepare their pupils for rural life, not only because of the obvious necessity for such training, but also because of the prestige that attaches to things taught in the school. This means that the teachers' training-colleges must give training to that end. The curriculum of rural schools should comprise reading, writing and arithmetic, health, physical training and games, agriculture and nature study, manual training (training in the use of tools and materials for boys, needlework and domestic science or housecraft for girls) and citizenship. Special emphasis should be given to health education.

11. In the belief of this Conference, without land reform in many countries, rural reconstruction will not rest on a permanent basis; serious consideration of this problem and the study of methods best adapted to local conditions are urgently recommended to Governments.

12. The Conference would request the League of Nations to make arrangements to collect and make available information regarding successful examples of rural reconstruction in various countries.

To that end, the Conference suggests that the information be collected by a special group of persons who are closely engaged in such work. The group will visit various countries and make a special study of rural reconstruction centres. Their report should be published for general information.

SANITATION AND SANITARY ENGINEERING

1. The Conference recommends that Eastern Governments should each constitute committees for small-village planning in order to avoid *laissez-faire* development, and that these same agencies should set up local standards dealing with details regarding siting, types of houses, building material, ventilation, lighting and heating, waste disposal and water supply. In particular, it is emphasized that the kitchen should not be inside the living part of the house and that cattle-sheds should be detached.

2. The Conference suggests that a good water supply should be provided in all rural areas.

The Conference further suggests that, when possible, grants from public funds should be made available to provide good water and that financial return on such schemes should not be a matter of primary consideration.

The Conference recommends that new water supplies delivered to rural areas should be of the same recognized standard of purity as those approved for delivery to large towns; no new pipe-line supply should be installed unless the purity of the water conforms to this standard.

Where the supply of water of the above-mentioned quality is not feasible, it is recommended that properly constructed wells with cover and pump should be provided where possible; existing wells should be improved, and requirements to prevent contamination of wells should be promulgated.

3. (a) The Conference is of the opinion that the proper disposal of human excreta is of the utmost importance to the health of the rural population.

(b) In those Eastern countries where the use of manure for agricultural purposes is of primary importance, human excreta and household refuse should be dealt with in a way suitable for placing the product on the land as manure.

(c) The question of the pollution of water in wells by pit latrines is a matter that needs further investigation, and it is recommended that Eastern Governments should consider undertaking such investigations.

4. (a) The Conference recommends that more research work concerning flies should be undertaken, and suggests that it should be based on the lines indicated by the League of Nations document *C. H. Hyg. rur. E. H. 15(I)*.

(b) The Conference recommends that the programme of study should also include investigations into the alleged efficacy of dung- and refuse-stacking and of composting as a means for the prevention of the breeding of flies.

NUTRITION

1. The Conference emphasizes the importance of diet in relation to health problems in the East. The available evidence suggests that under-nourishment and malnutrition are widespread and that much impairment of physical development and general health, low vitality and actual disease result from insufficient and improper diet. While the problem is difficult to attack, being largely bound up with economic conditions, the Conference nevertheless feels that there are possibilities of improvement and progress in many directions. It therefore hopes that Governments will increasingly support work in this field.

2. The establishment in each country of National Nutrition Committees is recommended. These may suitably include, in addition to nutrition workers, representatives of various departments of State, including public health, medical, educational, agricultural, animal husbandry and fisheries departments. The task of the Committees would be to advise their Governments on matters pertaining to the food and diet of the people.

3. The Conference considers that a central institute or laboratory concerned with nutrition research and its practical applications should exist in all Eastern countries.

4. The Conference recommends the training and employment of selected public health workers to act as specialists in the field of practical nutrition. Such workers may suitably be attached to central and provincial health departments. They can carry out field investigations, engage in propaganda work, organize school-feeding schemes, advise regarding the dietary aspects of maternity and child-welfare work, regulate diet in Government and charitable institutions, such as boarding-schools, mental homes, leper asylums and so on, and in general assist in the practical application of nutritional science.

5. The Conference recommends that close collaboration should be established between nutrition research institutes and agricultural and other departments concerned with food supply.

The nutrition worker can consult the agricultural expert about the practical possibilities of the changes and improvements in diet he recommends; conversely, the agricultural expert can obtain guidance from the former regarding desirable improvements in diet which may be furthered by crop-planning, better agricultural techniques, selective breeding methods, improved manuring, composting, etc.

6. The Conference emphasizes the fact that the degree of milling to which rice is subjected is of vital importance in connection with the problem of nutrition throughout the East. In many countries, the poorer classes consume foods other than rice in small quantities, and it is very difficult, for economic reasons, to increase the amount of supplementary foods in the diet; in such circumstances, the nutritive value of the main article of food, which is influenced by the degree of milling, becomes of great significance. The Conference recommends that only under-milled rice should be supplied in Government institutions. Efforts to popularize the use of under-milled rice by education and propaganda should be increased. It deplors the increasing tendency of urban and rural populations in the East to consume highly milled rice. It strongly recommends that Governments should make a thorough investigation of the nutritional, commercial, economic and psychological aspects of the problem, attention being given to the possibility of checking the spread of mechanical rice mills in rural areas, with a view to conserving the healthy habit of consuming home-pounded rice, and to means of making under-milled rice easily available everywhere for those who wish to purchase it. This problem might be among the first to be considered by the National Nutrition Committees recommended in paragraph 2.

7. The Conference notes the technical report which is appended and recommends that the report should be submitted to Governments for comment. The latter may suitably refer the report to the National Nutrition

Committees or to some other appropriate body. The technical report contains a number of suggestions about nutrition research. The Conference hopes that Governments will inform the Health Organization regarding institutions which would co-operate in carrying out investigations of the type outlined. It suggests that detailed reports on the progress of studies should from time to time be sent to the Health Organization, if necessary in the original language.

It is further recommended that the technical report on nutrition should be submitted to the League of Nations Technical Commission on Nutrition, and that the Health Organization should undertake to establish contact between that Technical Commission and nutrition workers in the East.

MALARIA

I. The importance of malaria.—Malaria kills more people and does more damage to physical, social and economic welfare in rural portions of Far Eastern countries (especially in the tropics and sub-tropics) than any other disease. This has been once again emphasized in the preparatory national reports and by the testimony of leaders of delegations to this Conference. Yet malaria is insidious and, except in epidemic form, it does not manifest itself with dramatic power sufficient to attract attention and funds commensurate with its ability to destroy health and prosperity. This Conference desires to emphasize the outstanding importance of malaria, and to urge lay and health administrators so to formulate their budgets that the amount of money and energy devoted to the control of this disease will be in proportion to its paramount importance.

II. Administrative policy as regards malaria control.—The Conference, in the first place, considers that the technical assistance of staff specially trained in malaria work is absolutely essential if an administrator is to deal successfully with malaria control. This consideration follows the general lines suggested by the League of Nations Malaria Commission as far back as 1924. Any malarious country which to-day has no health personnel skilled in malaria technique must be regarded as an anachronism. But the Conference believes that responsibility for malaria control should rest squarely on the minister or other officer in charge of the public health policy of a country and not on the technical expert.

The Conference, secondly, recommends that, since malaria is a focal disease in any country—absent in some rural areas, lightly prevalent in others, and moderately or heavily endemic elsewhere—the structure of, and programme for, rural health organization, including health units and health centres, should not be stereotyped, but flexible. In those areas where malaria is the outstanding social and health problem, the resources of the health administration, specially augmented where necessary, should be directed chiefly towards malaria control, even if this should entail the restriction of other public health activities, until malaria is no longer of major importance. As a rule, the physical debility and mental apathy of malaria-stricken peoples will not permit them to respond to a general public health programme, so that it is a logical procedure first to deal with malaria. On the other hand, where malaria is of minor importance, it may be dealt with adequately as part of an ordinary public health programme.

Thirdly, the Conference would like to emphasize the value of practical demonstrations of malaria control as a means of arousing the interest of lay (and even health) administrators. The lack of a good example of malaria control, well documented as regards statistics and costs, often explains official apathy and failure to appropriate funds for control programmes. The Conference recommends that, in countries where a malaria-control programme is poorly developed or is being projected for the first time, sufficient funds be allocated for at least five years to carry out a model project. This should include not only the controlled area, but also an equally carefully-studied area nearby in which

no control is carried out, so that a contrast may be available. Such a demonstration control project with its contrast area has very great propaganda value, much more than a score of surveys barren of practical results.

In the fourth place, the Conference emphasizes the vital need for administrative co-operation between the health and other Government departments, such as Agriculture, Education, Finance, Forestry, Irrigation and Public Works. Further, the Conference recommends that, in the development of rural malaria control, the aid of such local bodies as co-operation societies, health leagues and rural improvement centres, should be enlisted and utilized to the fullest possible extent.

III. Cost of malaria control in rural tropics.—The Conference notes that, in many rural areas, the greatest obstacle in the way of malaria control is the fact that such measures as the use of oil, Paris green, or drainage, cost more money than the rural communities can raise. The Conference would point out carefully that it has been amply demonstrated that malaria control is to-day, as a rule, financially feasible in cities and large towns, communities of Government or industrial employees, military cantonments, constructional projects, colonization camps and pilgrimage centres, and wherever agriculture is organized into sugar haciendas, coffee estates, tea gardens, rubber plantations, oil-palm, casuarina or coconut groves, and similar ventures. In such places, it is lack of organization, not lack of money, which delays malaria control. Indeed, in many rural areas, deficiency in organization, rather than in funds, is the real difficulty.

The Conference recommends that, in formulating programmes for the control of rural malaria, administrators pay due regard to the above distinctions and, further, that they give rural districts as much aid from central funds as possible, particularly when the legal rights pertaining to streams, tanks or other malariogenic waters are under their direct jurisdiction.

Secondly, the Conference recommends that, in order to reduce control costs for rural communities, every effort be made (a) to extend the free distribution of cinchona products, (b) to enlist the aid of the people themselves in minor control methods, and (c) to explore cheaper methods of control which use time more than money. Persistence rather than perfection in control is required for rural areas.

IV. Naturalistic methods of malaria control.—The epidemiology of malaria is intimately associated with the adjustments and responses of malaria-carrying mosquitoes to their environment. The natural factors which determine whether or not water is malariogenic are numerous and often complicated, since they are dependent upon physical, chemical and biological conditions. The deliberate manipulation by man of one or more of these natural factors so as to prevent mosquito-breeding, to destroy larvæ, or even to deviate adult mosquitoes from man to animals, has come to be known as Naturalistic Control, and the Conference wishes to draw special attention to the possibilities of reducing malaria in this way.

Peasants can be taught such minor naturalistic methods as herbage packing with green-cut vegetation; fostering natural enemies such as fish; removing sheltering vegetation; shading breeding-places by cultivating certain plants or using coconut palm leaves, or woven bamboo mats, where the dangerous mosquito requires sunlight; periodical sluicing of small streams to eliminate mosquito breeding. Other naturalistic methods such as utilizing natural tendencies of rivers to deposit silt, or to flood or flush; making fresh water salty or *vice versa*; changing water levels; agitating surface water; automatic sluicing of larger streams—these usually require engineering skill.

The Conference recognizes that all of the above methods have been successfully applied in selected areas, and it urges that each country, not neglecting to use standard methods where feasible, investigate the possibilities of such cheap procedures. Up to the present, exact biochemical and microbiological observations have been so few that application of naturalistic methods has been largely empirical. The Conference

emphasizes the need for reflective enquiry, so that naturalistic malaria control may be based more on reason than on authority. In the opinion of the Conference, great hope is offered for the control of rural malaria in selected areas by these naturalistic methods, which are relatively inexpensive and can suitably be carried out by the peasants themselves.

The Conference notes with satisfaction that the Health Committee of the League of Nations included in its plan of work for 1937-1939 the study of naturalistic methods of malaria control, a study which the Conference warmly recommends to workers in the East.

V. The effect of construction works on rural malaria.

—Although in some Far Eastern countries a fair degree of co-operation has been developed between health officers and engineers for the avoidance of malaria, yet the amount of engineer-made malaria in other countries is appalling. Specifically, the Conference calls attention to malaria due to improper siting and housing; indiscriminate aggregation of labourers; uncontrolled jungle clearing; excavations such as borrow-pits, brick-fields and quarry-pits; obstruction of natural drainage by road, railway and canal embankments with culverts too few and too high; impounding of water without regard to leakages, seepages and raised water-table levels; irrigation without drainage.

Co-operation with the health authorities would obviate many of these unfortunate occurrences at little or no additional cost. In other instances, the expenditure of such additional sums as would be necessary to avoid the production of malaria would be justifiable, because it is almost invariably found that the cost of remedial measures is disproportionately greater than the extra initial outlay required to prevent malaria.

The Conference recommends, first, that every effort be made by lay administrators to secure close co-operation between their engineers and health officers; secondly, that appropriate legislation be enacted to prevent the creation of malariogenic nuisances by engineering departments or contractors under their supervision; thirdly, that in the budget of every constructional project in malarious places there be an item for malaria control; and, fourthly, that engineers be instructed in the fundamental principles of anti-malaria sanitation before assuming executive responsibilities in the tropics. In the opinion of the Conference, this end would best be achieved by special pre- and post-graduate courses of instruction and by suitable pamphlets for subsequent guidance.

VI. Relationship between rural malaria and the activities of the peasants.—It is well known that the amount of peasant-made malaria in rural areas is considerable. Specifically, the Conference draws attention to malariogenic 'wet cultivation' such as rice and sugar-cane; neglected side channels; leaky pumps; wells; uncontrolled jungle and mangrove clearances; various agricultural pits holding water; fish-ponds; mill-ponds; ruts; hoof prints; and buffalo-wallows; waste irrigation water; ill-kept drains. The Conference considers it important that attempts be made to develop agricultural technique which will tend to eliminate malaria-carrying mosquitoes and at the same time to improve crops. There is no evidence that the average peasant is interested, or can be aroused to sustained interest, in malaria control. He requires more tangible returns.

The Conference strongly recommends further research to the end that malaria control in rural areas, perhaps along naturalistic lines, may be interwoven eventually with agriculture, pisciculture and animal husbandry. The need for specially trained malarial agriculturists may perhaps be as great as for malarial engineers. Certainly, in rural areas there must be an attempt to fit malaria control methods to the needs, habits, capabilities, and resources of the peasants.

VII. Distribution of anti-malaria drugs.—The Conference is in agreement that the first responsibility of the Government in any malaria campaign is to save from death and relieve from physical distress the malarious sick by making anti-malarial treatment

readily available. It subscribes, therefore, to the opinions expressed by the Malaria Commission of the League of Nations in its second report (1927) that the treatment of the malarious sick is the first step in any malaria policy and that 'wide distribution of quinine is a public duty which, whenever and wherever necessary, should be organized and paid for by the State'.

The Conference is also in agreement that, during malaria epidemics, it is the responsibility of a Central Government to make free treatment available to all; that, in ordinary times, where malaria is prevalent, free treatment should be provided for those who cannot pay. The Conference, further, is in agreement that the cinchona derivatives remain the drug of choice for mass distribution. While recognizing the usefulness of the new synthetic drugs in controlled therapy, the Conference is of the opinion that they cannot yet safely be placed in the hands of rural populations in Far Eastern countries. It wishes to call attention to the forthcoming report of the Malaria Commission of the League of Nations embodying the results of co-ordinated experiments with synthetic drugs on the treatment and prophylaxis of malaria in the field. This report was not available to the Conference.

The Conference recommends that every effort be made to widen the scope and cheapen the cost of mass distribution, especially of the less expensive totaquina and cinchona febrifuge. It realizes that the distribution of anti-malaria drugs at present is not so much malaria control as an alleviation of acute distress with reduction of mortality. Experience in many countries shows that the people can be induced to take just sufficient treatment to suppress symptoms even when the drug is given free.

The Conference recommends that health departments enlist the aid of Governmental or other reliable agencies in distributing cinchona products. When a special staff of dispensers is organized, the cost of distribution becomes a serious item. It is also suggested that any special programme for mass distribution be organized without supplanting the normal function of dispensaries. In certain restricted areas there might be considerable propaganda value in limiting the free distribution of anti-malaria drugs to those whose blood smears contain plasmodia.

VIII. Need for further research.—The Conference would like to emphasize a few special questions on which further research is urgently required in connection with the control of rural malaria. In the first place, while the systematic classification of anophelines is on a sound basis, there is a serious lack of information as to the bionomics even of those species known to be dangerous malaria carriers. Success in developing cheaper methods of naturalistic control must depend on a much fuller knowledge of the habits and intimate habitats of anophelines. This applies not only to anti-larval measures, but also to such potentially useful methods of attacking adult mosquitoes as insecticidal spraying.

In the second place, a much more definite understanding of the relationship between malaria, malnutrition, famine and poverty is required, as well as further elucidation of the factors concerned in malarial immunity, especially in so-called racial immunity.

In the third place, too little is known about the malaria parasite from the time it leaves the mosquito's proboscis until it appears in the peripheral blood. If this stage in the life history of plasmodia were known, it might be possible to accelerate research on the prevention of infection by drugs.

In the fourth place, a good deal more investigation is required to develop practical mosquito-nets for rural areas in the tropics, to forecast epidemics, and to make the use of zooprophylaxis practicable.

IX. Relation of malaria commission of the League of Nations to Far Eastern Countries.—The Conference desires to emphasize the value of the International Course in Malariology held at Singapore under the

auspices of the Health Organization of the League of Nations.

It believes that only officers experienced in malaria work should, for preference, be sent to this course. It also believes that the Health Committee might consider the possibility of giving a concurrent course for anti-malaria engineers at the same time and place. It further suggests the possibility of having a week's round table conference each year in which members of the League Malaria Commission from the East might usefully take part, for the dual purpose of advising the Malaria Commission on studies and problems in the East, and of comparing the conclusions of any investigations undertaken by or through them on behalf of the League.

The Conference welcomes the proposal, under the Health Committee's three-year plan, for the Malaria Commission to consider the advisability of holding, not earlier than 1939, an Inter-Governmental Conference on Anti-malaria Drugs, which would examine the following problems: present production as compared with world requirements, cost of production and market prices; relative costs of a plan of co-ordinated measures of treatment and prevention by the administration of drugs; methods of distribution.

PLAGUE

1. Since the tendency of pandemic plague to diminish in some parts of the world is offset by the possibility of its development elsewhere, and since, moreover, there is a growing danger of the dissemination of plague through the agency of modern communications, which are rapidly increasing throughout the world, the rural plague problem remains of great importance. It is therefore incumbent upon the Governments concerned to maintain the strictest vigilance by keeping their health services and permanent anti-plague organizations adequately provided with the necessary material and personnel.

2. In addition to the recognized methods of preventing the outbreak and spread of plague, such as rat-proofing of ships and buildings, the attention of the Advisory Council of the Eastern Bureau at Singapore should be drawn to the need for applying measures of control to rail, motor and other forms of land transport.

3. Apart from the destruction of rats (and rat fleas) by trapping, poisoning, fumigation, etc., the Conference emphasizes the necessity for improvement of existing dwellings and for the construction of new houses based upon rat-proof designs. The Conference recommends that Governments forward to the League Eastern Bureau at Singapore, for distribution to other administrations, any plans and designs they may approve from time to time. The Netherlands Indies Government has set an excellent example with its improved bamboo dwellings, and similar principles may be applied in communities where timber, mud, straw and the like are utilized.

4. (a) The Conference strongly recommends that mass vaccination be widely adopted in plague-infected areas and that statistical data be carefully compiled on a uniform basis.

(b) In view of the encouraging results obtained in Java by the use of a non-virulent live vaccine, it is strongly recommended that any country carrying out similar work should use a strain duly approved in respect of its antigenic power, and should apply the standard technique.

(c) At the same time it is desirable to collect further statistical data regarding the results obtained with heat-killed vaccine.

5. For all the purposes set forth in 4 (a), (b) and (c) above an exchange of technical information between the institutes concerned would be of great advantage.

ANKYLOSTOMIASIS

The Conference recommends the following measures for the combating of ankylostomiasis, in addition to general educational and hygienic measures:—

I. Treatment.—(a) Mass treatment and re-treatment should be given only to population groups in which harmful effects resulting from the infestation are clearly discernible.

(b) Individual treatment should be given as a matter of course to all persons on admission to a hospital or an institution in which such treatment can be given as part of the general routine.

II. Prophylaxis.—(a) Prevention of soil infestation being of paramount importance, the extensive building of latrines, if possible one to every house, seems to be the only permanent method of control. Governments should give assistance to further the building of latrines; their use should be encouraged by propaganda.

(b) More attention should be directed to the possibility of influencing the diet of tropical populations with the object of ensuring a sufficient intake of iron. Emphasis may perhaps be placed on iron contained in animal foods.

TUBERCULOSIS

1. In the anti-tuberculosis campaign in Asia, the greatest attention must be paid to the improvement of health by indirect methods, among these the raising of the standard of living with consequent improvement in physical and mental development is of outstanding importance.

2. A thorough study of the influence of nutrition is essential.

3. As regards the direct attack on the disease, a beginning should be made with a modest programme. The most effective plan is the gradual establishment and extension of a network of dispensaries co-operating with other Public Health agencies. These dispensaries, which should include the provision of some treatment among their functions, would furnish data regarding detection of early cases, family infection, school-inspection, house-visits, general hygienic education, etc., which would be of value for purposes of preventive medicine.

4. Anti-tuberculosis associations or voluntary organizations are of great value in stimulating public interest in tuberculosis as well as in attacking the social and economic problems connected with this disease: for example, assisting tuberculosis patients to obtain an adequate diet, suitable living accommodation and employment or temporary financial relief.

5. Although for economic reasons the system of sanatorium treatment cannot be as extensive as in Europe, it is desirable that sanatoria of a simple type should be set up in numbers appropriate to the development of the dispensary system.

6. Apart from these, it is desirable to establish a few fully-equipped sanatoria serving as centres for post-graduate work on tuberculosis and as central training institutes for auxiliary personnel; in these sanatoria, the general system to be applied in the treatment of tuberculosis may be worked out. In countries with restricted budgets, the beds occupied by very advanced cases in public hospitals can with greater advantage be used for other patients. Facilities for the cheaper institutional accommodation of such advanced cases should therefore be provided.

7. It is essential that, in Asiatic countries, complete and accurate data should be collected regarding the incidence and severity of tuberculosis.

8. Tuberculin tests and the method of appraisal of results should so far as possible be standardized on an international basis. Attention may be drawn to the method used for tuberculin tests in the Netherlands Indies.

9. Tuberculosis surveys may be carried out in villages to determine the incidence of the disease and the source of fresh infections.

10. The Conference strongly recommends that plans for a campaign against tuberculosis and schemes be drawn up, and carried out, in so far as resources permit, by the Governments of all countries in the East.

The Conference further recommends that, when such plans have been worked out, they should be sent to the Eastern Bureau of the League of Nations at Singapore

for communication to the other administrations. The question could be placed upon the agenda of the annual session of the Eastern Bureau Advisory Council in 1939.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF BURMA FOR THE YEAR 1936, INCLUDING ADMINISTRATION OF VACCINATION IN 1936-37

THE CHIEF DISEASES IN BURMA AND THEIR EPIDEMIOLOGY
Cholera.—Cholera was not widespread in the country. The death rate shows a drop of 0.49 compared with the previous year and 0.08 compared with the five-year mean. In the first five months of the year the disease was mostly confined to four districts in the Tenasserim division, where it continued from the previous year. In June and July there was a rise in the incidence of this disease in the Irrawaddy and Pegu divisions. Thereafter only stray cases were reported.

Anti-cholera measures.—On receipt of the news of an outbreak, the epidemic staff in the district is augmented, if necessary, and instructions are issued for the performance of intensive anti-cholera inoculation and for the purification of water supplies. Propaganda is also carried out to make these measures popular. The people have begun to appreciate the benefit of anti-cholera inoculation. As the cholera epidemic during the year was not very severe, the number of inoculations performed fell from 576,216 in 1935 to 206,608 this year. The districts in which the largest number of inoculations were performed are Thaton 31,685, Myaungmya 31,640 and Maubin 27,183.

Smallpox.—The death rate from smallpox is 0.01 in excess of the previous year but is 0.01 below the five-year mean. As usual the disease was most prevalent during the period March to May, while the lowest number of deaths was recorded in September. With the exception of Kyaukpnyu, Minbu, Pakôkku and Sagaing, mortality was reported from all districts. Of the 1,354 deaths during the year 8.20 per cent were among children under one year, 21.71 per cent among children over one and under ten years and the balance of 70.09 per cent were among persons over ten years. These figures reveal the necessity for revaccination among adults, especially in the rural areas.

Plague 0.19.—The death rate from plague this year is 0.08 below the previous year and 0.06 less than the five-year mean. As usual, the disease was most prevalent in the cold weather, i.e., January to March, November and December. The lowest mortality was recorded in the month of May. The Arakan division and the districts of Tavoy and Mergui were, as in previous years, free from the disease and five other districts returned no mortality from this cause during this year.

Anti-plague measures: (a) *Rat destruction.*—The total number of rats killed by trapping and smoking was 834,551 (840,576). As in previous years the vast majority, viz, 753,618, were reported as killed in the Rangoon Corporation area. Other towns in which rat destruction was carried out were Moulmein 10,933, Syriam 8,856, Myaungmya 5,667, Bassein 5,067 and Myingyan 4,296. In the rural areas rat destruction was reported from Insein, Myaungmya, Magwe, Mandalay and Sagaing districts.

Fumigation of rat holes with cyanogas has become an established method for keeping down the rat population in any area. The reports received from districts and towns in the country indicate that its use has become universal. Unfortunately many of the reports do not give detailed statistics of the number of rat holes cyanogassed and the number of connecting holes blocked. In Mandalay town, where cyanogas work is done thoroughly and systematically, 157,363 premises were inspected for the presence of rats; of these 16,832 were found to have rat holes. The number of rat holes treated with cyanogas during the year was 39,331 and the number of connecting holes blocked was 89,234.

(b) *Inoculation*.—During the year 171,041 persons (125,079) were protected with anti-plague inoculation. Of this year's total 77,947 were done in the rural areas and 93,094 in towns.

Fevers (provincial).—The death rate from fevers (8.67) has shown a rise of 1.36 compared with the previous year and is 1.74 in excess of the five-year mean. This group accounted for 39.71 per cent of the total mortality. A large proportion of the fevers is undoubtedly due to malaria. The largest number of deaths was recorded in the month of December in which month is also recorded the largest number of deaths from malaria in towns. The lowest number of deaths was in May.

Enteric fever.—The death rate (0.24) is 0.02 in excess of both the previous year and the five-year mean. The highest rates during the year were reported from Yandoon 1.51, Myitkyina 0.82, Mandalay 0.80 and Bhamo 0.75. It is considered that the total deaths reported due to enteric do not represent the true incidence; this is due to the comparative rarity of accurate bacteriological investigation into cases.

Dysentery and diarrhoea.—The death rate from this group of diseases (0.48) shows a decrease of 0.05 compared with the previous year but it is still 0.02 in excess of the five-year mean. The highest mortality was, as usual, recorded in July and the lowest in March.

Respiratory diseases.—There was an increase of 0.16 in the death rate from these diseases (1.15), compared with the previous year and 0.14 compared with the five-year mean. The lowest number of deaths was recorded in the month of May. In the other months figures of mortality were more or less evenly distributed, the highest number having been recorded in September. As usual, there was a marked preponderance of male over female deaths, the proportion being 138 : 100.

Beri-beri.—This disease is not notifiable in the rural areas and so its incidence can only be gauged from information contained in the annual public health and other special reports from the District Health Officers. In the *Upper Chindwin* it would appear to occur usually from October to March. It was specially noticeable among the employees of the Bombay-Burmah Trading Corporation, Ltd., though cases were also met with among the villagers. The Company substituted the supply of *atta* for rice to their employees and had all cases treated in hospital. In *Toungoo* district the disease continued to be fairly common among mahouts working in timber camps, while, as in the previous year, in *Pyapôn* it was confined to Indian coolies, whose low standard of living renders them liable to be attacked.

Goitre.—This disease is endemic in the Shan States, Bhamo, Upper Chindwin, Katha and Pakôkku districts. It is also prevalent in the districts of Henzada, Toungoo, Salween and Minbu. In the Kengtūng subdivision, Southern Shan States, it is very commonly found but the inhabitants there seldom go to hospital for treatment. In the Northern Shan States, Namhsan and Kutkai recorded the highest incidence and during the year 8,659 (6,673) cases were treated in hospitals. In the Chin Hills a certain kind of locally manufactured salt is popularly believed to be a cure for goitre. A sample of this salt was analysed by the chemical examiner, Rangoon, and was found, after purification, to be nearly 92 per cent sodium chloride with some traces of alkaline compounds. It contained no iodine.

Yaws.—This is known to be endemic in Victoria Point subdivision, Bokpyin township and elsewhere in the interior of Tenasserim and Palaw townships in *Mergui* district. It occurs most frequently among the Salons, Malays and Siamese but is also found among Burmans and Karens. During the year a sub-assistant surgeon of the medical department was deputed to carry out during the open season a survey and treatment of cases in Tenasserim, Palaw and Mergui townships. The district council agreed to meet the incidental charges of the survey, the pay of the sub-assistant surgeon was met from provincial funds and the cost of the drugs was borne by the Burma Red

Cross Society. During the period from March to May 327 cases were treated in 20 different villages. For the treatment of yaws in Victoria Point subdivision a sub-assistant surgeon attached to the Civil Hospital, Victoria Point, was ordered to visit the villages in the subdivision occasionally. The District Council's Local Fund in this connection paid the travelling allowance of one interpreter and the cost of drugs and other incidental charges. Yaws appears to be prevalent in the *Lower Chindwin* district, more particularly in Kani township. During the year a few cases were reported from Yinnabin and Budalin townships. The district health officer has applied to the Burma Red Cross Society for a grant to intensify the campaign against this disease. In the *Upper Chindwin* district the disease is believed to be common in several townships. Unfortunately many cases were not reported to hospital as the villagers do not appreciate that the cure is easy. A sum of Rs. 100 was expended on drugs from the Deputy Commissioner's Local Fund and the District Health Officer is submitting proposals to the Inspector-General of Civil Hospitals for the posting of a sub-assistant surgeon for three months to tour in the infected villages and give treatment by injection. It is hoped that sufficient funds will be available for the purchase of drugs in the ensuing year. In *Kyaukse* district yaws is present in Myittha and Sagaing townships. In the past only sporadic efforts have been made to deal with it but the District Council is now being requested to allot some money for treatment of cases. In *Mogôk* subdivision the disease was prevalent in the villages of Letpangon, Sezingon and Zegon and a few people turned up for treatment at the Civil Hospital at Thabeitkyin.

Leprosy.—This disease is only notifiable in two municipalities, namely, Maymyo and Mōnywa; in other towns figures of mortality alone are available. During the year 1936, there were 202 deaths from leprosy in towns which gives a death rate of 0.21. The largest number of deaths were recorded in Rangoon and Mandalay, probably because the asylums for the compulsory segregation of pauper lepers exist in these two places. During the year there were three leper colonies in Burma situated at Mōnywa, Minbu and Kengtūng (Southern Shan States). The colonies at Mōnywa and Minbu are controlled by non-official local Leprosy Relief Committees while the one at Kengtūng is run by the Roman Catholic Mission. To all these colonies clinics are attached in which leper patients, both in-door and out-door, are treated by specially trained doctors on specified days each week. In the Mōnywa colony there were at the end of the year 87 (77) inmates. The existing accommodation, consisting of seven cottages each housing eight patients, having proved inadequate to meet the growing demand, four new cottages were built. Excellent work is being carried out at this colony. The number of patients in Minbu colony at the close of the year was 38. There are in all five cottages, one having been added during the year for the accommodation of additional in-patients. Kengtūng colony had 105 resident lepers at the end of the year, this includes six children. All these colonies receive grants from the Burma Branch of the British Empire Leprosy Relief Association. Plans for the colony at Meiktila have progressed during the year. A piece of land measuring 10 acres has been acquired and a cottage for the accommodation of eight patients has been completed. A brick building, the expense of which has been met by a local philanthropist, is being constructed for use as a clinic and store-room. Water is available from an excellent well situated on the colony site. It is probable that this colony will be inaugurated before this report is printed.

In the absence of colonies we have to fall back on the establishment of clinics in attempting to combat this disease. But there is no doubt that the establishment of clinics does not do away with the necessity for colonies. The economic and physical difficulties experienced by people in attempting to attend at clinics are frequently insurmountable. Clinics for the treatment of lepers should have as their main object the

gaining of the good-will and confidence of those suffering from this disease. Cases should be followed up to their homes, contacts should be examined and the history of the disease in the village locality be thus worked out. Cases should be listed so as to distinguish between infectious and non-infectious types and the final object should never be forgotten, i.e., the effective isolation of all infectious cases from the community and especially from children, as the latter are so highly susceptible to infection. The ultimate aim should be the founding of communities forming leper villages in which the more able-bodied can help those less strong.

During the year six alien lepers are reported to have entered Burma through Rangoon, of whom one was sent to the leper asylum and the others were allowed to go to their residences.

Veneral diseases.—The general opinion among district health officers is that the incidence of this group of diseases is very high. Unfortunately they are not taken seriously in many of the districts. Much propaganda is needed to impress upon people the seriousness of these complaints and the importance of avoiding them in the interests of the generations yet to come. During the year, 320 deaths from syphilis and 15 from gonorrhoea were recorded in towns. These figures do not, however, give an accurate idea as to the extent of prevalence of this group of diseases. In the Rangoon General Hospital out of 796 post-mortem examinations carried out in 1936 signs of syphilis were detected in 15.58 (21.24) per cent, the corresponding percentages for 1934 and 1933 being 20.99 and 19.75 respectively. Among the 2,038 admissions into the four shelters of the maternity and infant welfare society, Rangoon, venereal infection was traced in 341 cases.

Rural health unit, Hlègu.—This health unit was started in the year 1929 with the idea of demonstrating to the people in a typical rural area what can be done to improve sanitary conditions by applying modern methods of public health, employing a personnel and equipment on a scale comparable with such services as police protection and general education. As in previous years the collection and study of vital statistics, control of acute epidemic diseases, health education, maternity and child welfare work, medical examination of school children, hookworm survey, waste removal, improvement of food establishments and water supplies, soil sanitation and laboratory work constituted the unit's main activities.

Improvement of environmental sanitation constituted one of the main functions of the unit. During the year 738 wells and tanks were inspected and as a result of the inspections 38 wells and 13 tanks were improved and 27 wells and 3 tanks were chlorinated. Food stalls, cattle-sheds and other premises inspected totalled 3,253. Additional bored-hole latrines numbering 262 were installed in 12 villages and the total number of bored-hole latrines in the unit area is now 2,087. Refuse removal was carried out with the Unit's lorry at Hlègu and Dabein where 1,370 loads of refuse were removed to the dumping grounds. Anti-rat measures were carried out systematically; 349 rat holes were fumigated with cyanogas, 1,193 connecting holes were blocked and 299 other rat holes were smoked; 6,030 rats were also trapped and destroyed.

Malaria.—It is very difficult to arrive at an actual estimate of the incidence of malaria in rural areas as village headmen, who act as death registrars in these areas, are apt to classify any rise of temperature as due to malaria. During the year 100,395 out of the 220,846 deaths in the rural areas were ascribed to fevers. It is believed that a fair estimate is that half the deaths described as fevers should be ascribed to malaria.

The urban death rate was 0.26 higher than the previous year and 0.18 in excess of the five-year mean.

Cinchona febrifuge and quinine tablets.—During the year the manufacture of cinchona febrifuge tablets for the replenishment of stocks in district treasuries was continued in Rangoon Jail. This drug is either issued free in necessitous cases, or is supplied to retail licensed vendors to sell to the public. During the year

treasuries sold 3,554,100 tablets (3,826,980). The largest decrease was shown in the Southern Shan States—719,820 and two other districts which showed a notable fall in sales were Northern Shan States—54,540 and Pyapôn—30,780. Increases in sales were returned from 24 districts, notably in Toungoo + 143,100, Pegu + 65,880, Minbu + 52,020 and Myitkyina + 51,480.

During the year 5,000 lbs. of quinine sulphate were received for free distribution from the Government of India. When making this supply the Government of India stipulated that this Government's allotment for the purchase of cinchona febrifuge tablets should not be reduced in the next three years. A provision of Rs. 22,500 was made for the purchase of cinchona febrifuge tablets for free distribution from the grant made by the Government of India for rural improvement work. These two grants made available a large quantity of quinine sulphate and cinchona febrifuge for wide and systematic free distribution. In order that there should be no confusion between the existing scheme for distributing this drug through district treasuries with the scheme for free distribution made possible by the two grants mentioned above, arrangements were drawn up for the distribution through district health officers of the free quinine and cinchona febrifuge purchased from the grant. It was realized that the task of distribution in the rural areas was beyond the limited public health staff and the co-operation of many other departments was asked for and obtained in distributing these drugs. The scheme was inaugurated in August during the year in the 40 districts of Burma, excluding Rangoon, and 2,540,610 tablets were distributed free. The largest distribution was made in the districts of Minbu 270,000, Hanthawaddy 231,840, Shwebo 214,560 and Yamethin 181,854. That the scheme is a success and has been worked energetically is shown by the fact that by the end of the year over 4,000 lbs. of quinine sulphate had been converted into tablets and supplied to district health officers. Besides this distribution of quinine sulphate tablets, a total of 298,800 cinchona febrifuge tablets were distributed from treasuries in 13 districts.

The result of this was that the average consumption of quinine and cinchona febrifuge per head of population this year rose from 1.20 grains in 1935 to 1.79. There is no doubt that this increase was mainly due to the expensive free distribution of quinine sulphate.

Maternity work.—As in the previous year, 34 midwives were employed by 11 voluntary child welfare societies for maternity work and they attended 5,807 (6,095) confinements. Local bodies such as municipalities, district councils and Deputy Commissioners' local funds employed 203 midwives and they attended 20,531 (19,447) confinements. The percentage of births attended by these midwives in urban areas is 29.50, while the corresponding figure for the rural areas is only 2.88. Details are not available as to the number of confinements attended by private doctors and private midwives in urban and rural areas. During the year statistics as to the extent to which mothers availed themselves of skilled midwifery service were collected in 13 towns having wholtime health officers. These statistics reveal that of the total births in these towns 19.55 per cent were attended by municipal midwives and midwives employed by child welfare societies; 5.88 per cent by private midwives; 2.52 per cent by private practitioners; 19.89 per cent in hospitals and 49.71 per cent by untrained midwives, the balance of 2.45 per cent being unattended. The provision of skilled midwifery service in the rural areas is very inadequate and its development is bound to be slow.

Child welfare work.—The only child welfare work in Burma which is not undertaken by voluntary child welfare societies is that of the Rangoon Corporation and the Rural Health Unit, Hlègu.

The total number of child welfare societies in Burma in 1936 was 47. Of these, 28 societies conducted 32 child welfare centres, thirteen of them employing trained health visitors, and eleven employing a nurse or midwife for child welfare work. The remaining four

societies relied on voluntary workers. Four new societies were formed during the year.

ANNUAL REPORT ON THE WORKING OF THE CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEAR 1936

At the beginning of the year under report there were 1,363 medical institutions of which 1,116 were in rural areas and 247 in urban areas. Forty-nine new dispensaries were opened during the year, eighteen closed and thirty transferred to other classes of institutions. Thus at the end of the year there were 1,364 medical institutions (1,118 and 246 in rural and urban areas respectively) at work in the Presidency, i.e., State public 191, State special 28, local and municipal funds 517, private-aided 67, private non-aided 94, railways 48 and subsidized rural 419.

(a) *In-door patients.*—The total number of patients treated in all classes of medical institutions during the year was 255,358 (130,945 males, 103,696 females and 20,717 children) as against 245,590 (129,661 males, 97,261 females and 18,668 children) in 1935 showing an increase of 3.98 per cent over the number treated in 1935.

(b) *Deaths.*—There were 12,182 deaths in all the medical institutions during the year. The ratio of deaths per cent to total treated for the last five years have been as follows:—

1932	4.39
1933	4.72
1934	4.89
1935	5.03
1936	4.77

(c) *Daily average attendance of in-patients.*—The daily average attendance of in-patients during 1936 in the Presidency was 11,656.03 as against 11,244.20 in the previous year. The increase per cent was 3.66.

(d) *Beds.*—The beds provided for in-door patients in hospitals of classes I, III and IV were 10,986 (6,205 men and 4,781 women) in 1936. The need for additional beds was keenly felt in many of the hospitals during the year.

(e) *Out-door patients.*—In all classes of medical institutions 16,032,812 patients were treated consisting of 7,482,765 males, 4,022,425 females and 4,527,622 children as against 16,570,958 (7,788,602 males, 4,015,155 females and 4,767,201 children) in the previous year.

(f) *Daily average.*—The daily average number of in- and out-door patients treated in medical institutions of classes I, III, IV and VII during the year was 11,656.03 and 109,226.04 respectively while the same during the previous year was 11,244.20 and 112,479.96 respectively.

The following diseases treated among in- and out-door patients in all the medical institutions in the Presidency during the year accounted for the largest number:—

Diseases of the respiratory system other than pneumonia and tuberculosis	..	1,235,295
Diseases of the digestive system	..	1,192,351
Diseases of the eye	..	1,169,367
Ulcerative inflammation	..	1,138,544
Diseases of the ear	..	1,124,431
Malaria	..	999,612
Diseases of the skin excluding tumours	..	859,021
Scabies	..	778,461
Diseases of the intestines	..	740,301
Pyrexia of uncertain origin due to infection	..	718,102

Tuberculosis.—The number of patients treated for tuberculosis (tuberculosis of the lung and other tuberculous diseases) in all the medical institutions was 75,279 during the year under report. The deaths were only 1,017 as compared to 1,413 of last year. The Tuberculosis Institute has continued to serve as a centre

for after-treatment of cases discharged from the Tuberculosis Hospital, Madras, and other hospitals and sanatoria in and outside the Presidency. As a further step in anti-tuberculosis work in Madras city, a tuberculosis clinic on up-to-date lines has been started for the examination of contacts, by the tuberculosis sub-committee of the King George V Thanksgiving (Anti-Tuberculosis) Fund, Indian Red Cross Society, as an adjunct to the Tuberculosis Institute, Egmore, and it is working successfully since last year. With a view to providing more accommodation and treatment for such cases, the Government have taken over Dr. Muthu's Sanatorium at Tambaram in Chingleput district. The Coimbatore District Tuberculosis Sanatorium Society has taken steps to establish and maintain a sanatorium at Perundurai. A tuberculosis clinic has been opened at the Government Victoria Caste and Gosha Hospital, Triplicane, as an experimental measure for one year. Observation of the employees of the Government Press continued as usual at the institute. Of the 26 cases sent to the institute for observation, 12 were found to have tuberculosis. Owing to the large demand for admission among patients suitable for hospital treatment, temporary arrangements have been made to provide more beds in the recreation and dining-hall of the hospital. The need for more accommodation for cases of tuberculosis is very great. Some thousands of beds in hospitals and sanatoria and tuberculosis clinics are required.

Leprosy.—The number of leprosy clinics functioning at the end of the year was 445 wherein about 70,000 injections are given every month. Several Government and local fund medical institutions in the Presidency have leprosy clinics attached to them. The purpose of leprosy clinics is to bring treatment within easy reach of every affected individual and the necessity for erection of separate leprosy sheds was keenly felt in many clinics where the attendance was high. With a grant-in-aid from the Silver Jubilee Fund, special clinics for the study of leprosy and its epidemiology will soon be established at Rayapuram, Saidapet, Vellore, Cuddalore and Tanuku. The Silver Jubilee committee have sanctioned grants to provide increased accommodation in the leper asylums at Salur, Kodur, Narsapur, Bapatla, Chingleput, Kumbakonam, Manamadurai and Mangalore. It is now necessary to carry on the work with greater efficiency and to organize special investigation units for intensive study of the disease particularly in children.

SEVENTY-FIFTH ANNUAL REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL FOR THE YEAR 1936-37

THE market price for cinchona products has again suffered no major change during the year under review, for quinine has been firmly held and remains securely linked with gold. Even the violent fluctuations of currency have failed to affect it, a rise of an anna an ounce being the limit of the change recorded. The steadiness of the position reflects the strength and foresight of those who negotiated the quinine agreements, while the apparent determination to maintain prices at a level commensurate at once with demand and with the costs of production may be taken as the best indication of the future stability of the industry. For there is as yet no sign of production outside Java on a scale or at a cost likely to affect the monopoly secured. That it is in parts of India cheaper to grow than to buy quinine has as yet no visible effect on prices for it is not unknown that the volume of production here is, and for years to come will be, insufficient to disturb the market. If proof of this were needed one might refer to the fact that it has not been a fall but a rise in price that has accompanied the placing in the market of considerable quantities of Government quinine.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL P. S. MILLS, C.I.E., is appointed Honorary Physician to the King, dated 29th March, 1938, *vice* Major-General D. P. Goil, retired.

Colonel D. H. Rai, Inspector-General of Civil Hospitals, C. P. and Berar, ceased to be Officiating Director of Public Health, C. P. and Berar, in addition to his own duties from 19th August, 1938.

Lieutenant-Colonel S. N. Makand returned from leave and resumed charge of the office of Director of Public Health, C. P. and Berar, from 19th August, 1938.

Lieutenant-Colonel T. C. Boyd, on the expiry of his leave, is reappointed to be Principal, Medical College, and Superintendent, Medical College Hospitals, Calcutta, *vice* Dr. Dabiruddin Ahmed.

The dates of the appointment of the undermentioned officers to the Civil Branch of the Indian Medical Service are as now shown against their names:—

Lieutenant-Colonel D. L. Graham. Dated 7th August, 1925.

Lieutenant-Colonel C. H. P. Allen. Dated 24th February, 1927.

Lieutenant-Colonel E. R. Daboo. Dated 9th October, 1928.

Lieutenant-Colonel J. L. Sen. Dated 13th July, 1925.

Major R. A. Haythorntlwaite. Dated 26th March, 1936.

Major J. L. Donnelly. Dated 2nd July, 1935.

Major W. J. L. Neal. Dated 18th July, 1935.

Major J. A. W. Ebdon on return from leave to rejoin the appointment as Principal and Professor of Surgery, Medical College, Vizagapatam, and First Surgeon, King George Hospital, Vizagapatam, and Chief Medical Officer, Vizagapatam Port.

Subject to the approval of the Secretary of State for India to the transfer of Major Jaswant Singh to the Civil Branch of the Indian Medical Service, that officer is appointed to the Medical Research Department on probation for 2 years, with effect from the 11th July, 1938 (afternoon), and is placed on foreign service under the Indian Research Fund Association.

Major D. Kelly returned from leave and resumed charge of the office of Civil Surgeon, Raipur, from 8th August, 1938.

Captain M. Sendak, who was attached to the office of the Civil Surgeon, Nagpur, for training, has been posted as Civil Surgeon, Saugor, where he assumed charge on the afternoon of 17th August, 1938.

Captain V. E. M. Lee, Civil Surgeon, Saugor, has been reverted to Military duty. He was relieved of his Civil duties in this province on the afternoon of 17th August, 1938.

LEAVE

Lieutenant-Colonel N. S. Jatar has been granted an extension of leave by 1 month and 6 days.

Lieutenant-Colonel T. H. Thomas, Officiating Professor of Medicine, Medical College, Calcutta, is granted leave for the period from the 2nd August, 1938, to the 1st September, 1939, in extension of the leave already granted to him previously.

Major K. S. Fitch, Civil Surgeon, Hooghly, is granted leave for 2 months, in extension of the leave already granted to him previously.

Major G. M. Irvine was granted 5 months and 28 days' leave on medical certificate, including 1 month and 1 day vacation, with effect from the 1st August, 1938.

Captain R. L. Raymond was granted 1 year's leave, with effect from the 31st August, 1938.

PROMOTION

Captain to be Major (probationary)

A. K. Gupta. Dated 15th July, 1938.

RELINQUISHMENT

Captain A. G. Khan (S. S.) relinquishes his commission on the ground of ill health. Dated 26th August, 1938.

Lieutenant A. A. Khan relinquishes his temporary commission. Dated 5th September, 1937.

RETIREMENT

Lieutenant-Colonel S. S. Vazifdar is permitted to retire from service, with effect from 1st August, 1938.

Lieutenant-Colonel J. A. Sinton, v.c., o.b.e., retires. Dated 4th August, 1938.

Lieutenant-Colonel B. H. Kamakaka, m.c., retires. Dated 22nd August, 1938.

Notes

BRITISH MEDICAL ASSOCIATION EXHIBITION, PLYMOUTH

18TH TO 22ND JULY, 1938

THE extensive display of fine pharmaceutical products shown by Burroughs Wellcome and Co. bore witness to the steadily progressive policy of the firm, several recent introductions being exceptionally noteworthy.

Much interest was manifested in 'Tabloid' brand Sulphonamide-P, the sulphanilamide preparation for oral administration, which is rapidly increasing in importance as its therapeutic value gains greater recognition. In an ingenious arrangement of illuminated photo-micrographic transparencies, the specific chemotherapeutic effect of sulphanilamide upon the hæmolytic streptococcus was beautifully demonstrated. In addition, the clinical use of sulphanilamide in such conditions as meningococcal meningitis and *B. coli*, *Pr. ammoniæ* and gonococcal infections of the genito-urinary tract was shown pictorially, other indications being also mentioned.

Another important exhibit was 'Wellcome' brand insulin—a product prepared with pure crystalline insulin—together with 'Wellcome' brand protamine insulin (with zinc) suspension, which, because of its prolonged blood-sugar-lowering effect, is being increasingly used as an alternative to or in conjunction with unmodified insulin.

A notable introduction which aroused considerable interest was 'Wellcome' brand calcium mandelate compound, for use in urinary tract infections. This preparation lacks the disagreeable taste characteristic of sodium or ammonium mandelate, and possesses a ready miscibility, two advantages making greatly for ease in administration.

Specimens of 'Tabloid' brand nicotinic acid, a product which has been introduced for the treatment of pellagra, were noted with interest.

VIROL AND SCHOOL CHILDREN

THE LORD LUKE, K.B.E., speaking at the 38th Annual General Meeting of Virol, Limited, said the public's attention had no doubt been attracted to the growing importance of investigation into the problem of nutrition; knowledge in this field had extended so rapidly that manufacturers of food preparations of a specialized character found it essential to maintain continual research. Modern discoveries had made the science of nutrition so complex that it was exceedingly difficult for the medical profession to evaluate the relative merits of the food preparations available, except by the fundamental test of direct experiment, under similar conditions to those prevailing in the intended field of application. Virol, Limited, had always recognized the need for such work, and reference was made in the report to the publication in October last of an important investigation into 'The Supplementary Feeding of School Children'. These researches were carried out on 864 children attending schools in the North and South of England.

Their growth-rates while on ordinary meals only were compared with their growth-rates when receiving

in addition a ration of one of three supplements normally used in schools, one of which was Virol. The results indicate the necessity of such supplementary feeding, and the superiority of Virol over the other two supplements. They also afford remarkable confirmation of the findings of the previous investigation on children of pre-school age.

BRITISH FUND FOR RELIEF IN CHINA

DR. BERNARD E. READ, acting director, Henry Lester Institute of Medical Research, Shanghai, writes:—

'There have been received through the British Fund for Relief in China twenty hundredweights of marmite, which have been distributed to Canton, Kunming, Hankow, Shanghai and Tientsin, about half of it going to Hankow and West China.

In Shanghai the disease incidence among the refugee population of about 200,000 has been estimated to be about 10 per cent. Of these about one-tenth have suffered from beri-beri, which does not include other types of general malnutrition. These 2,000 cases of beri-beri often suffered from multiple dietary deficiencies such as avitaminosis A and B, as manifested by the extensive amount of skin disease.

The supplies of marmite sent out to China have been of great value in the treatment of beri-beri. The high content of vitamin B in marmite together with the other extractives from yeast provided a valuable remedy for the cases of multiple dietary deficiency. The severe cases were given one ounce a day and the milder cases half an ounce, producing the expected result of a complete cure of the beri-beri cases of the dry type.

General deficiency disease has been too extensive for the limited supplies of marmite to be used for anything but therapeutic purposes along the lines indicated. The highly organized medical service in Shanghai has enabled us to use the marmite in the most effective way possible, in the treatment of sick people from the refugee camps.

At one time it was proposed to distribute it as a general nutritive to certain undernourished camps, with the view of observing its general beneficial value. But the constantly shifting character of the population in the camps, and the huge amount required, rendered this impossible.

We send our very grateful thanks for this valuable gift which has proven of such service to us in Shanghai.

It has been impossible with all the difficulties of communication to obtain at this juncture detailed reports from other centres. One consignment was sent to Hangchow for the treatment of beri-beri cases, and others who have used this marmite have expressed great appreciation of such a valuable gift. It has brought relief to thousands and saved from death many in the crowds of homeless, penniless, sick and starving refugees.

PACKAGING PROGRESS

PHARMACEUTICAL Specialities (May and Baker) Limited, of Dagenham, for many years have marketed the majority of their well-known preparations in tubes and glass bottles, enclosed in boxes, but these will now for the most part disappear from the pharmacy shelves to be replaced by aluminium containers in cardboard cartons.

Courage, as well as initiative, is needed to introduce a change by which an old and familiar packing, which has come to be regarded by chemists and medical men as a symbol of quality and purity, is abandoned in favour of an entirely new type which has still to make itself known, and even firms which succeed, by constant research, in maintaining their products in the van of scientific progress, may be excused for a somewhat conservative attitude towards their packings. But progressive improvement in design and materials necessitates periodic revision of packing methods if an anachronistic appearance is to be avoided and Pharmaceutical Specialities are acting wisely in taking this step.

The superiority of the new packings, however, is by no means based solely on their appearance. The aluminium containers are light and easy to handle. Their circular base gives them greater stability than the easily overturned bottles, whilst the convenient screw top and the absence of anything in the nature of a 'neck' make the contents easily accessible.

An innovation which will find favour with physicians and pharmacists alike is the printing of the average dose on both container and carton. Much time and trouble will be saved by the addition of these few words.

The change of packings, though not completely comprehensive, affects the majority of the firm's preparations, including Stovarsol Vaginal Compound, Proseptasine, Theogardenal, Gardenal, Arthrytin, Sonalgin and Soneryl. One notable exception to the change is Stovarsol which will continue to be sold in the little red box.

'M. & B. 693'

2-SULPHANILYL-AMINO-PYRIDINE

THERE has been so much discussion in both the medical and popular press on 'M. & B. 693' that it is already a familiar name to many medical practitioners. The manufacturers have adopted a very cautious attitude with regard to the drug and arranged for an elaborate series of clinical trials to be carried out to determine its precise value. The trials which so far have been completed have amply demonstrated the exceptional properties of 'M. & B. 693' and Pharmaceutical Specialities (May and Baker), Limited, advise us that it is now generally available. Two booklets have been prepared entitled '*M. & B. 693 Biological and Biochemical Data*' and '*M. & B. 693 in the Treatment of Pneumococcal Infections*' and copies will be sent to medical practitioners on request.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

CHEMOTHERAPY IN ACUTE SURGICAL INFECTIONS WITH PRONTOSIL AND ALLIED DRUGS

By P. N. RAY, B.A., M.B., F.R.C.S. (Eng.)
Additional Surgeon, Medical College Hospitals

K. S. ALAM, M.B.

and

B. K. GHOSE, M.B.

House Surgeons to the Additional Surgeon, Medical College Hospitals, Calcutta

THE introduction of a new remedy is usually accompanied by an excess of enthusiastic expectation, which is soon tempered down to reasonable limits on closer acquaintance and wider experience. The chemotherapeutic possibilities of 'prontosil' and allied drugs have not yet been fully assessed; nevertheless it will not be unprofitable to consider the present position. In this paper is embodied the experience gained in 100 consecutive cases of acute surgical infections treated with 'prontosil' and allied drugs.

Nomenclature of sulphanilamides

The triumphant entry of 'prontosil' and the publicity given to it in the lay press were soon succeeded by the appearance of close competitors, which have not been an unmixed blessing, although the price of this medicament has thus been brought down to a more economic level. The multiplicity of new drugs of this group has given rise to much confusion in nomenclature and usage. 'Prontosil red', the original preparation, is a registered trade name for a complex azo dye-stuff. 'Prontosil album' is a colourless derivative, chemically described as p-amino-benzene sulphonamide, being the amide of sulphanilic acid. The term *sulphanilamide* has therefore been adopted for it by the Council on Pharmacy and Chemistry of the American Medical Association. There is an allied group, bearing the chemical formula of p-benzyl-amino-benzene sulphonamide, which may conveniently be called *benzyl-sulphanilamide*. It is important to remember the difference in the chemical composition of these drugs because their therapeutic properties vary considerably.

TABLE I

Sulphanilamide	Benzyl-sulphanilamide
1. Prontosil album (Bayer).	Proseptasine (Pharmaceutical Specialities, May and Baker Ltd.).
2. Sulphonamide-P (Burroughs Wellcome and Co., British Drug Houses Ltd., Allen and Hanburys Ltd.).	
3. Streptocide (Evans Sons Lescher and Webb).	
4. Sulphanilamide (E. R. Squibb and Sons, Boots Pure Drug Co., Ltd.).	
5. Sulfamidyl (Abbot Laboratories).	

We may here consider, with a little more detail, the characters of the drugs of the prontosil series. It was shown by Domagk, in 1935, that a red diazo dye, prepared by Mietzsch and Klaver, possessed remarkable protective properties against experimental streptococcal infections in mice. This compound, subsequently known as 'prontosil red', is chemically described as 4-sulphamido-2: 4-diamino azobenzene and it has the following structural formula :—

It was put on the market in the form of the hydrochloride, possessing slight solubility in water. The tablets at first contained 0.3 gramme (5 grains) but later 0.5 gramme (7½ grains) of the dye. This was the preparation that was first used with success in puerperal sepsis.

Prontosil soluble.—Under this name a more convenient soluble form of prontosil was soon introduced. It is a complex chemical substance, being the disodium salt of 4-sulphonamino-phenylazo-1-hydroxy-7-acetyl-amino-naphthalene-3: 6-disulphonic acid. The following is its structural formula :—

It was first introduced as a 2.5 per cent solution, but it is now available as a 5 per cent solution for intramuscular injection.

Sulphanilamide.—While studying the pharmacological actions of prontosil, it was observed by the French workers Tréfouël, Tréfouël, Nitti and Bovet (1935) that it was excreted in a partially disintegrated form in the urine, from which p-amino-benzene sulphonamide could be easily extracted. They were able to show that the urine, when injected into mice under similar conditions, was equally potent. It was suggested by them that the much simpler chemical p-amino-benzene sulphonamide was the actual active principle of the coloured prontosil preparations and that the azo-linkage was unnecessary. The simple structure of sulphanilamide is shown by its structural formula :—

Benzyl-sulphanilamide.—'Proseptasine' (May and Baker) is the benzyl derivative of sulphanilamide, having the graphic formula of :—

It is supplied in the form of 0.5 gramme tablets for oral administration.

'Soluseptasine' is the trade name for disodium-p (γ -phenyl-propyl-amino) benzenesulphonamide- α -disulphonate and it has the following structural formula :—

This soluble form is intended for intramuscular, subcutaneous or slow intravenous use. The initial dose is 5 c.cm. of a 5 per cent solution for testing the patient's tolerance. It is followed four hours later by injection of 10 to 20 c.cm. of the solution, which may be repeated in twenty-four hours if necessary.

Mode of action

The mode of action of these drugs has become the subject of much controversy, and various theories have been advanced to explain their anti-streptococcal action. Considering that each of these preparations contains a 'sulphonamide' group in the *para* position, it was readily assumed that sulphanilamide was the actual active principle of the coloured prontosil preparations. This assumption was strengthened by the fact that prontosil has very little anti-streptococcal action in *in-vitro* experiments. It was, however, subsequently shown (Colebrook, Buttle and O'Meara, 1936) that sulphanilamide mixed with the human blood and serum *in vitro* had a definite anti-streptococcal action. It was later found (Fuller, 1937) that prontosil red compounds were split up in the body into sulphanilamide and its derivatives and were excreted in the urine (Tréfouël, Tréfouël, Nitti and Bovet, 1935). It was then *presumed* that sulphanilamide was the only effective agent.

Professor Domagk has opposed the 'sulphonamide hypothesis' on the strength of convincing biochemical experiments. It has been argued

(Brown and Bannick, 1937) that if sulphanilamide is the active therapeutic factor in 'prontosil', the excellent results obtained with a daily dose of 40 to 100 c.cm. of prontosil solution (2.5 per cent) are very puzzling. For on analysis 100 c.cm. of prontosil solution yield only 0.73 gramme or 11 grains of sulphanilamide! This argument holds good even for the new 5 per cent solution. As to the *modus operandi*, the views of Professor Domagk (1935) appear to be worthy of acceptance. It seems that prontosil exerts its anti-bacterial action directly as well as through increasing the immunological reactions of the organism. There is, however, little doubt that less complicated chemicals will be introduced in the not distant future (Hoerlein, 1937). It has been our experience too that prontosil red preparations are superior to sulphanilamide owing to their influence in bringing about a subsidence of fever, reduction in death rate, and lessening of complications.

Record of cases

The remarkable action of prontosil in streptococcal infections of various types has been fully confirmed by accumulated experience. Its action in puerperal infection has been remarkable; the rate of mortality has been brought down from 13.5 per cent to 1.4 per cent (Foulis and Barr, 1937). Anselm (1935) was so impressed with the result of prontosil in septic abortions that he undertook the treatment of puerperal infection irrespective of the bacteriological diagnosis. In every case the result was very good. In erysipelas, the result was no less satisfactory (Schreus, 1935), and it was confirmed by further experience (Snodgrass and Anderson, 1937).

We hope that an analysis of our own cases will not be unworthy of consideration. The first 70 cases of the series were treated by *oral administration* of the drug. As the result of experience thus gained, a method was evolved combining both intramuscular and oral administration.

TABLE II

	Disease	Number	Average stay in hospital (in days)	Number cured	REMARKS
1	Streptococcal septicæmia ..	3	..	2	Four cases of cavernous sinus thrombosis. Frontal osteomyelitis—one died. Broncho-pneumonia—two died.
2	Erysipelas, facial ..	6	8	6	
3	Cellulitis ..	10	13.4	5	
4	Acute osteomyelitis ..	6	..	5	
5	Chronic osteomyelitis, jaw ..	4	..	2	
6	Compound fracture ..	7	..	7	
7	Gangrene ..	5	..	5	
8	Acute funiculitis ..	2	8	2	
9	Filarial epididymo-orchitis and cellulitis.	6	21	6	
10	Abscess ..	9	..	9	
11	Carbuncle ..	1	..	1	
12	Gonorrhœa ..	1	..	1	
13	Cellulitis after burns ..	10	..	10	

The majority of the cases of this group could be definitely regarded as serious, particularly the cases of cellulitis and septicæmia.

series was any anti-streptococcal serum given. Gmelin (1935) reported a similar fall of temperature on the second or third day.

TABLE III

Number of cases	CURES		DEATHS		REMARKS
	Number	Percentage	Number	Percentage	
70	61	87.1	9	12.9	Including late cases of sinus thrombosis.
64	61	95.3	3	4.7	Excluding four late cases of sinus thrombosis and two of broncho-pneumonia.

If the six moribund cases of sinus thrombosis and septic broncho-pneumonia were excluded, the rate of mortality would amount to 4.7 per cent, which may be regarded as a satisfactory improvement.

Acute funiculitis and epididymo-orchitis of filarial origin

A dramatic result was seldom missed in cases of acute funiculitis and scrotal cellulitis of filarial origin (case 6). It may be remembered

TABLE IV

	Disease	Number of cases	Number of days to fall of temperature	Highest average temperature	REMARKS
1	Erysipelas	5	2.4	102.2	
2	Cellulitis	10	4.0	102.0	Non-diabetic.
3	Cellulitis following compound fracture.	4	5.8	102.0	Cases admitted into hospital with this complication.
4	Acute appendicitis ..	2	2.5	100.8	Following acute tonsillitis.
5	Filarial funiculitis and epididymo-orchitis.	7	2.6	102.7	Irrespective of the secondary bacterial infection.
6	Gas gangrene	2	2.5	102.2	Mixed anærobic and streptococcal infection.

Acute streptococcal infections: erysipelas, septicæmia, cellulitis

A study of the latter series of 30 consecutive cases of acute surgical infection is not unprofitable (table IV). Prontosil red solution was injected daily intramuscularly in addition to the oral administration of prontosil red or album tablets. There were a number of dramatic results. This line of treatment was carried out in a number of cases of septicæmia, complicating cellulitis, lacerated wounds, and untreated compound fractures, which were brought to the hospital in a grave state of infection. The effect of prontosil in streptococcal septicæmia was undisputable (case 1), but it was found equally effective in staphylococcal infection (case 2). The value of pre-operative prontosil therapy in cases of undoubted surgical risk is well illustrated in these two cases. In cellulitis (case 3) the result was invariably satisfactory. In erysipelas, the temperature was brought down to normal, on an average, within three days (cases 4 and 5). In cases of facial cellulocutaneous erysipelas the normal was touched on the fourth day. In no case in this

that, in this condition, a secondary infection, not infrequently streptococcal, is not necessarily present (Ray, 1934). In a number of cases both the blood culture and culture of aspirated fluid were negative for the streptococcus.

Gas gangrene and anærobic infections

A few words on the treatment of gas gangrene, of which excellent reports have already been published (Bohlman, 1937), will not be out of place here. We have already mentioned two cases, in each of which the patient was delirious and both anærobic organisms (*B. welchii*) and *Streptococcus hæmolyticus* were present (case 7). In one case, owing to the drowsy semi-conscious state of the patient and the positive history of an accident, it was not quite clear whether he had not a head injury in addition; as no permission for a high amputation was obtained from the relatives, 'prontosil' was injected as a last desperate resort, and in 24 hours the temperature came down with return of consciousness! The limb was later amputated without any further complication. In every case of street accident, a prophylactic dose of anti-gas

gangrene serum was administered as a routine measure.

Prontosil therapy as an adjunct to operative measures

We can divide all cases into two broad groups: (i) those in which no operative treatment was

various types of streptococci but particularly the hæmolyticus. It also appears to possess a very pronounced action against staphylococcal and gonococcal infections.

An instance of the unexpected efficacy of prontosil is seen in cases of urinary infection. In spite of the periodic claims to the discovery

required, and (ii) those in which further operative procedures were indicated. To the first group belong the majority of cases of erysipelas, septicæmia following trivial injuries and acute funiculitis and epididymo-orchitis of filarial origin. To this group may also be assigned puerperal infection, post-operative peritonitis, acute tonsillitis and cervical lymphadenitis and Ludwig's angina. In the last two conditions, Klee and Römer (1935) seem to be the first who tried 'prontosil' with excellent results. By its timely administration in acute funiculitis, it may be claimed that in our series there was not a single fatal case. In septicæmia and cellulitis following furuncles and so-called minor injuries, the results were invariably satisfactory (cases 8 and 9). It would be somewhat difficult to assess the value of prontosil in cases of the second group, which comprised neglected infected compound fractures, spreading cellulitis and infective gangrene. It is to be clearly understood that prontosil medication is no substitute for operative treatment. This drug must be regarded as a potent adjuvant to timely surgical interference, if this is necessary. As a pre-operative measure in cases of utmost gravity, prontosil cannot be surpassed. In two cases of post-operative broncho-pneumonia after high abdominal section, prontosil therapy proved to be very effective.

Urinary infections and gonococcal urethritis

It will be evident from our statistics that prontosil possesses a truly specific action on

of new and specific disinfectants, it cannot be said that the ideal remedy has yet been discovered. The action of prontosil is most marked in acute cystitis, but chronic cystitis, with retention or pyonephrosis, does not show any

marked improvement. Helmholtz (1937) is of opinion that prontosil is bactericidal for the *Staphylococcus aureus*, *Escherichia coli* and organisms of the proteus and pseudomonas group but it seems to have no action on *Streptococcus faecalis*. It also seems to be more effective in alkaline than in acid urine. Its action in gonorrhœa was accidentally noticed by us.

According to Cokkinis (1937) a clinical cure is obtained in about a week's time after oral administration of the drug. Orr (1937) reports 87 per cent recovery with complete absence of complications.

Dosage and modes of administration

In the new packing of prontosil preparations, the tubes contain 20 tablets of 0.5 gramme (7½ grains) each and 'prontosil soluble' 5 c.cm. ampoules of a 5 per cent solution.

In cases of moderate severity, one ampoule is injected intramuscularly twice daily together with one tablet of prontosil red every three hours until the temperature comes down. In about 6 per cent of cases prontosil red gives rise to vomiting or anorexia. In these cases prontosil album is better tolerated.

In cases of great severity or when the patient is drowsy or unable to swallow, three or four ampoules may be injected without any untoward result. It is seldom necessary to continue

Prontosil soluble is not to be injected intravenously and it is not necessary to do so. In toxic cases, maintenance of water balance is as important as a liberal supply of glucose.

Contra-indications.—It does not appear that there are any absolute contra-indications. In nephritis and hepatic cirrhosis no more than the usual caution is necessary. In diabetes, pregnancy, cardiovascular disease and severe toxæmia, there are no definite contra-indications.

Tolerance and manifestations of toxicity

In this series we have not met with any disagreeable reactions. In about 6 per cent of cases, prontosil tablets may give rise to vomiting or anorexia. We have not met with any cases of cyanosis. Of the manifestations of toxicity, sulphæmoglobinæmia is probably the most important. It is believed that the combination of hæmoglobin with the free hydrogen sulphide in the alimentary canal is indirectly pro-

the injections after the temperature touches normal. The oral administration is continued for another three or four days, but only 2 or 3 tablets need be given daily.

As a prophylactic measure in infected cases or where complications are apprehended, one or two ampoules are injected before any operative measure is carried out.

The usual recommended average maximum daily dose for adults of normal weight is 5 grammes (75 grains), given in 3 or 4 doses after meals. Usually 3 to 4 grammes are sufficient. It has been our practice to administer glucose freely during the period of intensive prontosil therapy. As to age and sex, we have found no dangers or untoward effects. As a rule, children are given half the adult dose and infants a quarter or sixth of the adult dose. Infants are given the powdered tablet in human milk or in tea (Püschel, 1935).

moted by the possible formation of p-acetyl-amino-benzene sulphonamide in the body during sulphanilamide therapy. Preparations, such as liquorice powder, containing sulphur should also be avoided. Hydrogen sulphide is more easily liberated when the contents of the large intestines are liquid. Consequently, anthracene and saline purgatives are best omitted. The use of the commoner aniline derivatives, like phenacetin, acetanilide, phenazone, amidopyrine and sulphonal are also deprecated.

The urine becomes yellowish red in colour after the administration of prontosil red preparations and it may continue so after withdrawal of the drug for 48 hours. To remove prontosil stains from linen a solution containing 2 grammes of soda and 3 grammes of sodium hydrosulphite per litre may be used, but 3 grammes of 'burmol' in a litre of water will be found more convenient.

Diet.—Light or milk diet is well tolerated while meat and egg dishes should be avoided.

Poisoning by Elixir Sulphanilamide.—A brief reference to this unfortunate episode in the United States of America may be made here without moralizing. An elixir was made up containing 10 per cent sulphanilamide and 72 per cent diethylene glycol and two or three teaspoonfuls were recommended every four hours for one or two days. The number of deaths exceeded 60. The deaths were not by the sulphanilamide but by the solvent diethylene glycol (Editorial, 1937 and 1938).

Summary

1. Prontosil and allied preparations have definite anti-streptococcal action and are therefore indicated in all cases where the *Streptococcal hæmolyticus* is implicated.

2. In erysipelas and streptococcal septicæmia, prontosil red may be regarded as a specific. In none of these conditions need anti-streptococcal serum be given.

3. In our experience, prontosil red preparations appear to be of greater efficacy than prontosil album and allied sulphanilamide preparations.

4. In acute funiculitis and epididymo-orchitis of filarial origin, a dramatic result is usually achieved, even in those cases where no secondary bacterial infection could be discovered.

5. In acute urinary infections, gonococcal urethritis and acute staphylococcal infections the drug has proved to be of great value.

6. In our experience, treatment by intramuscular injections is best combined with oral administration of prontosil red tablets. In about 6 per cent of cases, the latter may give rise to vomiting or anorexia when it may be replaced by prontosil album tablets.

7. There are no definite absolute contra-indications to the use of these preparations. The following drugs are to be avoided during prontosil therapy: anthracene and saline purgatives, sulphur-containing preparations and commoner aniline derivatives like phenacetin, acetanilide, phenazone, amidopyrine and sulphonal.

8. In a series of 70 consecutive cases, excluding six late cases of sinus thrombosis and septic broncho-pneumonia complicating facial cellulitis, the rate of mortality was 4.7 per cent.

9. In a subsequent series of 30 consecutive cases, the rate of mortality was *nil*. In case of erysipelas the highest average temperature was 102.2°F. which was brought down to normal in 2.4 days. In facial cellulitis, the normal was touched on the fourth day. In two cases of gas gangrene, the result was unexpectedly gratifying. In this group of cases, intramuscular injection of prontosil soluble was combined with oral administration of the drug.

10. This drug may be regarded as a powerful adjuvant to timely surgical interference, if this

THE SURGICAL TREATMENT OF EPIDEMIC DROPSY GLAUCOMA

By E. O'G. KIRWAN, M.D., F.R.C.S.I.

LIEUTENANT-COLONEL, I.M.S.

Professor of Ophthalmology, Medical College, Calcutta

IN a previous article written by me in 1934, I pointed out that, as long as the visual fields in this variety of glaucoma show no defect, immediate operation can be postponed in the hope that the general disease and with it the glaucoma will be cured before the optic nerves become permanently damaged by the increased intra-ocular tension.

The patient should be kept absolutely quiet and should refrain from eating rice or mustard

(Continued from previous column)

is necessary. As a pre-operative measure in cases of utmost gravity, prontosil can hardly be surpassed.

In conclusion, we wish to record our indebtedness to Brevet-Colonel R. N. Chopra, C.I.E., K.H.P., I.M.S., Director, School of Tropical Medicine, to Lieut.-Colonel T. C. Boyd, I.M.S., Principal, Medical College, and to Lieut.-Colonel E. H. Vere Hodge, C.I.E., I.M.S., Professor of Medicine, Medical College, for much valuable help and advice. To Dr. B. P. Tribedi, Professor of Pathology, and to Dr. Bhupen Mukherji, the Clinical Pathologist, we are indebted for laboratory data. We also wish to thank the nursing staff and junior members of our house staff for their diligent and willing co-operation.

Instruments for the surgical treatment of epidemic dropsy glaucoma.

oil, but, as soon as defects in the visual fields become evident, operation should not be delayed. One would think in this type of glaucoma, which is a temporary one, that a temporizing operation could be done, as the patient will get well spontaneously when the infection is removed, and that all that is necessary is to keep the tension down until this end is achieved by repeated anterior sclerectomies. In practice this is not sufficient, as it takes a considerable time to get the disease under control, in spite of the withdrawal of rice and mustard oil from the diet and the use of eliminative treatment.

Anterior sclerectomies have been carried out in a large number of cases, but this type of treatment has been abandoned, as the tension of the eye becomes as high, or even higher, 12 hours after operation.

In the past the Elliot sclero-corneal trephining operation with a 1.5 mm. trephine was the popular one; it undoubtedly brings down the tension to normal and the optic atrophy ceases to progress. The tension seldom rises again, once the decompression has been carried out.

Unfortunately, with the lapse of time, the bad results of sclero-corneal trephining are seen. These are a low form of irido-cyclitis, enophthalmitis, hypotony, and secondary cataract.

For the last year I have replaced the Elliot sclero-corneal trephining operation by an anterior sclerectomy, which is a modification of the Lagrange operation.

In the Eye Infirmary, Medical College Hospitals, Calcutta, 192 operations by the modified Lagrange technique have now been done and up to date I have seen none of the late serious complications that one sees in the case of Elliot's operation. In this type of operation, in order that the operation may be useful and not injurious, the following points must be observed:—

- (1) Tissue excised should consist only of the sclerotic and no corneal tissue, since corneal tissue proliferates and obstructs the opening.
- (2) The ciliary body must not be injured, because it is the hilum of the eye.
- (3) The incision should not be wide enough to permit the vitreous to escape.
- (4) The site of puncture should be about 2 mm. behind the limbus and thus in purely sclerotic tissue.
- (5) A small buttonhole iridectomy should be done.
- (6) Fistulization, the real and original object, is obtained by simple sclero-resection at the site physiologically adapted to it.

The operation is easy and rendered as external as possible.

The steps of the operation are as follows:—

Under local anaesthesia a conjunctival flap is turned down. The surface of the sclera is

(Continued at foot of next column)

THYROID METASTASES IN BONE

By M. M. CRUICKSHANK

LIEUTENANT-COLONEL, I.M.S.

Professor of Surgery, Madras Medical College, Madras

THIS subject interests both the surgeon and the pathologist, because of the questions, hard of solution, to which it has given, and still does give rise.

Secondary tumours in bone must arise in one of three ways:

(1) By direct extension of the tumours from the tissues into the substance of the bone. Such are not metastases in the true sense, but are classified as secondary contact tumours, for example, the secondary contact carcinoma found in the tibia following long standing ulceration undergoing malignant change.

(2) By the lymphatic stream; a method disproved by Piney, who by his investigations confirmed the statement of Roger and Josué that lymphatics could not be demonstrated in bone, a statement which cast doubt on Sampson Handley's theory of centrifugal permeation of lymphatic vessels by malignant cells.

(3) By the blood stream; the emboli gaining access to the blood stream and being held up by the capillaries of the bone marrow, especially in those bones rich in red marrow, such as the bones of the thoracic cage, pelvis, skull, upper ends of humerus and femur.

Having decided on the method of dissemination of malignant cells, another, and perhaps, a more difficult, problem presents itself, summed up in the question, 'Can a benign tumour disseminate or not?' It is an axiom in pathology

(Continued from previous column)

exposed right up to the limbus. A small keratome is now introduced at a distance of 2 mm. from the limbus into the anterior chamber. The aqueous humor is allowed to escape very slowly. The upper margin of the wound is depressed, allowing the root of the iris to present. A small buttonhole iridectomy is done. With a little massage, the iris springs back into position. With a pair of scissors curved on the flat, a small sclerectomy is done, the portion of the sclera cut off being 1 to 1.5 mm. in height and 2 to 3 mm. in breadth. The conjunctival flap is then turned back and stitched up with a continuous suture, which is removed on the fifth day. The eye is dressed on the third morning and a drop of 1 per cent atropine put in. There is usually very little reaction.

In this operation the filtrating cicatrix is flat and does not encroach on the cornea, as in the Elliot trephine operation. One should remember Lagrange's advice (1937):—'Do not touch the cornea, for it proliferates, and do not touch the ciliary body, for it is resentful'.

Figure 3

Figure 2

Figure 4

that dissemination is a feature of malignant neoplasms and of these alone; a benign tumour would cease to be benign did it metastasize.

Considering in particular the thyroid gland, confusion has arisen because thyroid metastases have been found to be functionally active and to consist of what microscopically appears to be normal thyroid tissue. The classical case is that of Eiselsberg, in which cachexia strumipriva followed removal of a carcinomatous thyroid; this was relieved when a secondary deposit appeared in the sternum, the patient relapsing when the sternal growth was removed. This leads to the question, 'Can a malignant thyroid produce a benign or a malignant metastasis?'

A normal thyroid, a colloid thyroid, a thyroid containing a small adenoma, a thyroid containing a malignant adenoma, each has at some time or other been reported as having produced a metastasis consisting of normal thyroid tissue.

In the case of the malignant gland, the French term 'the return towards the normal' simply describes what, so far as exhaustive examination can show, appears to be normal; the critic, however, affirms that time and further pathological investigation would show that both the thyroid gland and the metastasis were far from normal.

From a pathological standpoint the dividing line between malignant and non-malignant can nowhere probably be drawn with so great difficulty as in this matter of thyroid tumours. The epithelial appearances, the character of cells, the mitoses, the structure of vesicles, all vary so widely, not only in different malignant adenomata but in one and the same adenoma, that a personal factor, even amongst skilled microscopists and able pathologists, seems to cloud the diagnosis: tissue, passed as normal by one, is declared malignant by another equally capable pathologist.

Is it surprising, then, that anomalous names, such as metastasizing adenoma, benign metastasis, benign metastasizing goitre, have found their way into the literature of these puzzling conditions?

The clinical fact, or observation, remains that tumours identical with normal thyroid tissue do occur in bones of patients who present no apparent abnormality of their thyroid glands.

That these 'benign metastases' are never single (Eberhardt), but always found at post-mortem examinations to be multiple, is not the opinion of Joll, who affirms that even after careful post-mortem examination the osseous growth may be the sole metastasis present. Either statement would be naturally difficult to prove even after the most meticulous examination.

Joll (1923) presents a series of 44 cases of metastases in bone where either no abnormality, or a benign form of tumour, was found in the thyroid.

The interest in these problems was again aroused and the difficulties in clinical diagnosis were demonstrated when a case was admitted

into my wards in the General Hospital, Madras, in February of this year, presenting the features of a meningioma.

The patient, a female Hindu aged about 55, stated that a lump on the right side of her head, which had been there for over one year, had begun to increase in size, and was now definitely painful. There was no history of headache, visual disturbance or of vomiting. Examination revealed a tumour mass about the size of a lime involving the upper anterior aspect of the right frontal bone. The skin was freely movable over the tumour, which was soft and pulsatile. Over the skin ran several dilated superficial veins. Palpation gave rise to some slight discomfort and confirmed, more fully than did inspection, the pulsatile nature of the growth. The woman affirmed that, apart from the tumour, she was in perfect health and could give no history of any previous illness.

X-ray examination showed a large erosion in the right frontal area (plate XVI, figures 1 and 2).

A diagnosis of meningioma was made.

On 7th February, 1938, I performed the first stage of the removal of the so diagnosed meningioma. A horse-shoe flap, base downwards, at the superciliary ridge was made. To give access, a ring of bone about $\frac{3}{8}$ inch broad was removed all round the tumour, the bone being freed from the tumour mass with the aid of scissors. This done, the scalp flap was sutured back in position.

On 18th February, the second stage of the operation was done. The 'dura', which encapsuled the tumour, was cut with the diathermy knife, bleeding being readily controlled by hot pads, where the coagulating current proved insufficient. Only one large vessel had to be ligated and the tumour was readily enucleated.

On removal it was evident that the 'dura', which I imagined had been incised, was still lying intact on the brain surface, which showed no signs of having been subjected to any degree of pressure.

The diagnosis of a gumma, or sarcoma, was now made but with no great enthusiasm for either.

On 22nd February I received the following report from Dr. Tirumurti, Professor of Pathology, who kindly examined the specimen for me:

'The specimen suspected to be a meningioma appears on microscopical examination to be composed of typical thyroid tissue. It is not a meningioma. The condition is probably one of "benign metastasizing struma".'

This report led to a careful examination of the patient's thyroid gland and further radiological examination of the skeleton. Nothing abnormal could be detected about the patient and she was discharged well on 14th March.

Four months later the patient was written to and appeared in hospital, stating that she had no complaints and was perfectly well. Examination, however, revealed, in the right lobe of the

thyroid, a small nodular mass about the size of a hazel nut, of which the patient was quite unaware.

Further radiological examination of the skeleton proved negative. The question of operation and removal of the right lobe of the thyroid was considered, but the patient settled any doubts by deciding that there would be no operative interference in her case.

The differential diagnosis in such a case must be difficult. Cases presenting such features as the one reported have been mistaken for meningioma, for gummata and for primary sarcoma of bone, though the latter diagnosis should never be made before the possibility of malignant disease elsewhere has been eliminated.

Other conditions might, of course, be considered, though more readily excluded, such as lipoma, dermoid cyst, meningocele, hæmatoma, subpericranial abscess. X-ray investigations will materially help in the diagnosis, but a metastatic tumour may simulate a primary sarcoma, because the perpendicular spicules of new bone are not always present in sarcoma and are not invariably absent in the secondary tumour.

The subject of treatment is a controversial one.

Barthels states that the thyroid carcinoma, which produces bone metastases is of relatively low virulence and, therefore, to remove a single metastasis could not be described as meddlesome surgery and that the removal could be followed by thyroidectomy.

'As a rule the benefit to be expected from operation in secondary growths of bone is but transitory. Recurrence, either locally or in other bones, must soon end life. There are a few striking exceptions' (Joll).

In Joll's opinion, because of these exceptions, resection of the secondary tumour, if feasible, might be carried out and followed by thyroidectomy.

The interest in this case lies in these facts :

(1) that no thyroid history could be obtained;
(2) that clinically and by radiological examination only one skeletal metastasis could be found;

(3) that the thyroid gland, until recently, presented no detectable abnormality;

(4) that the suggestion that a benign thyroid may produce either a benign or a malignant metastasis is not reasonable, because, even if a biopsy were permitted and the result of examination of the thyroid were returned as 'normal thyroid gland', time would prove that the thyroid gland was not normal and that an insidious atypical malignant growth had been overlooked; and

(5) that a malignant thyroid may produce a benign metastasis. Again, time would prove that the metastasis was not benign.

SPONDYLOLISTHESIS

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S.E.

Surgeon

and

P. KESAVASWAMI

Radiologist

King George Hospital, Vizagapatam (S. India)

Low back pain is very common in India. Out of 300 cases examined and treated for low back pain within the last 7 years, only one case showed a true spondylolisthetic condition. It is difficult to state the incidence of this condition in India as there are no published records. Neugebauer in 1884 described this condition first among women. On investigation it is reported that no cases of spondylolisthesis were noticed in the Government Maternity Hospital, Madras, where more than 3,000 deliveries are conducted every year. The following case illustrates a true spondylolisthetic condition :—

A Hindu male, aged 35, was admitted in 1936 for the treatment of constant pain in the lower part of the left half of the back and buttocks. He was a *dhoby* (washerman) by occupation. This pain started suddenly while lifting a bundle of wet clothes eight years ago. It was treated by massage as a case of sprain. He recovered and carried on his work. Ever since he has had similar attacks and with the same treatment he got relief. Three months before admission, he found the pain was more severe and constant.

On examination, the spine was found to be foreshortened with a groove encircling the body at the level of the loin. The hollow above the sacrum was very

Fig. 1.—X-ray picture which shows the slipping forward of the body of the 4th lumbar vertebra with discontinuity between the pedicle and neural arch.

marked. Movement in the lumbo-sacral region was very painful. The hip joint was found to be normal. On x-ray examination, the body of the 4th lumbar vertebra was found to have slipped forward leaving the lamina behind (figure 1). The 5th lumbar was found

to be sacralized completely. A cervical rib was found on both sides (figure 2).

Under spinal anaesthesia, a bone graft of Albee's type was done, fixing two spines above and two spines below the 4th lumbar, on 28th July, 1936

Fig. 2.—X-ray picture of the lower part of the neck and upper part of the chest showing cervical ribs on both sides. This shows the existence of more than one congenital abnormality in the spine of this case.

Fig. 3.—X-ray photograph of the lower lumbar spine showing the bone graft in position.

THE MORTALITY OF OPERATIONS FOR VESICAL CALCULUS IN INDIA

By E. W. HAYWARD, F.R.C.S.E.
Principal Medical Officer, Jodhpur State
and

B. L. MEHTA, M.B., B.S. (Bom.)
Windham Hospital, Jodhpur

IN continuation of the figures published in the *Indian Medical Gazette* of February 1937, we have now been able to analyse the results of a further series of 224 cases done in the Windham Hospital, Jodhpur, between September 1936 and March 1938.

Our methods have not changed, and we need add nothing to the details we have already given of the anaesthetic and operative procedure. The only change that we have made is that

(Continued from previous column)

(figure 3). The patient was discharged on 3rd September with advice to report for another operation to fix the bodies in front. It is reported on enquiry that he died six months after discharge from hospital and the cause of the death is not known.

Anatomical study of the specimens of lower lumbar and sacral vertebrae available in the Medical College Museum was done to find out if there are any showing the defect between the neural arch and the pedicle, as pointed out by Willis. No such specimens could be found in the anatomy department of the Medical College, Vizagapatam. Two specimens were kindly lent for study by Professor Koshi of Medical College, Madras, from his collection. They show the lack of fusion of the neural arch with the pedicle.

Points of interest

1. The rarity of such reported cases in India.
2. Spondylolisthesis had occurred in the 4th lumbar with the 5th lumbar completely sacralized.
3. There were cervical ribs on either side with no symptoms, showing that the spinal column had more than one congenital abnormality.

separate figures for suprapubic lithotomies by the open and closed methods have been kept instead of having them all grouped together.

The number of cases concerned is too small for the drawing of any reliable conclusions but, in so far as any conclusion at all can be drawn, it does not appear to affect the mortality whether the closed or open method is used. The patient of course prefers the closed method as it reduces the time in hospital as well as avoiding the misery of wet dressings, whereas the open is perhaps preferable to an indwelling catheter in cases of high blood urea.

The mortality at different ages is shown in the following table :—

was still rather septic three weeks after operation and was being washed out. Condition suddenly deteriorated and death occurred four days later, no diagnosis being made. No autopsy.

D. Age group 41 to 60 years

- (6) Uræmic patient before open suprapubic, which gave temporary relief. Blood urea then steadily rose. Autopsy revealed shrunken kidneys with many adhesions and an enlarged heart with pericardial fluid.
- (7) Rupture of bladder during litholapaxy.

TABLE

Age group	SUPRAPUBIC LITHOTOMY									LITHOLAPAXY			TOTAL OPERATIONS		
	Open cases	Died	Percentage mortality	Closed cases	Died	Percentage mortality	Total cases	Died	Percentage mortality	Total cases	Died	Percentage mortality	Cases	Died	Percentage mortality
1 to 7 years.	57	1	1.75	34	91	1	1.1	12	103	1	0.97
8 to 15 years.	13	2	15.4	12	25	2	8	6	31	2	6.4
16 to 40 years.	7	1	14.3	4	1	25	11	2	18.2	31	42	2	4.8
41 to 60 years.	14	2	14.3	8	1	12.5	22	3	13.6	20	1	5	42	4	9.5
61 and over	2	1	1	100	3	1	33.3	3	1	33.3	6	2	33.3
TOTAL ..	93	6	6.4	59	3	5.1	152	9	5.9	72	2	2.77	224	11	4.9

The causes of death were as follows :—

A. Age group 1 to 7 years

- (1) Heat exhaustion on second day after operation in May. No post-mortem examination.

B. Age group 8 to 15 years

- (2) Very feeble child with a 2 years history and 75 grammes blood urea for which he was treated for six weeks before operation, twenty-four hours after which he died. Autopsy revealed bilateral pyonephrosis.
- (3) Patient was quite fit before and did fairly well for some days after operation. Then blood urea rose steadily to 200 grammes and he died of uræmia 3 weeks after operation.

C. Age group 16 to 40 years

- (4) The open suprapubic case faded away and died six weeks after operation, autopsy revealing unilateral pyonephrosis.
- (5) The closed suprapubic wound was completely healed and the patient apparently cured except for a bladder which

- (8) Closed suprapubic under local in extremely feeble old man whose basal rhonchi increased after operation, autopsy revealing right lower lobe pneumonia and left basal consolidation.

- (9) Rupture of bladder during pre-operative filling, followed by immediate open suprapubic; the patient however just faded away in four days.

E. Age group 61 and over

- (10) Litholapaxy under local as patient too feeble for any anæsthetic. Died of shock and pulmonary complications on third day.
- (11) Closed suprapubic. Wound healed completely. Patient faded away with both bases involved and unilateral orchitis and was removed moribund on the 15th day.

The mortality of different types of stones

Again no relationship was noticed between the chemical composition of the stones and the death rate.

Seasonal mortality

Again in the coldest months of December and January there were no deaths at all. The patients who died for no fully ascertained cause, nos. 1, 3, 4, 5, 8, 10 and 11, all died in the hotter months, except nos. 4 and 8 who died in February and March, respectively. We still feel that adverse climatic conditions may just turn the scales against a case.

The mortality at different concentrations of blood urea

Of the 121 cases over 7 years of age in the series, 104 had their blood urea estimation done before operation, the results being shown in the following table, which seems very definitely to show that the higher the blood urea, the greater the risk. Also open cases seem to do better than closed suprapubics. It is, however, realized that the total number of cases with high blood urea

PRE-CANCEROUS CONDITIONS OF THE CERVIX UTERI AND THEIR TREATMENT*

By J. CHAKRAVERTI, M.B. (Cal.), M.C.O.G.,
Assoc. Professor of Obstetrics and Gynaecology of the Carmichael Medical College, Calcutta, Gynaecologist and Obstetrician to Sir Kedarnath Maternity Hospital, Calcutta, Visiting Surgeon to Chittaranjan Sevasadan, Calcutta

A SUMMARY of the survey of the reports of the Public Health Commissioner with the Government of India (Russell, 1935) shows that the

*Read at a clinical meeting of the Obstetric and Gynaecological Society of Bengal, on 4th July, 1937.

(Continued from previous column)

We have therefore had a series of 192 cases of vesical calculus with unsuspected renal calculus present in only just over 2 per cent.

TABLE

Blood urea	SUPRAPUBIC LITHOTOMY									LITHOLAPAXY			TOTAL OPERATIONS		
	Open cases	Died	Percentage mortality	Closed cases	Died	Percentage mortality	Total cases	Died	Percentage mortality	Cases	Died	Percentage mortality	Cases	Died	Percentage mortality
25 to 50 ..	25	2	8	13	2	15.4	38	4	10.5	49	2	4.09	87	6	6.89
50 to 60 ..	8	1	12.5	2	1	50	10	2	20	1	11	2	18.2
Over 60 ..	4	1	25	1	1	100	5	2	40	1	6	2	33.3
TOTAL ..	37	4	10.8	16	4	25	53	8	15.09	51	2	3.92	104	10	9.61

is very small and conclusions must be drawn only tentatively.

The simultaneous occurrence of renal and vesical calculi

Of the 224 cases in this series, 192 had their entire genito-urinary tract radiographed. No dye was used, it being assumed that no shadow in a straight radiogram and no suggestive history meant no kidney stone. Cost was the main reason for not using either an intravenous dye or doing a retrograde pyelogram. Of these 192 cases, in five who had a history of renal colic kidney stones were found in four and a ureteric stone in one, while in four others with no suggestive history kidney stones were revealed. The diagnosis was confirmed at operation in only three cases, as three of the others were considered unfit for operation and three refused it.

(Continued at foot of next column)

Summary

There is little to add to the remarks passed in the summary of the previous series, except to say that we hope the reduced mortality, 5.9 per cent for suprapubic lithotomy, can be maintained, if not improved upon, and that the litholapaxy rate of 2.77 will not rise higher, although it must vary according to the number of those who have to be taught to use a lithotrite, an art which we fear some will never learn.

The chief factors affecting the mortality of vesical calculus operations still appear to be the general condition of the patient, his age, his blood urea and to some extent the climate.

The incidence of unsuspected renal calculus in cases of vesical calculus was found to be 2 per cent.

In conclusion we must thank Dr. Bal Kishan Vyas for much help in collecting our information

incidence of cancer in India stands at a figure not far removed from that in western countries. It also shows that the highest incidence is during the age period of 40 to 50 years, i.e., ten years earlier than in Japan or in western countries and the United States of America.

As regards regional distribution, a preponderating incidence of carcinoma in one organ is counterbalanced by lesser incidence in other organs and disparity between the incidence figures of different provinces appears to be the subject of the same attempt at equilibrium. On the average, the incidence of cancer in the female generative organs is over 50 per cent of all cancers. Of this, cancer of the cervix is the highest, over 75 per cent. As far as is known at present, primary carcinoma occurs more frequently in the uterus than in any other organ and it causes death of one out of every thirty-five women over the age of thirty-five years.

No part of a woman's body undergoes such a strain as the cervix which in an adult is only one inch in length and forms a minor and somewhat subservient part of the whole uterus. From birth to involution this part changes widely in structure. In foetal life there is the fusion of the two great genital ducts with their solidification and canalization. In infancy and childhood, it occupies an abdominal position forming two-thirds of the whole uterus. At puberty, its position is in the pelvis forming only one-third of the whole organ. In adult life, it is subjected to frequent trauma and exposure to infection. Then comes the changes due to pregnancy, parturition, and at last involution and rest set in. In old age, it is converted into a mere knob or dimple. The greatest of all these changes is that during parturition when, within a few hours' time, its canal, the calibre of which was only a few millimetres, becomes enormously stretched to allow the passage of the foetal head. Naturally the mucous membranes are broken, muscles stretched and lacerated and the whole cervix thrown open to infection. In this small portion of the uterus there are four different varieties of epithelial lining from below upwards, viz, squamous, high columnar, transitional, and low columnar. It receives the watery alkaline secretion of the body of the uterus, forms a thick glairy mucoid secretion of its own and is bathed in the creamy acid secretion of the vagina—the importance of which is very little known. Lastly, its hidden situation and comparative insensitivity to pain, combined with the patience and shyness of the sex, favour any diseased condition progressing deeply before being complained of by the patient. When we consider the large amount of inconvenience, suffering and misery, often terminating in death, that arise out of the various kinds of disturbances originating in this small area, it would seem that, while much has been said and written, there still remains a lot to be done by those who

are teachers and leaders in gynaecology and obstetrics.

At present the problems that confront the profession, particularly the specialists in obstetrics and gynaecology, are :—

(1) Is carcinoma of the cervix curable ?

(2) Is carcinoma of the cervix preventable ?

The answer to the first is qualified and conditional. It is admitted by all that with modern methods of treatment properly applied many, if not all, cases of carcinoma are curable. We know of cases of cure of 5 or even 10 years' duration but few of 20 years. It would be fair to say that improvement in the results following the treatment of carcinoma is to be obtained only if the cases are diagnosed in the early stage of the disease. In order to get them early, the cancer-consciousness of the medical profession as well as that of the general public must be properly awakened. To bring down the death rate of carcinoma of the cervix, much more is required than the sharpening of the diagnostic acumen of the family doctors and general practitioners. Of equal importance is the education of the public by allaying their fears, calming their prejudices and removing ignorance of which every part of India is full. This is on the whole a far more difficult problem which is not strictly within the scope of this discussion.

The other problem—Is carcinoma of the cervix preventable ? It sounds rather absurd for a disease to be called preventable when its real ætiology is still unknown. True it is that, despite strenuous research work, all over the world the real cause of cancer is still in darkness. I am not a pessimist in this respect and I hope some day, in the near future, some lucky man may find out the real cause of cancer like Schaudinn's discovery of the spirochæte. When we stop to consider that little more than sixty years have passed since the origin of cancerous growth has really been understood, we need not be discouraged with the progress that has already been made. The contribution to literature has been enormous and our knowledge has been much clarified regarding the predisposing factors, ætiology, gradation, prognosis and treatment of carcinoma.

Carcinoma of the cervix differs widely from carcinoma of the other regions of the body in its onset, behaviour, progress and response to treatment. It has been shown that the condition is preceded by pregnancy in over 90 per cent of cases. In other instances a history of inflammation, erosion or some instrumentation, such as dilatation, can usually be traced. Cervicitis and erosion are prone to follow laceration from child-bearing and the former may follow any instrumentation of the cervix. I think the important ætiological factor is not laceration but rather the consequent inflammation and chronic irritation.

Whereas every one will admit the existence of pre-cancerous conditions, it is extremely difficult to define them to one's satisfaction. It is, however, not a disease of separate entity. On reviewing the literature which is mostly contributed by the German and American scientists, one is struck by the loose manner in which the word is used. According to TeLinde (1933), for a lesion to be considered 'pre-cancerous' it must be established that the incidence of carcinoma developing in such cases is greater than that of carcinoma in persons free from such a lesion; in other words, it is a condition developing in the course of the healing of a very chronic cervicitis with or without laceration. K. V. Bailey (1930), in his well-known paper on 'An enquiry into the basic cause and nature of the cervical cancer and the relation between cervicitis and cervical cancer', states :—

Cervicitis or erosion of the cervix is definitely related to carcinoma of the cervix. This relationship is effected through the agency of a factor common to both, viz, an associated inflammatory exudate in contact with the epithelium. This is the intermediate causal factor and is constant. The basic cause of cervical carcinoma is to be found in this constant factor which is associated with all cell reaction, including that of cancer inception.

The line of junction of the squamous and columnar epithelium is usually at the external os. In practice, it is found that the cylindrical epithelium may extend to the outside of the cervix or the squamous epithelium may extend up into the canal, the line of junction being correspondingly placed. In the former, the glands which are situated outside the cervix are prone to become infected. In chronic cervicitis the muco-purulent discharge from the glands macerates the squamous epithelium, leaving a denuded surface with scattered islands of more resistant epithelium. This stage of inflammation is called erosion. The cylindrical epithelial lining, less susceptible to the inflammatory exudate, grows down over the raw area without changing its character. As the inflammation subsides the columnar epithelium, no longer bathed with mucus, loses its vitality, while the squamous epithelium regains its vigour. The latter grows back to its normal position on the outside of the cervix by proliferating under the edge of the cylindrical epithelium and gradually replacing it. If the cervix has been lacerated or everted some of the cervical glands are exposed to the vagina. In growing over the new external os at the edge of a laceration, the squamous epithelium surrounds and invades the ducts of the glands. Sometimes it fills a duct and forms a plug which may grow inwards for some distance, or, rarely, may extend beyond the area of erosion into the cervical canal and deep down into the muscle, involving normally-placed glands. This is called epidermization of the glands and ducts of the cervix.

When a cross section through such a part is seen under the microscope, a first glance gives the impression suggestive of carcinoma. In fact, it may be wrongly diagnosed as carcinoma

by one not trained in gynæcological pathology and occasionally experts have been known to differ in their opinion as to the nature of these islands of squamous epithelium. In such an event, the guiding points for establishing a diagnosis of malignancy are :—

- (1) breaking of the basement membrane;
- (2) hyperchromatic and mitotic characters of the nuclei;
- (3) irregular and indefinite cell outline;
- (4) in contradistinction epidermization follows the gland outlines, i.e., 'trellis-like network of the glands', instead of the haphazard invasion of malignancy.

Lastly, a detailed study of a series of sections will clear the salient features of benignancy or malignancy.

This process of repair does not always follow an orderly sequence. The chronic cervicitis may flare up and subside from time to time. The two types of epithelium are thus put into a state of restlessness, sometimes over a long period. In view of the unstable equilibrium of epithelial growth it is not at all unnatural that the latter may be excessive and thus encourage the development of carcinoma (Pemberton and Smith, 1929). Another point in favour of the view that the exudation of chronic cervicitis stimulates cancer formation is that patients with procerdentia very rarely suffer from cancer of the cervix.

Leucoplakia of the cervix is another condition which predisposes to cancer formation. Leucoplakia was known long ago but its importance and frequency were not realized till Herr Hinselmann began to discover the small size of the areas by the aid of the colposcope. My experience of leucoplakia is very meagre as I have seen but few cases in my practice. They may be rare here or we might find them more frequently if the colposcope were used to detect them. In regard to its tendency to malignancy, some workers claim that leucoplakia of the cervix is not a pre-cancerous lesion. But Hinselmann (Davis, 1934) states that all leucoplakia observed for a long enough time has become malignant and he cites cases. The changes are seen mostly in the cells themselves and not in their invasive power.

The diagnosis of early cervical carcinoma is often difficult, but it means much to the patient as it gives her a relatively good chance for life. While chronic cervicitis, erosion and lacerations are considered as pre-cancerous, the superposition of any of the following conditions on them must raise suspicion of early carcinoma.

- (1) A localized hard nodular feel. This must be distinguished from deep-seated, pent-up secretion under tension in a Nabothian follicle. Puncture with a surgical needle will settle the question. Sometimes, glairy fluid as much as two teaspoonfuls comes out.
- (2) Indurated area on either lip, especially if the overlying surface is granular.
- (3) Small ulcerated area.
- (4) Extreme localized vascularity.
- (5) Deposition of calcium salts,
- (6) Friability of surface.

It requires experience and careful speculum examination in good light to detect these conditions, while the application of Schiller's test and modern colposcopy are certainly additional aids involving finer technique in detecting them earlier.

Biopsy and microscopic examinations, however, are the only means of establishing the diagnosis with certainty. By histo-pathological examination diagnosis becomes easy in most of the cases, the condition being obviously benign or malignant. In some cases, however, the diagnosis is difficult, and in a very small percentage it may be almost impossible. By a careful weighing of the clinical history, a thorough local examination combined with the results of special tests, if possible colposcopy and where necessary biopsy and microscopy, carcinoma will rarely be overlooked even in its early stage.

Sometimes, objections are raised to biopsy on the grounds of (1) acceleration, (2) dissemination and (3) infection of the growth. Personally, I think the danger of spread by instruments is overrated. Even on theoretical grounds the danger can be minimized by searing the cut surfaces of the wound with a cautery. Biopsy is best performed with a sharp knife or punch. The tissue should be excised from the most suspicious area with a certain amount of healthy tissue retaining the mucous surface. A colposcope helps considerably in performing biopsy more perfectly and finely. After receiving the tissue it should be cut into three pieces and the pathologist asked to put them in one block. Thus a series of sections at three different levels is made and there will hardly be a chance of missing a suspected area. Excluding the competency of the pathologist, much depends on the surgeon for the result of the biopsy. The pathologist should be considered as a consultant and not a prophet. He should be supplied with all the available information in order to arrive at a right decision. In a doubtful case the opinion of a second pathologist should be sought. When two pathologists disagree regarding the diagnosis of a section from the cervix, it can be concluded with considerable assurance that the growth is benign. But the patient should be kept under observation and another section made two months later. It is here that close co-operation should exist between the clinician and the pathologist, neither of whom should be guided by preconceived ideas and prejudices in the study of cervixes undergoing these chronic inflammatory processes. I think this would be the only possible means of finding out the link between pre-cancerous conditions and early carcinoma of the cervix.

Most treacherous, however, is an endocervical carcinoma. The portio vaginalis and external os look healthy. The cervix as a whole is bulky, spindle or barrel shaped. The endocervical mucous membrane is found to be vascular and granular, as determined by the passage of a sound. Only the curette and microscope will

settle the diagnosis. Fortunately, this type of carcinoma is very rare.

Because it is admitted that there is a distinct relationship between carcinoma and chronic inflammatory conditions of the cervix and because the time interval from the onset of one to the development of the other is not known, it is always advisable to treat the pre-cancerous conditions at the earliest possible opportunity. Gynaecologists and obstetricians are so engrossed with bigger problems and bigger operations that this part of the question here in India is entrusted to the hands of a junior officer of the out-patient department.

As most of pre-cancerous conditions follow childbirth, the question of prophylaxis arises. Here, if my information be correct, the cervix is neither examined nor stitched for laceration unless there is sufficient post-partum hæmorrhage from the torn area. In some clinics, lacerations of the cervix are treated as a routine measure. Personally, I think our practice is better as there is less risk of increasing the morbidity which is already too high in Bengal in comparison not only with other countries but also other provinces in India. But I would certainly emphasize the importance of examination of every puerperal woman once post-natally in the fourth to sixth week. This will reveal and give a chance to rectify many gynaecological affections, pre-cancerous conditions being some of them.

Treatment

Gynaecologists owe a lot to Hunner (Eden and Lockyer, 1935) who first used the cautery for the treatment of chronic cervicitis and erosion in 1906. He used the Paquelin cautery which was replaced by the nasal electric cautery by Dickenson. Cauterization of the cervix, if properly done, will save many lives and give comfort to a greater percentage of women than any other simple procedure in surgery. It must be emphasized, however, that it is an operation that must be performed properly, otherwise its results will be disappointing. This is true in the more chronic, deep-seated infections of the cervix, where there is a great excess of connective tissue and the glands lie far beneath the surface. In a moderately bad case cauterization has to be repeated a second or third time at an interval of four to six weeks. Just a word about cauterization—the linear cauterization of the canal must be done deep inside, gradually becoming superficial at the external os, otherwise eversion of the lips results after healing. The glands in the portio vaginalis are attacked by point puncture from the surface.

It is safer to hospitalize the patient for cauterization. Topical application of caustics, of which there are many, is useless, and is a mere waste of time, energy and money. It is sometimes beneficial in a limited number of cases in which the erosion is superficial and follows a recent labour or abortion. I have

not had the opportunity of using the zinc-chloride porous pencils of Aleck Bourne—a distinct advantage of this method is that the treatment can be safely carried out in the out-patient department. I have also had no experience of conization of the cervix which in the United States is practised widely.

If the erosion is complicated by laceration the cervix should be repaired. Usually the area of erosion is included in the denudation. If not, the remaining part has to be cauterized. If the erosion is complicated by multiple laceration which has passed beyond the stage of repair or the cervix is very bulky and there is some degree of prolapse—low amputation of the cervix will be the treatment of choice. Either Sturmdorf or Bonney's method usually gives a smooth external os.

Radium.—In the treatment of chronic inflammation and erosion, my experience is very meagre.

Although it has not been proved scientifically that the treatment of the diseased cervix is a prophylactic against cancer formation, there are some suggestive facts in support of this. In a series of 3,814 trachelorrhaphies, 740 amputations and 1,408 cauterizations of the cervix, a total of 5,962 cases covering a period of 52 years at the Free Hospital for Women in Boston, only five were known to have developed cancer of the cervix and these were all in the trachelorrhaphy group. More convincing are the figures of Leuin, who in 613 cases of cancer of the cervix found only two in which a previous cervical repair had been performed. Thus, in these series not one patient whose cervical specimen was suspicious but not malignant has been found to have developed cancer.

My figures are too small to be compared with those mentioned above and my experience is not sufficiently mature to enable me to make a bold statement. I can, however, say that none of my pre-cancerous cervixes treated on the above lines has developed cancer yet.

Hysterectomy.—For nearly a decade hysterectomy, particularly by the vaginal route, has been very widely performed here in fairly young women, the indication being pre-cancerous cervix. Of late the condition has gone from bad to worse, so much so that students of the present day put down pre-cancerous condition of the cervix as one of the indications for hysterectomy! Literature fails to support this extreme view. I cannot trace the origin of this idea which has spread out like a conflagration and affected nearly all the specialists here. To be honest, I am not an exception to this craze. But the time has come when we should stop for a moment and review the results of our actions in the past and present and decide what should be done in future.

Can we say, we are justified in removing an organ so important to the sex because we are

THE widely divergent results obtained by various workers concerning the possibility of the

(Continued from previous column)

unable to differentiate with certainty a non-cancerous from an early carcinoma stage? Personally, I think hysterectomy should not be done for pre-cancerous conditions which can usually be cured. On the slightest suspicion of early malignancy, biopsy and microscopic examinations should be made to settle the diagnosis. In case of doubt one must wait, observe and see. As Ewing says 'It is not true that a pathological condition must be either cancer or not cancer. It may be neither the one nor the other'.

Trouble may arise from keeping a patient waiting for a long time in suspense. In such a case it is difficult, if not impossible, for the doctor to take his patient into his confidence and, in the happy event of a negative finding, it would be only human for the patient to protest with no uncertain voice that there had been a lot of fuss and considerable expense for nothing. It often happens that the doctor is more worried from the difficulty of trying to convince a patient and her relations that something ought to be done than by ignorance of what advice to give. Hysterectomy should be reserved for cases in which other methods of treatment are not possible and the pre-cancerous condition is complicated by other diseases, e.g., fibroid, inflammatory adnexa, uncontrollable uterine bleeding and prolapse of the uterus after menopause, etc.

On the rare occasion, when hysterectomy is contemplated because of pre-cancerous conditions, it would be wise and safe to have a second opinion. By this means not only does the patient get a fuller benefit of professional opinion but the members of the profession are also mutually benefited.

antimalarial action of prontosil led the present writers to try this drug in monkey malaria. Their *raison d'être* was that *Plasmodium knowlesi* is very suitable for testing the therapeutic effectiveness of a drug against malaria, for this plasmodium has been shown usually to produce an intense infection in *rhesus* monkeys causing the death of the animal if not promptly treated with a potent antimalarial remedy.

Experiment 1.—Monkey (*Silenus rhesus*), 2.420 kilogrammes in weight. On 2nd August, 1938, it was inoculated with 0.5 c.cm. of heavily infected blood showing rings and growing trophozoites.

Date	Parasites per c.mm. of blood	Treatment	REMARKS
8-8-38	Very scanty parasites seen in thick films.
9-8-38	12,380	..	Growing trophozoites and schizonts.
10-8-38	138,000	Prontosil soluble intra-venously 0.5 c.cm.	Chiefly rings and a few growing forms.
11-8-38	184,000	Do.	Nearly all stages of schizogony present.
12-8-38	1,200,000	Do.	Monkey very ill.

Died at 3-30 p.m.

Smears of heart blood, spleen and liver crammed with parasites and pigment-bearing mononuclears.

Experiment 2.—*Silenus rhesus* weighing 4.224 kilogrammes, inoculated with 1 c.cm. of heavily parasitized blood. Incubation period 5 days.

Date	Parasites per c.mm. of blood	Treatment	REMARKS
10-8-38	Scanty rings	..	
11-8-38	9,260	..	Only ring forms.
12-8-38	68,400	Prontosil soluble intra-venously 1 c.cm.	Chiefly rings and a few mature schizonts.
13-8-38	312,000	Do.	Growing trophozoites, schizonts and a few gametocytes.
14-8-38	880,000	Do.	Monkey very anæmic. Blood showing normoblasts. Howell-Jolly bodies, polychromatophilia, demilune cells, etc.
15-8-38	Animal died at night. Autopsy was not done.		

Experiment 3.—*Silenus rhesus* weighing 2.528 kilogrammes, inoculated with 1 c.cm. of blood

from the monkey of experiment 2 when the latter showed a parasite count of 68,400 per c.mm. Incubation period 4 days.

Date	Parasites per c.mm. of blood	Treatment	REMARKS
16-8-38	Very scanty parasites in thick smears.
17-8-38	18,400	..	Rings only.
18-8-38	120,000	Prontosil soluble intra-venously 3 c.cm.	Trophozoites, schizonts and scanty gametocytes.
19-8-38	448,000	Do.	Trophozoites and a few schizonts.
20-8-38	88,400	Do.	Marked anæmia. Total R. B. C. 1,800,000.
21-8-38	Scanty	Do.	Large mononuclears with ingested hæmoglobin pigment and degenerating parasites.
22-8-38	0	Do.	

The blood was examined almost daily until 17th September: scanty rings were found on 28th and 31st August and on 14th to 17th September. On 27th August the animal was well and the red blood count was over 6 millions.

Comments.—After 3 heavy doses amounting to 9 c.cm. had been given, the infection was practically eradicated. Very scanty parasites, however, appeared on the ninth day after the treatment had been discontinued and a low-grade infection has persisted since. It may be mentioned here that after the apparent extinction of the infection (with *P. knowlesi*) following the treatment with quinine or atebirin, the parasites appear again in the blood. In the case of quinine, however, scanty infection may persist for some weeks or even months, and eventually clears up. But with atebirin the state of affairs is quite different, that is, the initial infection is checked much more quickly than with quinine or prontosil, but the relapse is often of a severe nature, associated with rapid multiplication of the parasites leading to fatal termination, if the animal is not promptly treated. It thus appears that the action of prontosil in monkey malaria is more like quinine than atebirin.

Discussion

Díaz de León (1937) was the first to lead the experiment with sulphonamide in malaria. He treated 15 cases of *P. vivax* with a dosage of 6 tablets of Rubiazol* daily for 4 days, and then 3 tablets a day till the contents of one bottle (quantity not specified) were exhausted.

*Rubiazol is the French name of prontosil.

Only in one severe case he had recourse to an injection of 10 c.cm. of a 5 per cent solution in addition to the oral administration mentioned above. All his cases recovered.

Hill and Goodwin (1937) successfully treated 5 cases of *P. vivax* and 95 cases of *P. falciparum* with intramuscular injection of prontosil soluble (10 c.cm.) every twelve hours. Usually, not more than 4 injections were required in each case. Their results were very satisfactory.

Read and Pino (1938) dealt with 3 cases of *P. vivax*. The initial doses were 6 tablets (1.8 grammes) in 24 hours. Afterwards the dosage was reduced to 3 tablets a day. The patients who were suffering from distressing vomiting had intramuscular injections of prontosil soluble. They noted that sulphonamide has a poor specific antimalarial action because it has neither a sufficiently definite action on the schizogony cycle, nor is it a remarkable gametocide.

Very recently Pakenham-Walsh and Rennie (1938) treated a case of induced malaria (*P. vivax*) with prontosil. They gave 3 grammes of prontosil daily for 3 days. The temperature came down and the parasites cleared up, but a week later the fever relapsed and the parasite counts were nearly as high as in the original attack.

The failure of the latter workers may be due to the use of inadequate dosage, as is apparently confirmed by our experiments on monkey malaria. It will be seen from the experiments detailed above that a daily dose of 0.5 c.cm. was given to the first monkey as this was considered to be the proportionate dose, regard being had to the comparative weights of man and monkeys. This dose being of no avail, it was doubled. As this also failed we at last tried a still larger dose of 3 c.cm., which is overwhelmingly out of proportion to the human dose, and this succeeded in checking the course of the disease, leading to apparent recovery of the animal, although scanty parasites appeared in the blood later on, as also occurs following treatment with quinine.

To sum up, doses of 0.5 and 1 c.cm. altogether failed to check the multiplication of *P. knowlesi* in *rhesus* monkeys. But the disproportionately heavy dosage of 3 c.cm. proved effective. We may conclude, therefore, that prontosil in heavy doses has a definite action on plasmodial infections (at least on the monkey plasmodium), but does not possess any advantage over those drugs already in use.

STUDIES ON THE ACTION OF SYNTHETIC ANTIMALARIAL DRUGS ON INDIAN STRAINS OF MALARIA

CILIONAL IN THE TREATMENT OF 'CRESCENT CARRIERS'

By R. N. CHOPRA, M.D., F.R.C.P. (Lond.),
 SC.D. (Cantab.), C.I.E., K.H.P.

BREVET-COLONEL, I.M.S.

B. M. DAS GUPTA

and

B. SEN, B.Sc., M.B.

School of Tropical Medicine, Calcutta

CILIONAL was introduced by Schulemann of Messrs. Bayer-Meister-Lucius, Germany, a few years ago. It belongs to the plasmochin series of preparations and has the composition di-alkyl-amino-alkyl-amino-oxy-quinoline. Its action on the gametocyte of *Plasmodium falciparum* was claimed to be as potent as that of plasmochin, in doses far less than any that produced toxic symptoms.

A total dose of 0.18 to 0.3 gramme (in daily doses of 0.06 gramme) proved sufficient to make the crescents disappear from the peripheral blood. Atebrin was also given at the same time to control the asexual cycle. Regarding the toxicity of the drug, the makers have stated, after a series of experiments in mice, guinea-pigs, rabbits and cats, that it is about three times less toxic than plasmochin. Clinical trials on human beings have fully supported these findings. Daily doses of three times 0.01 gramme up to three times 0.06 gramme have been borne without toxic effects. Even the last-mentioned dose has been given for seven days without causing any subjective symptoms.

Missiroli and Mosna (1938) have recently treated a series of *P. falciparum* gametocyte carriers with varying doses of cilional. The gametocytes were enumerated, flagellation was looked for, and the infectivity of the blood for anophelines was determined each day for a week following the administration of the drug. A field experiment was also carried out with a population of about 1,000 individuals where malaria was hyperendemic. From 1st May to 15th October, 1937, cilional was given to the whole population including infants and children every three days in doses ranging from 1 to 6 cgm. These workers conclude that in respect of its toxicity the drug is far superior to plasmochin and that addition of such a drug to quinine or atebrin will give a complete anti-malarial remedy.

As Chopra and Basu (unpublished) have noted that daily doses of 0.06 gramme for four days were not sufficient to check the development of the parasite in the mosquito, we tried a larger dose, i.e., 0.09 gramme daily for five days in the following cases.

Patient I., aged 28 years, admitted to the hospital on 12th August, 1938, with a history of fever for three

days only. On the day of admission quite a good number of rings (*P. falciparum*) were found. On 13th August the patient was given prontosil, 2 tablets four times daily for 5 days. Rings were completely eradicated and gametocytes appeared for the first time on 16th August.

16-8-38	..	3	
17-8-38	..	42	
18-8-38	..	43	
19-8-38	0.09 gramme	85	
20-8-38	0.18 "	64	
21-8-38	0.27 "	20	
22-8-38	0.36 "	3	Very scanty parasites present, showed marked degenerative changes.
23-8-38	0.45 "	0	One parasite seen in the thick film.
24-8-38	..	0	
25-8-38	..	0	
26-8-38	..	0	
30-8-38	..	0	

Comments.—This is apparently a case with fresh infection as the patient is said to have had no febrile attacks during the past few years. Prontosil controlled the schizogony cycle, but it had no action on the gametocytes. Crescents made their first appearance in the blood about the eighth day of the initial fever. We may attribute the gradual reduction in number and finally the complete eradication of the gametocytes to the effect of cilion, as it seems unlikely that in a primary infection the crescents would disappear with such unusual rapidity. It should be noted that after the treatment with cilion there is a definite increase in the number of crescents followed by a marked decrease culminating in total extinction.

Patient P., aged 38 years, admitted on 9th August, 1938, for pain in the abdomen. History of fever (? malaria) two months back. Spleen not palpable. While in hospital, he had an attack of fever with rigor on 16th August. Next day a fair number of rings and crescents were found in the blood. Put on to atebirin on 18th August for 5 days. On 21st August blood showed crescents only.

Date	Total dosage of cilion	Crescents per 500 leucocytes	REMARKS
23-8-38	..	62	
24-8-38	..	76	
25-8-38	0.12 gramme	362	
26-8-38	0.18 "	8	
28-8-38	0.36 "	0	Very scanty crescents found in thick films.
29-8-38	0.45 "	0	
30-8-38	..	0	
31-8-38	..	0	

Comments.—This is a case of relapse. Both sexual and asexual forms were present in the blood. Atebrin eradicated the asexual cycle.

A total dosage of 0.36 gramme of cilion practically exterminated the crescents, although there was a surprisingly remarkable rise in the crescent count after the administration of the first few doses.

Patient C., aged 16 years, admitted on 23rd August, 1938, with a history of intermittent fever with rigor for a month. Spleen just palpable. On the day of admission, the blood (thick and thin films) showed crescents only.

Date	Total dosage of cilion	Crescents per 500 leucocytes	REMARKS
23-8-38	..	95	
24-8-38	..	100	
25-8-38	0.12 gramme	82	
26-8-38	0.21 "	118	
27-8-38	0.3 "	6	
28-8-38	0.39 "	0	None in thick films.
29-8-38	0.45 "	0	
30-8-38	..	0	

On 31st August, 1938, the patient had a slight rise of temperature. Scanty rings and no crescents were found in the thick films. Put on to prontosil 2 tablets four times a day for 5 days.

1st September .. Rings: no crescents.
 2nd " .. Scanty rings: no crescents.
 3rd " .. Very scanty rings: no crescents.
 4th " .. Very scanty rings in thick films: no crescents.
 5th " .. No parasites seen in thick films.

Comments.—This is a chronic case showing only crescents in the blood. No asexual forms could be detected even in thick films on careful search. Crescents completely disappeared after a total dosage of 0.39 gramme. Almost immediately after receiving a full course of cilion the patient had fever, blood smears showing only rings. He was put on prontosil which apparently checked the fever and the infection gradually cleared up. Evidently cilion did not show the slightest action on the schizogony cycle in this case.

Patient R., aged 22 years, admitted on 25th August, 1938, with a history of fever (? malaria) for one year. Spleen 2 inches below costal margin. Blood on admission showed both rings and crescents. On 26th August, put on to prontosil for 5 days. On 30th August, crescents only were seen in the thick and thin blood films. On 2nd September, 1938, put on to cilion 0.03 gramme three times a day for 5 days.

Date	Total dosage of cilion	Crescents per 500 leucocytes	REMARKS
30-8-38	..	120	
31-8-38	..	92	
1-9-38	..	385	
2-9-38	..	380	
3-9-38	0.12 gramme	408	
4-9-38	0.21 "	80	
5-9-38	0.3 "	32	
6-9-38	0.39 "	15	
7-9-38	0.45 "	0	
8-9-38	..	0	Mostly degenerating.

Comments.—Before the administration of cilional the crescent count did not show any downward tendency but the infection practically cleared up after a total dosage of 0.39 gramme.

Discussion.—Those concerned with the treatment of malaria are agreed that plasmochin has a very markedly destructive action on the gametocytes of *P. falciparum*. On the other hand, most of them complain of its toxicity. Further, the toxicity appears to be a phenomenon of individual susceptibility rather than one of dosage. One cannot ascertain beforehand whether a particular patient will or will not develop toxic symptoms.

Knowles and Das Gupta (1931) have, however, found that the dosage advocated by the manufacturers was unnecessarily large and a much smaller dose could eradicate the crescents from the blood in the case of the Indian species of *P. falciparum*. These workers showed that a total dose of 0.06 gramme (0.02 gramme daily for 3 days) was sufficient to destroy all crescents, even when the infestations were heavy and the cases treated with such a small dosage, under their observation, never developed any untoward symptoms.

The destructive action of plasmochin on crescents may be studied under the microscope. Within 24 hours of commencing administration of plasmochin the crescents are seen to become swollen and their outline irregular, and the chromatin breaks up.

Whitmore (1929) stated that a single dose of .019 gramme is sufficient to render non-infectious, for *A. albimanus*, all crescents in the blood at the time the single dose is taken. Lately, Chopra and Basu (1937) also made similar observations and found that a dose of .02 gramme prevented further development of the crescents in *A. stephensi*. Since 1931 the senior author has treated no fewer than 500 crescent carriers in the Carmichael Hospital for Tropical Diseases with plasmochin, using the small dosage advocated by Knowles and Das Gupta (1931). In no case were there any toxic symptoms exhibited by the patient, nor was there any evidence to show that this small dose had ever failed to exterminate the crescents. Under these circumstances the question of toxicity of plasmochin does not arise when it is administered in proper doses, at least in this country. On the other hand, cilional, as will be seen from the foregoing tables, requires a much larger dose and longer time to achieve the same result. It therefore follows that there is no justification for using cilional in place of plasmochin which has acquired an unchallenged reputation for its action on crescents.

Summary and Conclusion

A total dosage of 0.35 to 0.4 gramme of cilional, administered as a dose of 0.03 gramme

(Continued at foot of next column)

THE ISOLATION OF *VIBRIO CHOLERÆ* FROM NON-CHOLERA INDIVIDUALS

By C. L. PASRICHA

MAJOR, I.M.S.

M. N. LAHIRI

and

P. C. DAS

(From the Cholera Bacteriological Enquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)

ALTHOUGH there are many records of the finding of vibrios in the stools of healthy individuals, there is no means of establishing whether the strains isolated were those conforming to the vibrio now generally accepted as *Vibrio cholerae*. Recent work on the antigenic structure of vibrios has shown that *V. cholerae* possesses a specific 'O' antigen and that the thermo-labile 'H' antigen is shared by a large group of vibrios. The important practical application of these findings is that, because of this inter-relationship that exists between *V. cholerae* and certain other vibrios through common antigenic factors, it is no longer possible to rely, as was formerly done, on an agglutination test performed with an H and O serum for the identification of *V. cholerae*. Serologically, *V. cholerae* can be distinguished from certain other vibrios by agglutination test performed with a pure O serum.

During the past five years the stools of more than 2,000 in-patients in the Carmichael Hospital for Tropical Diseases have been examined for vibrios. The individuals examined were suffering from a variety of diseases, other than cholera, and there was no history of either a

(Continued from previous column)

three times a day, is usually sufficient to eradicate practically all gametocytes of *P. falciparum* from the blood and even this high dose has been borne by the patients experimented upon, without any ill effects.

On considering the points discussed above we cannot, however, help arriving at the conclusion that plasmochin is preferable to cilional, inasmuch as a much smaller dose of the former effects the eradication of crescents in a comparatively short time, and as the dosage of plasmochin (as advocated by Knowles and Das Gupta) is not at all toxic and perhaps cheaper than its rival.

recent attack of cholera or contact with the disease. Vibrios were found in a certain percentage (the highest being about 10 per cent) of these individuals. The vibrios isolated were all inagglutinable with cholera O serum. About 20 per cent of the vibrios from non-cholera individuals were agglutinable, often to full titre with cholera H and O serum. In the first half of this year, *V. cholerae*, i.e., vibrios agglutinable with cholera O serum, were isolated from three individuals.

The examination of the stools for vibrios was carried out after a two-stage enhancement in peptone water and isolation on Aronson's medium.

Brief notes of the individuals from whom *V. cholerae* was isolated are given below :—

No. 1.—Hindu male, aged 22, resident of Punjab. In Calcutta for 2½ months before admission for ill-defined abdominal symptoms. Examined twice and vibrios found only once on 12th April, 1938, the day after admission to hospital.

No. 2.—Mohammedan male, aged 16, resident of Calcutta (Tollygunge area), admitted for chronic diarrhoea and progressive weakness. Vibrios isolated on 12th April, 1938, the day after admission.

No. 3.—Mohammedan male, aged 15, resident of Calcutta (Entally area), suffering from malaria. History of an attack of dysentery six months prior to admission but there were no gastro-intestinal symptoms on admission. Examined twice and vibrios found once (24th May, 1938) on the first day after admission.

The vibrios isolated were typical monoflagellate vibrios, biochemically of Heiberg's group I. They were agglutinable to full titre with cholera (Inaba) 'O' and H and O serums and were not agglutinated by a pure Ogawa serum. They produced no hemolysis of goats' red blood cells. They were not phage-contaminated and were acted upon by the different types of cholera-phage.

Unfortunately, it was not possible to make further examination of these three individuals at the time of isolation of the vibrios. They were traced after discharge from the hospital and none of them developed cholera. It will be noted that the three individuals came from different parts of Calcutta and that the vibrios were isolated from the first stool examined after admission to the hospital, and that the second examination of the stools was negative in all three. This suggests that the infection had been acquired outside from different sources.

Summary

The isolation of *V. cholerae*, i.e., vibrio agglutinable to full titre with cholera O serum, from three non-cholera individuals is recorded. From the results of the examination of a series of 2,000 stools it appears this finding is of extreme rarity.

BLOOD CULTURE IN CHOLERA

By A. J. H. DEMONTE, I.M.D.
and

S. K. GUPTA, M.B., D.T.M.

From the Bowel Diseases Research Department,
School of Tropical Medicine, Calcutta.

GREIG (1914) found vibrios in many organs at post-mortem examination, but failed to isolate vibrios from the blood during life. We are not aware of any further attempt to examine the blood of cholera patients for the presence of vibrios. As opportunity existed for examining a series of patients the blood of 26 cholera patients was examined for the presence of vibrios. This examination was carried out during the height of the cholera season, all the patients had typical cholera symptoms and in all *V. cholerae* was subsequently isolated from the stools.

The blood was collected as early as possible after onset of symptoms. In two patients the blood was collected 3 hours after onset, in four 4 hours, in four 5 hours, in five 7 hours and in five 9 hours. In twenty of the patients therefore the blood was collected within 9 hours of the onset of symptoms, in the remaining six after longer periods. Approximately 5 c.cm. of blood was withdrawn under the usual aseptic conditions and inoculated into a bottle containing 100 c.cm. of peptone water. A few drops of the blood were also seeded on to nutrient agar. There was no growth of any organism from any of the samples.

Summary

Blood of 26 cholera patients was examined for the presence of vibrios. The blood was collected as early as possible in the disease, in 20 patients within 9 hours after onset of the symptoms. Vibrios were not isolated from any of the samples; this confirms Greig's findings.

VIBRIOS FROM CERTAIN NON-HUMAN SOURCES

By M. N. LAHIRI
and

P. C. DAS

From the Cholera Bacteriological Enquiry, Indian
Research Fund Association, School of Tropical
Medicine, Calcutta

VIBRIOS which in their biochemical activities resemble the *Vibrio cholerae* but differ from it in their thermo-stable O antigen have been isolated from various sources. Recently, Pasricha, Chatterjee and Das (1938) found such vibrios in the majority of the samples of Calcutta surface waters examined by them; and the vibrios were present also on the bodies of flies and cockroaches. In the present report the results of the examination of stools of a series

of certain domestic and laboratory animals are recorded.

Freshly-passed faeces of the animals were collected and enhanced through two peptone-waters. The first enhancement was carried out in a flask containing 150 c.cm. of 1 per cent peptone-water and after incubation overnight one c.cm. from each flask was transferred to a tube containing 10 c.cm. of peptone-water. This was incubated for six hours and the surface growth plated on Aronson's medium. It is interesting to note that better results were obtained on Aronson's medium than on bile-salt agar which medium gives better results with cholera stools.

Samples of stools from 195 animals of 13 different species were examined. The results are shown in table I.

TABLE I

The results of the examination of the stools of different animals for the presence of vibrios. Fifteen animals of each species were examined

Animals	Number of animals in which vibrios were isolated	Percentage of animals in which vibrios were recovered
Horse ..	10	67
Mule ..	Nil	..
Buffalo ..	8	53
Cow ..	7	47
Sheep ..	3	20
Goat ..	2	13
Pig ..	7	47
Mice ..	Nil	..
Rats (white) ..	2	13
Guinea-pigs ..	6	40
Rabbits ..	1	7
Monkeys ..	8	53
Cats ..	Nil	..

The results of the examination of single specimens show that except for mules, mice, and cats, vibrios are found in the stools of the majority of the animals. The stools of the laboratory animals were examined daily for seven days and it was found that the isolation of vibrios was extremely irregular. Further samples of stools of cats and mice were examined but with negative results.

Seventy-five strains of vibrios were studied in detail. All were inagglutinable with cholera 'O' serum (Inaba), 33 or 44 per cent were agglutinable to full titre with cholera 'H' and 'O' serum. Biochemically 41 strains were of Heiberg's group I, 32 of group II and one each of group III and group VI. Fifty-four of the 75 strains produced indole and 16 strains hæmolyzed sheep's red blood corpuscles.

A search was made for the presence of bacteriophages active on the strains of vibrios isolated from the animals. A series of fifty samples of stools were examined both by the direct method and after repeated passage of the

SOME EPIDEMIOLOGICAL FEATURES OF PLAGUE IN BENGAL WITH SPECIAL REFERENCE TO CALCUTTA

By S. RAGHAVENDER RAO, L.M.S. (Hyd.),
D.T.M., D.P.H. (Cal.)

Assistant Plague Officer, Hyderabad-Deccan

No detailed information regarding pestilences in Bengal is available before the Mohammedan period. Farishta, a contemporary of Akbar, mentions the occurrence of bubonic plague in Bihar in 1548.

A very devastating pestilence ravaged Gaur*, the medieval capital of Bengal, in 1573. During this epidemic 'Thousands died daily; living were wearied with burying the dead. Corpses of Hindus and Mohammedans were thrown into the swamps, the tanks and into Bhagirathi. This created the stench which only intensified the disease. The few people that survived the plague left the city, which was never again populated to any extent' (Lambourn, 1918). Akbar's General, Munim Khan, who had been specially deputed to drive away Daud Khan

*This place is situated in the present-day district of Malda.

(Continued from previous column)

stool filtrates on vibrios isolated from the samples. Bacteriophages active against vibrios isolated from the animals were not found in any of the samples. Eight of the fifty samples of stools showed the presence of cholera phage, the predominating type being cholera phage type A. The cholera phages isolated were feeble in their activity and were found irregularly, suggesting that they are present as contaminants in the animals.

Summary

The stools of certain domestic and laboratory animals were examined for the presence of vibrios. It was found that vibrios are present in the majority of the animals. Vibrios were not found in the stools of mules, cats, and mice.

The vibrios isolated resembled *V. cholerae* in their morphology and biochemical reactions, but differed from *V. cholerae* in being inagglutinable with pure 'O' serum. Forty-four per cent of the vibrios from animals were agglutinable to full titre with cholera H and O serum. This stresses the importance of the cholera 'O' serum in the diagnosis of *V. cholerae*.

Bacteriophages active against the vibrios isolated from the animals were not found in a series of fifty stools. This with the irregular isolation of vibrios from the stools of laboratory animals suggest that vibrios are present in the stools of animals as contaminants.

from Bengal, also died of this disease. As to the nature of the disease which appeared in such a severe epidemic form, there is considerable controversy. The modern historians in Bengal generally believe this to have been malaria. Creighton (1817) believes it to have been plague. No reference to the appearance of buboes in this epidemic is to be found anywhere. At the same time it is to be remembered that plague was prevalent in northern India at this time.

eighteenth century unequivocal statements are lacking. The earliest reference to a pestilence resembling plague in Calcutta occurs in *Transactions in Bengal* and it relates to 1770. The following passage from it, quoted by Cook (1900), gives a good description of this epidemic :—

‘There was not a corner in the city or any lurking place in the vicinity of Calcutta where the living, the dying and the dead were not mingled or heaped together in melancholy confusion. The daily employment of hundreds was to remove the dead in proportion as they became a nuisance to the public’.

There is nothing in the description to identify the disease with plague, but the unusually high mortality of 76,000 within a period of two months suggests an extremely fatal disease like plague. Again, Dr. Ling in his book *Tropical Diseases* gives his experience of a prevailing sickness in Calcutta, which probably refers to the epidemic of 1770, in the following words :—

‘If the season be very sickly some are seized with a malignant fever of which they soon die. The body is covered with blotches of a livid colour and the corpse in a few hours turns quite black and corrupted’.

The statement recalls description of the Black Death in England by Defoe, which is generally accepted as plague.

More definite evidence of incidence of plague in Calcutta in 1780 is in Busteed's (1908) *Echoes from Old Calcutta*. He says—

‘Diseases of a mysterious kind seem to have occasionally appeared and claimed their victims. The local purveyor of news records in perplexity in August 1780, “We learn that several people have been suddenly carried off within these few days by tumours in the neck, symptoms of a very unusual nature”’.

Death in a few days by ‘tumours in the neck’ suggests plague and the fact that the years (1770, 1776 and 1780) are all close to one another seems to strengthen the case in favour of the disease being plague.

Toynbee (1888) refers to a severe outbreak of a deadly malady at Chandernagore, which Dr. Wise, the Assistant Surgeon, investigated and pronounced it to be a kind of fever. It caused considerable panic among the local inhabitants, who believed that it was plague. Here again the nature of the disease is in doubt. However, the possibility of its having been septicæmic plague cannot be excluded.

This brings us to the last pandemic of plague in Bengal, which is generally believed to have started in 1898, the infection being introduced from Bombay. The first case officially

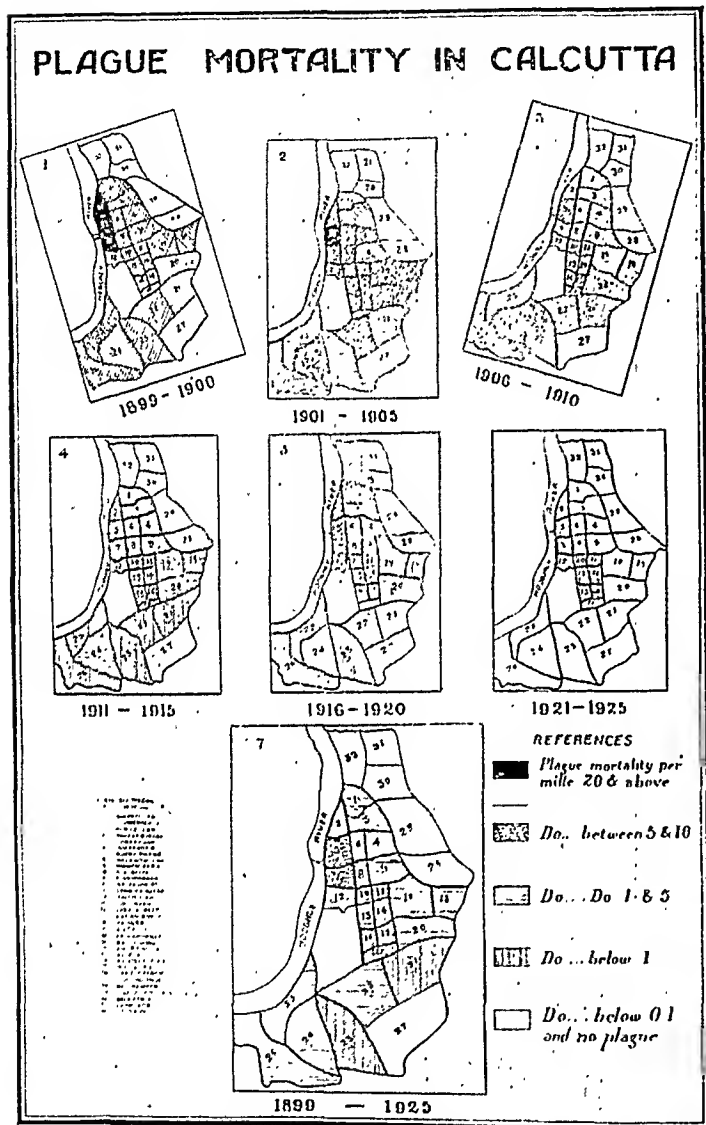

Fig. 1.—Plague mortality in Calcutta from 1899 to 1925.

It is not impossible that the infection was introduced by the invading army into a non-immune population with such devastating results. Further, recent experience in Bengal outside the city of Calcutta is that usually the cases are either of septicæmic or of pneumonic type. Possibly this fact explains the absence of buboes during the epidemic at Gaur.

A number of European writers have mentioned Calcutta city from time to time, but with regard to the incidence of plague in the

recognized as plague was in April 1898. However, a careful perusal of records available leaves no room for doubt that the introduction of this disease into Calcutta city must have occurred at least three years earlier and that it took place independently of Bombay. A portion of the Shropshire Regiment arrived in the city from Hongkong in 1895. They had, while in Hongkong, been employed on duties in connection with plague preventive measures. Two men of the regiment died of plague in Hongkong. In Calcutta there occurred among these soldiers several cases of fever with buboes, but with no mortality. Venereal infection was definitely

An extract from the Editorial article of the *Indian Medical Gazette* (January 1897) is, in this connection, particularly illuminating as regards the attitude of the authorities :—

'We had no intention of referring to the Shropshire Regiment, but as the Medical Board have published the fact that cases of non-venereal buboes have occurred among the soldiers of that regiment, we cannot help remembering the fact that they came from Hongkong at the beginning of 1895; that they were very active in attempting to stamp out the plague; that fatal cases occurred amongst them; and that they have suffered from non-venereal buboes ever

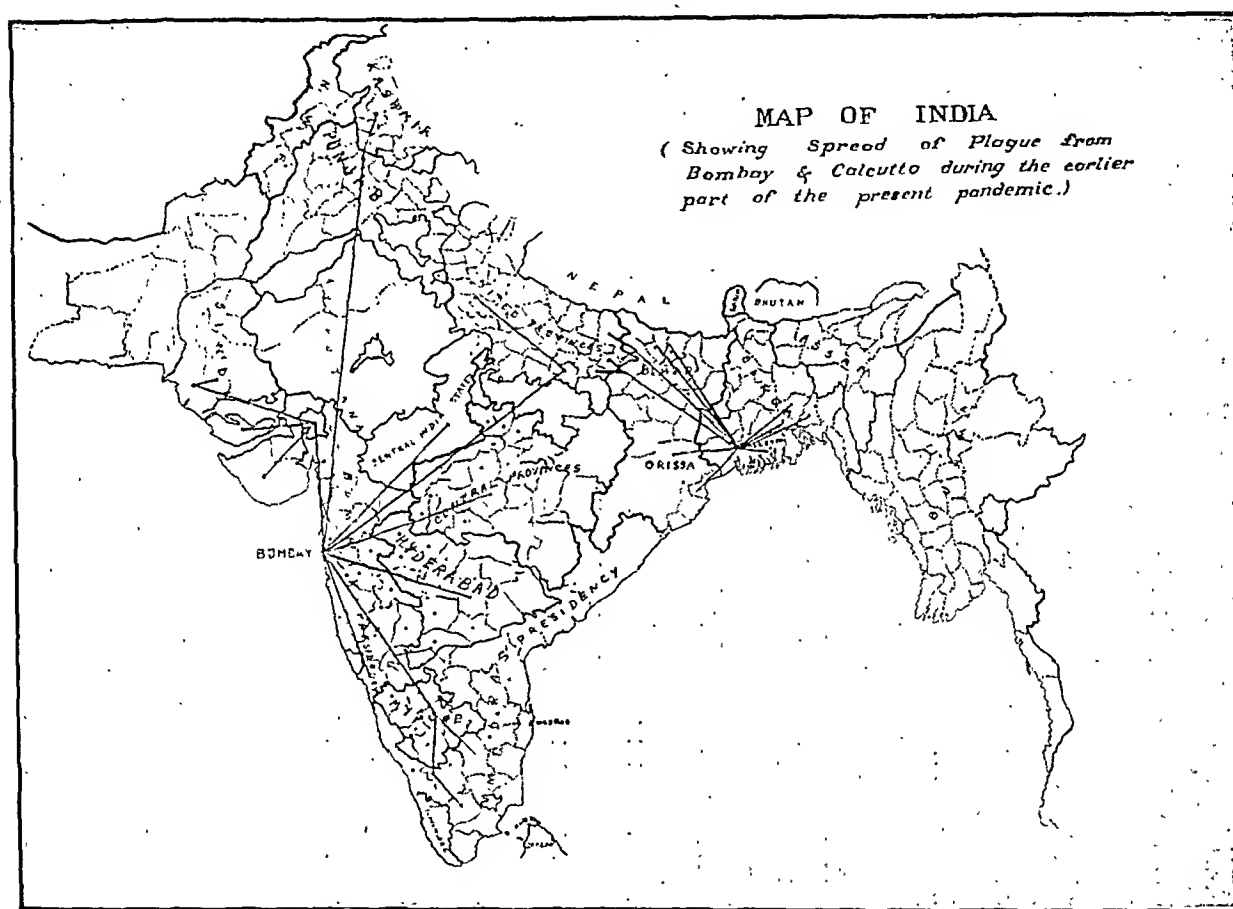

Fig. 2.—Map of India showing spread of plague in India during the earlier part of the pandemic with Calcutta and Bombay as separate sources of infection.

excluded. Authorities, however, were reluctant to admit them as cases of plague. A few cases which occurred in 1896 and 1897 among the civil population were considered by the Health Officer, Dr. Simpson (1897), to be plague cases, but the Medical Board discredited his bacteriological findings and declined to accept them as cases of plague. Dr. Simpson also drew attention to the mortality of rats in large numbers in grain godowns. At the same time the local practitioners stated that they came across cases of fever with enlarged glands in the civil population. Some of these cases ended fatally. All these indications of a slowly developing infection in the community however went unheeded.

since; and it is a significant fact that it is only since the Shropshire Regiment came from Hongkong that difficulties in diagnosis regarding these buboes appear to have arisen . . .

The attitude of the Medical Board is easily understood, and from many points of view, especially the commercial, appears to be laudable; but when viewed from a wider aspect, it is a short-sighted policy, and not likely to be in the best interests, either of the public or even of the mercantile community. We have an example in Bombay of a similar policy as that pursued by the Medical Board and its results. Bombay concealed its first cases, then minimized them, and now it is face to face with a severe

THE INDIAN MEDICAL GAZETTE

[Nov., 1938]

epidemic, its trade is ruined, and by its flying population it is likely to spread the disease far and wide.

This brief presentation of some of the available evidence suggests that the disease in question must have been plague. In all probability plague was introduced into Calcutta about 1895, independently of Bombay, and the disease appears to have had such a very mild course during the two or three years that even the nature of infection was not correctly diagnosed. The disease which was more or less smouldering for these three years suddenly flared up during

VII), Colootola (ward VIII), Fenwick Bazar (ward XIII), and Beniapur (ward XX). Calcutta city was officially declared infected on 30th April, 1898. This announcement is said to have created such a panic that people rushed away from Calcutta and in their hurry to leave the city, a number of lives were lost at the railway station due to stampede. Then the extension of the disease took place both in respect of the period of the year and in the area involved with the result that by the year 1900 cases occurred throughout the year, and no part of the city was free from infection,

the first quarter of 1898. Rat falls were noticed in the middle of April 1898 in a printing house on the riverside in ward VII and in the course of three or four days other localities in the neighbourhood also became involved. On 17th April, 1898, a corpse was discovered by the police in Kapalitola Lane; on post-mortem examination the diagnosis of this was confirmed bacteriologically. Within a week, several cases were reported not only from the neighbourhood of Kapalitola Lane but also from wards situated at a distance from it, viz, Shampookur (ward I), Coomartooly (ward II), Burra Bazar (ward

as may be seen from the accompanying table and the map. This, however, did not last long and in 1907 the tide turned. The intensity of the epidemic gradually diminished and the part of the year when cases occurred became more and more restricted, and the area involved diminished year by year being more and more confined to the northern wards of the city, viz, wards V, VI, VII and VIII. Finally, the disease virtually disappeared from the city of Calcutta in 1925. From the districts it had disappeared much earlier as will be seen later. Thus, we see that the fugitives from the city of Calcutta were responsible for the introduction

of plague into almost all districts in Bengal and also of what now constitutes the two provinces of Bihar and Orissa. The accompanying map of India shows the extent to which the plague spread in India with Calcutta and Bombay as separate sources of infection.

In the presidency of Bengal, outside the city of Calcutta, the plague infection was unable to take a deep root. In several cases it only resulted in small outbreaks of pneumonic or septicæmic plague. Table II gives the course of events in Bengal during the pandemic of plague, while table I gives similar details about the city of Calcutta.

gradually to other wards and within the course of three or four years practically each and every ward in the city was affected. In the later period, as mentioned before, when the infection began to clear, the wards affected late were the first to become free from infection. The wards that reported cases till the end were the wards first infected or those in their immediate neighbourhood.

Do like causes operate in the progress and decline of pandemics of plague in the world as in Calcutta? If so, a detailed study of happenings in a comparatively small unit like Calcutta city should be of great importance from the

*The yearly averages for these periods are given.

It will be seen that the brunt of infection was borne by Calcutta city and the districts in its neighbourhood. The general phenomena of expansion and retraction observed in plague epidemics throughout the world was also a noticeable feature here. Epidemics first started in Calcutta and then began to spread to the outlying districts, the severity of epidemics being in inverse proportion generally to the distance of the districts from Calcutta. Again the outlying districts became free from infection earlier, and towards the close of the period (1923-24) we see that it was Calcutta alone that was still reporting deaths from plague.

The same phenomena observed on a miniature scale in the events occurring in the city of Calcutta itself. The disease first started and was severe in wards V, VI and VII where the conditions for the spread of infection were very favourable. It then began to spread

point of view of the elucidation of this universal phenomenon.

The search for the explanation of the phenomena of succession of epidemics has engaged the attention of the epidemiologists from the dawn of scientific medicine, but we seem to be nowhere nearer the goal than was Hippocrates or Galen. Various theories have been put forward from time to time. Hippocrates first observed the sudden and almost simultaneous epidemics over large areas and was probably also aware of their recurrence at longer or shorter intervals. He sought for the explanation of these variations of the epidemics in the changes in the atmosphere, and his opinions were later summed up in the phrase 'Epidemic constitution of the atmosphere'. This doctrine was revived later by Ballonius. It was Sydenham that further expanded this theory and gave it a touch of mystery, and said that the variations in the

epidemics were due to some invisible changes in the bowels of the earth. He tried to prove, by collecting statistics regarding the epidemics in the past, that there are gradations, modifications and affinities among epidemics occurring in successive cycles of years, and that in certain conditions such epidemics must be considered as a whole and not separately.

Mere statistical evidence alone cannot be of much value unless some laboratory evidence also is forthcoming. The modern revivalists of Sydenham's epidemic constitution theory, in a modified sense, seek explanation of secular periodicity in the facts such as the eleven-year sun-spot cycle, which profoundly influences the climatic factors and with which the spread of the disease transmitted by insects is closely associated.

Last in the field in this respect is Gill (1928) who comes forward with the 'quantum theory' which tries to explain that epidemics are generally caused by a loss of balance between the quantum of infection and immunity factors. Whatever the merits of this quantum theory may be as an explanation of the short-term variation in the plague incidence it affords no satisfactory explanation of the long-term periodicity of plague, as immunity to plague both in human beings and rodents, acquired either by natural infection or produced artificially, does not seem to last for a long time or much less to be transmitted to succeeding generations.

To get an insight into the mechanism of long-term periodicity of plague is not only of academic interest, but also might possibly lead us to the discovery of certain factors which could be controlled by human efforts and thus save the community from the periodic visitation of these disastrous epidemics.

The following remarks of Colonel Sokhey (1937) in this connection bear quotation:—

'It is a comparatively quiescent period after a severe pandemic with just a few cases of plague here and there. These factors make the present period an ideal one for further study and any expenditure that may be incurred would be well worth it. If this period once passes without our acquiring all the knowledge we need to understand the phenomenon fully and thereby devising intelligent means of preventing fresh pandemics[sic]. Unless deliberately prevented, pandemics are likely to come again as they have come in the past'.

SOME OBSERVATIONS OF PRACTICAL IMPORTANCE AND INTEREST FOR THE MALARIOLOGIST

By M. M. SYDDIQ, M.B., B.S., L.R.C.P., M.R.C.S. (Eng.),
 D.O.M.S. (Lond.), D.P.H., D.T.M. & H. (Lond.)
 Chief Malaria Officer, Hyderabad-Deccan

I. Paris green

PARIS GREEN as ordinarily used (1 or 2 per cent) is effective against anopheline larvæ, and culex larvæ only when breeding in clean waters like those of paddy fields. In sullage waters culex larvæ are much more vigorous and resistant, and surface sprinkling of Paris green has no effect whatever on them.

Our observations have led us to believe that the larvæ die by swallowing small particles of Paris green. It was suggested that if Paris green could be applied in such a way that it sank in water, where, after disintegration of the mass, particles gradually rose, the culex larvæ would consume these particles and perish. With this object in view balls containing Paris green were made. The balls are made up of finely sifted road dust to which two per cent of Paris green has been added. They are made up by gradually adding water to produce a suitable consistency for making up into balls. Each ball weighs about two ounces, that is to say, about 1,000 grains, and contains 10 grains of Paris green powder (see figure 1).

They dry and keep well when made up, and a number can be kept in stock. These balls

Fig. 1.

added to small collections of water are fatal to culex as well as anopheline larvæ. It is as well also to powder the surface in known anopheline breeding places.

(Continued from previous column)

- Simpson, W. J. (1897). *Indian Med. Gaz.*, Vol. XXXII, p. 68.
 Sokhey, S. S. (1937). *Ann. Rep. Hasliane Inst., Bombay*, 1936. Govt. Central Press, Bombay.
 Toynbee, G. (1888). *A Sketch of Administration of Hooghly District from 1795 to 1845*. Calcutta.

Two balls are sufficient for about 8 cubic feet of water.

The balls are not effective when the depth of water is greater than 5 feet; they are therefore unsuitable for wells.

It should be noted in this connection that 'Malaria' (Burmah-Shell Co.—mixture of kerosene, crude oil and cresol) used by this department is not 100 per cent effective against culex larvæ and pupæ in sullage waters; in such contaminated water the film is irregular. Even after very heavy application some larvæ and many pupæ persist after as long as three days. Our observations on Paris-green balls have been confirmed by Doctor Dallal of Bombay.

II. Paris green and paddy fields

That one per cent Paris green applied once a week has no untoward effect on rice crops has been amply proved by our experience here. We have actually kneaded Paris green into mud growing very young plants. No bad effects were observed. But two per cent Paris green applied twice a week is absolutely destructive

Fig. 2.—Showing crops destroyed by Paris green in the foreground, with a normal crop in the background.

to rice plants. The accompanying photograph amply upholds this statement (figure 2).

The question has been raised that even one per cent Paris green might adversely affect delicate flowering plants. Our experience in public

and private gardens does not substantiate this view.

III. Larvæ in mud

It was observed that pits that had practically dried up and remained untreated after a rain-fall overnight contained larvæ 5 to 6 days old. In this connection there is no question of a thin pellicle of water on the surface. These places look like ordinary moist earth. When such mud is taken and water poured over it larvæ revive after some minutes. During laboratory experiments they have never survived after more than 24 hours, but in the paddy fields after depletion of all water they were still alive after 72 hours. In this connection it must be remembered that farmers are apt to be very vague about time. Besides, the fields are not given perfect slopes to drain away all water after inlets are stopped and outlets opened. Some water remains standing and only gradually dries up.

In moist mud in pits where definite numbers of larvæ were placed and then were allowed to dry out, the following observations were made. From the nature of the experiments it is not possible to make absolutely exact statements, but every effort has been made to arrive at a good working hypothesis.

The type of the soil, the temperature and humidity will play an important rôle in this matter.

It will be seen that pupæ are more resistant than larvæ, and anopheline larvæ keep alive longer than culex larvæ. Moisture is sufficient to keep them alive for some time. Death eventually takes place, either through desiccation or starvation, as the mouth brushes cannot be utilized under these circumstances.

The question arises as to whether these larvæ under such circumstances are capable of carrying through their different developmental stages. Experiments have shown that the development of larvæ is considerably retarded when they are kept in mud and the pupa does not develop into the imago.

In his report on antimalarial measures in Java and Indo-China, Dr. C. F. Chenoy, Deputy

TABLE

Showing larvæ and pupæ alive when specimens were taken at definite hours after all free water had disappeared

					12 hours	24 hours	36 hours	48 hours
Larvæ, anopheline	30 per cent	12 per cent	2 per cent	Nil
Larvæ, culex	20 "	8 "	Nil	Nil
Pupæ, anopheline	40 "	15 "	5 per cent	Nil
Pupæ, culex	40 "	15 "	5 "	Nil

Director of Public Health Department, H. E. H. the Nizam's Government, writes :—

The principle underlying the method of periodical drying out of rice fields is to observe its influence on larval fauna. Experiments were carried out in Java and the method advocated there is to flood the rice fields for nine continuous days and then dry out for two consecutive days. This was repeated as long as was necessary. I am told that the result of this experiment has been that 75 per cent of the larval fauna-breeding was completely controlled.

In this experiment, I am told that about 7 per cent of the yield of the crop of paddy was less and the Java Malaria Department are of opinion that probably this was mere coincidence but will have to be carefully controlled before such measures are widely applied.

In Indo-China, Government have taken up this method on a larger scale and the method applied is still more rigorous. The method is as follows:—

The fields are irrigated for three days and for the other three days water is stopped, the result being the fields are completely dry for full 24 hours out of the six days. In these rice fields, the Indo-China people say they have not been able to find a single larva.

Further they mention that the quantity of paddy is nearly equal or equal to that of the fully irrigated fields.

In the case of half-dried or dry pits the practice here, during the rainy weather, is to place lumps of road dust soaked with 'Malariol' in them. When the rain falls and the larvæ emerge, at the same time oil also spreads and destroys them.

The problem of dealing with larvæ in running water, often highly polluted, is extremely difficult. Pits and big wells which are in the process of being filled in by street refuse breed mosquitoes and are difficult to deal with. Here some larvicide is necessary which is instantaneous in its effect. With this object in view several chemicals were tried; some of them proved quite efficacious in the laboratory, but they have not been successful in the field.

The following were tried :—

- (1) Copper sulphate.
- (2) Potassium permanganate.
- (3) Malariol with excess cresol.
- (4) Formaldehyde gas—obtained by first applying bleaching powder and then 40 per cent formalin.
- (5) Carbide.
- (6) Calcid—gives off HCN when it comes in contact with water.
- (7) Crude sulphuric acid, just acid to litmus.
- (8) Sodium chloride.
- (9) Larvetol—this is giving encouraging results but yet it is premature to make a statement.

In running waters in 'kuteha' drains we have found that if pieces of wood are placed across the drains at suitable distances according to the amount of breeding, these pieces of wood block the larvæ to a great extent and there is no impediment to the flow of water. If oil is applied to such drains, it also is retarded by these

pieces of wood and remains in contact with larvæ long enough to kill them. The accompanying photograph explains the method (figure 3).

Fig. 3.—Showing a piece of wood placed across a drain.

'Pyroicide 20' and 'Pyretol 19'—these products have been placed on the market as extracts of pyrethrum flowers. We have tried them in a closed room as insecticides, diluted with kerosene oil 1 in 20 and 1 in 19. No direct aim at the mosquitoes is necessary. Half an ounce of the mixture was freely sprayed in a closed room (600 cubic feet) in which a large number of mosquitoes, both *Culex* and *Anopheles*, were let loose. All of them died in four hours. It is of additional interest that bed bugs, lice, fleas and even crickets placed in glass cylinders in the room were also found dead after 12 hours.

Mosquito repellents

Oil of citronella still holds the field in this direction but its effect can be made more lasting when it is combined with other substances in the form of a cream. The following is a good formula :—

Bees wax	2 drachms.
Spermaceti	4 "
Coco-nut oil	4 "
Liquid paraffin	1 ounce
Oleum citronella	1 "
Acid carbolie	10 minims
Fuller's earth	4 drachms

The bees wax and spermaceti should first be melted in a water bath, the oil and other ingredients added after melting, except oil of citronella and acid carbolie which should be added just before resolidifying. It is a clean preparation, easy to apply, easy to carry about and the effects are more lasting.

VARIATIONS IN THE PLATELET COUNT IN TYPHUS ASSOCIATED WITH HÆMATURIA

By R. L. HAVILAND MINCHIN, M.D.,
CAPTAIN, I.M.S.

Additional Professor of Medicine, Medical College, and
Physician, General Hospital, Madras

THE case of typhus fever described here, though resembling in many ways the type that has been described as occurring in many parts of India, presents certain striking characteristics which make it worthy of record.

On 27th July, 1938, a Hindu male, aged 14, was admitted into the General Hospital wards under my care; he stated that he had not been out of Madras city for seven months, and up to nine days previously had been in perfect health.

Nine days before admittance he developed a low fever associated with headache and pain in the joints, but no rigor. At no time had the temperature exceeded 102°F.

The day before admittance, i.e., on the eighth day of the fever, he developed petechial red spots all over the body; these spots did not vanish on pressure, were of a red-brown colour, and were more or less evenly distributed all over the body, on the face, soles of the feet, and palms of the hands. The doctor attending the case suspected the condition to be one of typhus and sent a specimen for blood agglutination against *Bacillus proteus*. The same evening the urine was found to be bright red in colour.

(Continued from previous page)

My thanks are due to the Director, Medical and Public Health Department, H. E. H. the Nizam's Government, for his permission to publish these notes and to Dr. C. F. Chenoy, Deputy Director of Public Health, H. E. H. the Nizam's Government, for his very useful suggestions. Also to my staff for assisting me to complete this work.

Summary

1. An effective method of applying Paris green to destroy culex larvæ in small pits containing sullage waters has been described.
2. Two per cent Paris green applied twice weekly is very harmful to rice crops.
3. A new observation about the capability of larvæ to survive in mud for some time has been made and the practical utility of this observation discussed in connection with paddy fields.
4. Difficulty of dealing with mosquito larvæ in running waters is mentioned and results of some larvicides tried to that effect are given. A method to deal with this difficulty is described.
5. Results of experiments on adult mosquitoes with Pyrocid 20 and Pyretol 19 are given.
6. A formula for a mosquito repellent is given.

The next day I was called to see the case as the boy was passing almost pure blood, and was showing definite signs of blood loss. I advised his transfer to hospital so that transfusion could be carried out if necessary. At this time, in addition to the rash and hæmaturia, subconjunctival hæmorrhages of both eyes had appeared and areas of hæmorrhage existed under the mucous membrane of the tongue and lips. On taking the blood pressure, however, no new areas of hæmorrhage appeared. Examination of the heart at this stage showed no enlargement, but the presence of a systolic murmur in the mitral area. Telephone report from the bacteriological laboratory gave agglutination of blood up to 1 in 200 against *B. proteus* X19(O).

On the following day, in spite of the bacteriological report, the possibility of the condition being due to purpura hæmorrhagica was considered and a complete blood examination was carried out, the results being—

Red blood corpuscles	3.10 million per c.mm.
Hæmoglobin	60 per cent.
White blood corpuscles	8,750 per c.mm.
Polymorphonuclears	75 per cent.
Lymphocytes	19 "
Monocytes	5.5 "
Eosinophiles	0.5 "
Thrombocytes	25,000 per c.mm.

The urine continued to consist of almost pure blood, so the boy's and his parents' blood were typed and found compatible. The parents were told to keep in touch with the hospital so that transfusion could be done if necessary. In the meanwhile the patient was given an alkaline mixture and large volumes of fluid to drink to keep the renal tract free from blood clots.

The progress in this case will be seen from the temperature chart in the previous column and the tabular statement below :—

The low platelet count at the height of the disease is of importance, as this without the report on the Weil-Felix reaction might have

Date	Day of disease	Symptoms	Blood and laboratory reports
1-8-38	11	Hæmaturia still marked, no new spots.	Thrombocytes—28,000 per c.mm. Blood culture—sterile. Weil-Felix X19(O)—1 in 200. <i>Bact. typhosus</i> , para A and B all negative. Urine culture—negative.
2-8-38	12	Unchanged.	Thrombocytes—29,000 per c.mm. Leucocytes—9,060 per c.mm. Erythrocytes—2.4 million per c.mm. Hæmoglobin—49 per cent.
3-8-38	13	Urine slightly clearer, clinical improvement.	Thrombocytes—29,000 per c.mm. Leucocytes—9,060 per c.mm. Weil-Felix X19(O)—1 in 3,200. X2(O) negative; XK(O)—1 in 50.
4-8-38	14	Urine only shows trace of blood. Transfusion not done because of clinical improvement. Rash fading.	Erythrocytes—1.94 million per c.mm. Thrombocytes—30,000 per c.mm.
5-8-38	15	Improvement maintained.	Thrombocytes—38,000 per c.mm.
6-8-38	16	Do.	Thrombocytes—54,000 per c.mm.
8-8-38	Temperature normal—rash almost gone. Patient wishes to leave hospital. Left on 9th; blood taken for Wassermann reaction. Report positive.		

Discussion.—Clinically this case appears to be one of tick typhus, the rash corresponding exactly to that described as occurring in this disease by Rogers and Megaw (1935); but it is difficult to explain how this boy, who had not been out of Madras city for seven months, could have been bitten by ticks; on the other hand, the serological reports are all against this diagnosis and the high agglutinin titre against *B. proteus* X19(O) suggests that the condition was one of louse or flea typhus, and the environment of this patient is also more in favour of this hypothesis.

It is unfortunate but not surprising that *B. proteus* could not be recovered from the urine of this case, but this has never been done in India. Incidentally, injection of the blood obtained at the height of the disease into rats failed to produce signs of disease.

The symptom of profuse and dangerous hæmaturia which was so prominent in the patient does not appear to have been previously described as a complication of tick typhus though Mulvany (1935) described a similar case which he considered was enteric, but which well might have been typhus.

The appearance of the rash might possibly have been confused with syphilis and in favour of the diagnosis is the positive Wassermann reaction at the end of the fever. This, however, appears to be an almost constant finding at the end of attacks of typhus.

given rise to a diagnosis of purpura hæmorrhagica. This count is of interest as it does not appear to have been made previously and in the case here described clinical improvement corresponded with and was preceded by a rise in the number of blood platelets*.

Summary.—An unusual case of typhus is described where profuse hæmaturia is the main symptom. The differential diagnosis is discussed and the rise in platelet count with clinical improvement is noted.

I am grateful to Dr. G. S. Viswanathan, Clinical Pathologist to the Madras General Hospital, for hæmatological reports and Lieut.-Col. M. M. Cruickshank, I.M.S., Superintendent, for permission to publish this report.

Rogers, L., and Megaw, J. W. D. (1935). *Tropical Medicine*. J. and A. Churchill, London.

*The first clinical improvement was noted on the 3rd August, but on the 4th August the platelet count had only improved by 5,000, which, in view of the large technical error in platelet counting, is an entirely negligible figure. It cannot therefore be said that the rise in the platelet count preceded the clinical improvement.—Editor, I. M. G.

A Mirror of Hospital Practice

A CASE OF TAPE-WORM SIMULATING ACUTE APPENDICITIS

By D. A. GANGOLLI, L.C.P.S.

Medical Officer in charge, Dispensary, Bhayndar (District Thana)

A. B., a strong and well-built man, aged about 30 years, complained of severe pain in the abdomen with high fever. The patient had gone to bed apparently normal the previous night, and the pain and fever had set in suddenly since the morning. The pain was generalized all over the abdomen and was more marked in the right iliac fossa. On examination the whole abdomen was found rigid and board-like with definite and marked tenderness in the right iliac fossa more or less at the McBurney's spot, where a small lumpy mass about the size of a small orange was felt. The patient was lying on his back with the right leg drawn up to relax the abdominal muscles. His face was anxious and drawn, with the lips and tongue dry. Temperature was 104°F. and pulse 136 per minute. He had vomited twice since the morning and the vomiting was preceded by nausea. He had also passed a stool since morning which on inspection appeared to be more or less normal. A blood slide was examined, but neither malarial parasites nor definite leucocytosis could be found. The case appeared to be one of acute appendicitis. But the sudden high rise in temperature to 104°F. led to a doubt about the diagnosis as experience has shown that an initial temperature higher than 102.5°F. is against appendicitis. As smallpox cases had been reported to be occurring round about the district, and as acute abdominal pain with vomiting is not uncommon at the onset of acute infective fevers, the patient was kept under observation. He was given a simple diaphoretic mixture, and hot fomentations were applied to the abdomen.

Next morning the patient was practically in the same condition. Temperature was 103°F. and pulse 124 per minute. He passed one stool, in the morning after a severe colicky sensation, which contained a small gelatinous piece resembling the segment of a tape-worm. In spite of his seemingly acute condition he was given 30 minims of carbon tetrachloride in one ounce of saline (containing two drachms of magnesium sulphate) and four hours later he passed a stool consisting more or less entirely of a tape-worm, the mass being as big as a tennis ball. With this the patient felt very much relieved, the pain in the abdomen lessened and the lumpy mass in the right iliac fossa disappeared. The diaphoretic mixture was continued for the day, and an intramuscular injection of quinine 6 grs. was given.

From the third day onwards the pain and tenderness in the abdomen gradually disappeared, temperature and pulse came down to normal and the further recovery of the patient was quite uneventful.

Discussion

In this case the lumpy mass in the right iliac fossa was undoubtedly caused by the distension of the cæcum due to the presence of an enormously long tape-worm within it, and the bulging disappeared simultaneously with the ejection of the worm. The pain and tenderness in the right iliac fossa were due to typhlitis with erosion of the mucous membrane of the cæcum. Probably there was concurrent appendicitis as well in a mild form due to obstruction of the appendicular opening leading to stagnation of its contents. When the worm was expelled, naturally the obstruction in the appendicular opening was also relieved. The concomitant

high fever in this case is difficult to explain. On a suspicion of co-existing malaria, as it is endemic here, the administration of a quinine injection was felt necessary.

AN AMBULATORY CASE OF FRACTURE OF THE LUMBAR VERTEBRÆ

By B. L. CHOPRA, L.R.C.P., L.R.C.S., L.M.,
D.P.H., D.T.M. (L'pool)

Divisional Medical Officer, North-Western Railway, Karachi

A GANG-MAN, while working on the open line, was knocked down by a shunting engine and fell on his back. Soon after he was seen by a doctor and kept in bed for about 10 days after which time the employee wanted to go back to duty. His request was acceded to and he continued his work for about six months.

During this period he used to complain of pain in his back, off and on. Thereafter the pain became constant and he could not carry on his duties efficiently and again reported sick at Panipat Railway Hospital whence he was sent to the Divisional Hospital at Delhi where I saw him. I suspected some old fracture in the lumbar region and sent him for x-ray examination which revealed two fractures in the bodies (2nd and 5th lumbar vertebræ).

The man was kept under treatment for about four months at Delhi and then given a supporting spinal leather-belt and discharged fit for a light job which I believe he is performing up till now.

The remarkable point about this case is that in spite of such a serious injury to the spine the man continued to work for about six months, and it is this point that makes it worthy of record.

My thanks are due to the Chief Medical and Health Officer, North-Western Railway, Lahore, for his kind permission to publish this case.

SPONTANEOUS RUPTURE OF THE HEART

By MOHD. MOHSIN ALI ABBASI, M.B., B.S.
Ripon Hospital, Simla

THE dead body of a male, sweeper by caste, aged about 48 years, an hotel employee in Simla, was brought for post-mortem examination on 4th April, with the report that the deceased had complained of stomach pain at 9 a.m. on the previous day. He drank some tea at noon and had kept up until about 6 p.m. when he took to bed and expired at 10-30 p.m.

Previous history.—Nothing elicited except that he had previously suffered similar attacks of pain from time to time.

General physical examination.—He was a well-built man, 5 feet 2 inches in height, aged about 48 years, with grey hairs. No mark of any injury was discerned on his body, nor was there any history of trauma.

Post-mortem examination.—Abdominal section revealed nothing as to the cause of death. There was a small subperitoneal ecchymosis over the right side of the inferior vena cava close to the root of the transverse meso-colon; and small groups of ecchymoses were present on several appendices epiploicæ of the pelvic colon.

On opening the thorax there was found some ecchymoses in the fatty tissue overlying the pericardium. The pericardial sac contained about 8 ounces of fluid and clotted blood. The heart was soft and flabby. The left ventricle was thin-walled and its front surface presented an area about one and a half inches in

diameter within which were several lacerations situated half-way between the root of the aorta and apex of the heart and just to the left of the interventricular septum. Two of these lacerations penetrated into the cavity of the ventricle; the others were superficial. The affected area of the ventricle was outlined by adherent blood clots, both on the epicardial and endocardial surfaces. The lining membrane of the root of the aorta showed numerous yellow atheromatous patches.

This case is reported as one of spontaneous rupture of the heart without any evidence of causal exceptional effort or strain.

The heart muscle showed evidence of degeneration attributable to coronary disease. The condition is rare. Goodall and Weir (1927) have recorded 18 cases of spontaneous rupture of the heart muscle.

My thanks are due to Lieut.-Colonel A. Sargood Fry, I.M.S., Civil Surgeon, Simla East, who conducted this post-mortem examination and has permitted me to send these notes for publication.

HOMICIDE BY A PATIENT APPARENTLY SUFFERING FROM CEREBRAL MALARIA

By GEO. P. FRANCIS, I.M.P.

Sub-Assistant Surgeon, Jail Hospital, Moulmein, Burma

A KAREN FEMALE, aged 26, was admitted to the District Jail, Moulmein, as an undertrial prisoner with the following history:—

She was married about three years ago and lived happily. A daughter was born to her about a year ago, since then she had been having repeated attacks of malaria. She was under the treatment of a Burmese *Se Saya* (physician) of her village. On the night of the 2nd February, 1938, she retired to bed with her husband with nothing unusual in her demeanour. At about 4 a.m. the next morning, the neighbours hearing strange noises emanating from their bedroom, broke open the mat-wall partition and found the husband lying hacked to death with several cut wounds and the wife lying prostrate over his body with a *dah* in her hand. The headman of the village who was also present seized the *dah* and placed her under arrest when she stated that her family *nat* (spirit) had persuaded her to do the murder.

She was suffering from fever for about a month, and the *Se Saya* saw her last about four days before the incident. After arrest she was treated at an outlying civil hospital from the 3rd to the 6th February, 1938.

6th February, 1938. On admission to the Moulmein Jail, she was very weak and unable to walk. She refused to take nourishment. She had a temperature of 99°F., with pulse 90 and respiration 24. She was restless, looked very much depressed and was not able to answer questions. At times she was very violent and tried to bite other prisoners near her and wanted to commit suicide. She looked dazed and had no idea of her surroundings. She was reported as having fits frequently. Her tongue was furred and coated, bowels constipated, and spleen palpable. No other abnormalities were detected. She was given a dose of saline mixture and put on bromides.

7th February, 1938. Temperature 99.2°F., pulse 88, respiration 24. She was restless and kept on staring at people. Slept off and on. Mental condition same.

8th February, 1938. Temperature 99.4°F., pulse 92, respiration 24. Blood examined for malarial parasites, result negative. An injection of quinine dihydrochloride was given in the morning. Her mental condition improved marvellously. She was later able to take her nourishment well, behaved well, slept well and could talk sensibly.

9th February, 1938. Temperature normal. An injection of quinine was repeated. Her mental condition

improved to such an extent that from this day onwards she was normal and worked with other prisoners voluntarily.

She made uneventful progress and was able to stand her trial in court, where she was surprised to hear that her husband was murdered and that she was accused of the crime. She became hysterical on hearing this news.

In the medical evidence it was deposed that she was suffering from cerebral malaria on admission to the Moulmein Jail, that it was possible she might have been suffering from this complaint for several days or more, that her sanity would be affected and that probably she would not know the nature of the act, whether it was wrong or contrary to law. The other evidence recorded was found to support the view that the accused committed the offence while she was suffering from cerebral malaria.

The court accepted the evidence, and she was directed to be discharged.

In conclusion, I express my gratefulness to Major T. J. Davidson, I.M.S., Medical Officer and Superintendent, District Jail, Moulmein, under whose supervision the case was treated, for his many valuable suggestions and kind permission to make use of the records available in publishing this case.

A CASE OF SPONTANEOUS HÆMATOMYELIA

By S. AHMAD, F.R.C.S.

CAPTAIN, I.M.S.

Civil Surgeon, Sitapur

and

RANBIR SINGH, M.B., B.S., P.M.S.

Medical Officer in charge, Sadar Hospital, Sitapur

A MOHAMMEDAN male, aged 30 years, was admitted into the Sadar Hospital, Sitapur, on the 20th May, 1938, at 8 a.m., complaining of retention of urine and faeces.

The history was that at 8 p.m. on the previous evening he took a cold bath, changed his clothes and sat down. He felt sick and vomited three times. Next he wished to get up to pass urine but was unable to do so. He was brought to the hospital at midnight and taken back home after he had his urine drawn. He refused to be admitted on this occasion.

He gave a history of syphilis about a year back.

Condition on admission.—There was complete flaccid paralysis and loss of sensation below the lumbar region with retention of urine, the bladder being distended up to the umbilicus. Except the complete loss of tendon jerks in the lower extremities, the central nervous system showed no other abnormality. The patient complained of no pain and was generally comfortable except for the retention noted above. Temperature—100°F.; heart, lungs, etc., normal.

His urine was drawn regularly and the condition closely watched. In view of the history of syphilis potassium iodide and mercury were given by mouth. On the 22nd, his temperature rose to 103°F., power of speech was suddenly lost, breathing became stertorous, and he became unconscious. The coma deepened and he died at night.

Comments.—A case of spontaneous hæmatomyelia, diagnosed clinically, is described. It appeared to spread from below upwards.

It is of interest that there was no history of injury direct or indirect precipitating the disease.

Girdle pain which is described as usually present in such a condition was absent in this case.

Lumbar puncture could not be done because of the unwillingness of the patient.

Indian Medical Gazette

NOVEMBER

PROFESSION OF PHARMACY IN INDIA

PHARMACY, in the sense in which the term is used in western countries, is practically non-existent in India; for this reason few medical men in this country realize the important part that the pharmacist plays in the practice of scientific medicine and as a unit in an efficient health service in any country. The pharmacist is the custodian of the drugs that are such an essential part of our equipment. He prepares, compounds, and dispenses drugs, and on his expert knowledge and efficiency will depend to a large extent the purity and potency of the preparations used by the doctor. The physician of to-day, whose time is fully occupied in diagnosing his cases and prescribing treatment, has no time left to dispense his own medicines, as he used to do in the past; the wider scope of medicine as a science also makes it impossible for him to devote time systematically to the study of pharmacy. In the matter of drugs, their dispensing and preparation, therefore, the physician will have to depend more and more on the advice and guidance of the pharmacist. Further, the physician in western countries is beginning to turn to the pharmacist for information in connection with new preparations and drugs. This means that pharmacists have constantly to keep themselves abreast of current medical knowledge, in so far as it deals with drugs, so as to be in a position to discuss intelligently such matters with the physician. The relation of pharmacy to the practice of medicine in everyday life is therefore intimate and the pharmacist forms an integral part of the health service of which the practitioner is the central figure.

Compared with their status in Great Britain, on the Continent of Europe, in the United States of America, and in nearly all other civilized countries all over the world, the status of the pharmacist in India is a most deplorable one. The profession of pharmacy in India is represented by a class of people known as 'compounders', whose status and functions are ill defined and duties multifarious. They compound and dispense medicines, including the most potent preparations and deadly poisons, in many cases in complete ignorance of their properties and potency. In many of our hospitals and dispensaries they also work as dressers, as laboratory and hospital assistants, and as male nurses; they give anaesthetics and assist at operations; they carry on the duties of the medical officer when he is temporarily away, and usually pass as a 'doctor' before the lay public. In fact, 'compounders' in India form a very heterogeneous group of people who indulge in every conceivable form of medical activity outside

their legitimate duty of compounding, dispensing and supplying medicines according to the prescription of the physician.

The evidence produced before the Drugs Enquiry Committee, appointed by the Government of India in 1930-1931, regarding the character and quality of work turned out by compounders as a whole, in this country, was far from being complimentary. The public and medical men from all over India expressed dissatisfaction with their work. Charges of ignorance, carelessness, lack of responsibility, and dishonesty were levelled at them. There seems little doubt that many of them ply a profitable trade in all kinds of spurious and faked products.

This is a very unsatisfactory state of affairs and unless something is done to improve the status of the pharmacist and limit the practice of pharmacy to a properly qualified group of people, the advance of medical practice in India and of the health service of the country is bound to be retarded.

At present, the practice of pharmacy in India is subject to no laws or restrictions whatsoever. The titles of 'chemist' and 'druggist' have no significance, as they are freely used by anybody who may choose to adopt them. There is nothing to prevent the most ignorant person from opening a chemist's shop and dispensing the deadliest poisons, whilst the qualified chemist next door is in no way protected against unscrupulous competition.

The present state of affairs can best be described, not so much as a vicious circle but as a morbid stasis. There are few opportunities for obtaining a pharmaceutical education, so that there are few qualified pharmacists; this means that unqualified pharmacists come into the field. As the latter can practise with no legal disabilities, and as he has no background of a, comparatively speaking, expensive education and training, and no professional pride or status to lose, the qualified pharmacist is from the commencement economically handicapped when he comes into competition with numerous, often unscrupulous, unqualified rivals. He has to sink to the level and practices of his rivals, or go under. In these circumstances it is not surprising that there is no great rush of candidates for pharmaceutical qualifications, and no incentive to anyone to extend the facilities for such training.

There is another aspect of this problem. While the profession of pharmacy is in this entirely uncontrolled and unsatisfactory state, it will be almost impossible to implement any legislation aimed at the control of the manufacture and sale of drugs and at the limitation of the practice of drug adulteration and of the trade in spurious drugs that is at present widespread in India.

Pharmacy is a noble profession and has been recognized as such in all the more advanced western countries. There is no reason why the

practice of pharmacy in India should not be brought up to the same high level. The two most important requirements at the present moment appear to us to be, firstly, an improvement of the educational qualifications of those who take up the profession, and, secondly, the enactment of legislation preventing the practice of the profession by unqualified persons.

Pharmacy is an essential public service, and has proved its value beyond dispute. Without an efficient pharmaceutical service, scientific medical practice and honest drug trade and industry cannot prosper. The drug control movement which has been initiated by the Government of India is now making headway and the present seems to be a most suitable time for building up a profession of pharmacy in India with the same educational background and actuated by the same high ideals as exist in other countries. The present situation may be a serious one, but it is not one that cannot be remedied by efficient co-operation of the State and the profession.

Below we are publishing the presidential address of Colonel Chopra delivered before the Third Annual Conference of the Bengal Pharmaceutical Association. In this address, Colonel Chopra has laid stress on the close relationship of the profession of pharmacy with the other

health services in India, and he considers the time most opportune for the enactment of legislation on the lines indicated above, which are broadly speaking those suggested by the Drugs Enquiry Committee of which Colonel Chopra was chairman. As no legislation of this kind should be undertaken by government without the advice and co-operation of those mainly concerned (in this case the pharmaceutical profession), the formation of representative bodies such as the Bengal Pharmaceutical Association is a welcome sign that the profession itself is fully alive to its shortcomings and its needs. It is now the duty of the central and provincial governments to take advantage of this new spirit and to assist them in every way by the introduction of legislation and the extension of training facilities.

ERRATA

In the last issue, in the article LATENT SYPHILIS IN THE TROPICS, by Major S. D. S. Greval and others, the following errors need rectification:—

page 588, column 2, para 3, lines 5 and 6:

for 'not gratification of sexual desires, illicitly', read 'not gratification of illicit sexual desires'.

page 590, column 1, II, 2:

for 'with a M.H.D.', read 'with 3 M.H.D.'

same page, column II, 7:

for 'not left for further detections and tests', read 'not left for further dilutions and tests'.

Medical News

BENGAL PHARMACEUTICAL ASSOCIATION THIRD ANNUAL CONFERENCE. PRESIDENTIAL ADDRESS, 1938

I. PROFESSION OF PHARMACY AND DRUG CONTROL

GENTLEMEN,

I consider it a great honour and a privilege to be here this afternoon to preside over the deliberations of the Third Annual Conference of the Bengal Pharmaceutical Association. Your representatives have once again prevailed upon me to accept the Chairmanship of your Association for the second time in succession. I had fervently hoped that the mantle of this office had fallen on some one with more leisure than I have, and who could more actively associate himself in all matters connected with the furtherance of the aims and objects of this association. Your assurance, however, that this can be achieved by my remaining President for another term, and my deep interest in the profession of pharmacy in India, in its organization, growth and prosperity has persuaded me to accept this signal honour with all the responsibility attached to it. I can assure you that, so far as it lies within my power, I will, with your co-operation and help, do my best to further the interests of this association, which is perhaps the most representative body of the profession of pharmacy in this country.

PHARMACY AND PUBLIC HEALTH

I will start by saying that the profession of pharmacy is an integral part of the noble profession of medicine and in almost all progressive countries in the world it is an important link in the chain of educational programme designed for public service, public welfare and public utility. In these days there are unquestionable signs of national awakening in every department of life in this country, and which department could be of greater importance for sound nation building than the one concerned with public health? No wonder then that in every province of India ways and means are

being devised which will improve the health of the people and provide them with better facilities for prevention and cure of disease. One of the important factors which will contribute largely towards the attainment of this object is an efficient medical and public health service, of which the profession of pharmacy and control of food and drugs form an integral part.

PHARMACY IN INDIA AND THE WORK OF THE ASSOCIATION

Training of pharmacists.—It is a matter of great concern to me that the profession of pharmacy in India is even now not properly organized, and, unless an association such as this makes a genuine effort to devise ways and means to improve the existing state of affairs, there is danger of matters drifting from bad to worse. In an address to this association on a former occasion not long ago, I dwelt on the deplorable state of pharmacy in this country and how this state of affairs could be remedied. I need not therefore dilate on it again. It will suffice here to state that the training of the pharmacists in India is most unsatisfactory and is not commensurate with the duties and responsibilities attached to their calling. Pharmacy is a definitely neglected profession in this country and the advantages accruing from the promotion of pharmaceutical education have not been sufficiently appreciated. If the present needs of the country in the matter of an efficient public health service are to be adequately met and if the tremendous undeveloped drug resources of the country are to be utilized, it is essential that the training of the pharmacists should be improved. Secondly, it is important that a correct conception of the nature of the profession and its functions and importance should be appreciated by the public. For this purpose an active educational propaganda has to be carried out.

It is a matter of great satisfaction to note that this association, during the last two years of its existence, has done very useful work in both these directions. Fully appreciating the fact that improvement in the

standard of basic education and professional training is essential, this association made representations to the State Medical Faculty of Bengal to revise the present curriculum of the so-called compounder's course and bring it more in line with the recommendations made by the Drugs Enquiry Committee. In response to this, a committee was appointed by the Faculty under my chairmanship and I am glad to be able to say that this improved curriculum as originally drafted by the association has been generally accepted by the State Medical Faculty of Bengal and is now awaiting final sanction of the Government. I have every reason to hope that this will be approved. When this new and improved curriculum comes into force, I feel sure that a sound foundation will be laid on which the structure of the profession of pharmacy in India will rapidly rise.

Educational propaganda.—With regard to work of educational propaganda, the association has also achieved signal success. From the very inception of the Bengal Pharmaceutical Association, it was our intention that it should have a journal of its own; financial considerations however stand in the way of attainment of this object. Early this year Mr. Mundy, the managing editor of the *Indian and Eastern Chemist*, very kindly agreed to allow this well-known journal to act as the official organ of our association and through its columns it has been possible to carry out an educational propaganda among the pharmacists as well as among the public.

WIDENED SCOPE OF THE ASSOCIATION

Another important achievement of the association during the last year was the widening of the scope of its activities and inclusion in its fold not only of the pharmacists but all those interested in drugs, their manufacture, storage, handling and distribution. The pharmacists, pharmaceutical chemists, pharmacologists and dealers in drugs are all united under its aegis and all can profitably join hands in developing an ethical drug trade and thereby serving the community. This widening of the scope and activities of the association is a move in the right direction and promises immense possibilities in future. This association is now in a position to formulate ways and means for the improvement of the drug trade and industry on healthier and more ethical lines. It is gratifying to note that a number of firms and individuals representing the drug trade and industry have already joined the association. It is hoped that committees will be formed within the association to chalk out the programme of work in various branches with a view to eliminating, as far as possible, factors which have up till now hindered progress.

II. CONTROL OF DRUGS

The control of drug adulteration is, as you will all agree, an essential part of any public health campaign. Let us for a moment visualize the state of affairs existing in India at the present time with regard to drugs. From all the evidence that is available, both published and unpublished, there is hardly any room for doubt that the market in India is flooded with drugs and chemicals of defective strength and inferior quality. A large number of the most useful and important medicinal drugs on the market in India are often grossly and systematically adulterated to an extent difficult to imagine or believe in a civilized country. In order to satisfy the demand for 'cheap' remedies that would fall within the limited means of the people in general, substitution of genuine medicinal products by rubbish has been resorted to by a number of manufacturers, both indigenous and foreign. Potent remedies such as sera and vaccines, antigens, organic, arsenic and antimony compounds are being freely sold without their quality having ever been tested. The position emphatically is a source of very great danger to the public. Adulteration in other spheres might lead to a mere financial loss, but in the case of medicinal drugs it takes a heavy toll of human life.

I might mention in this connection the enormous growth of trade in quack remedies that has occurred

in India during the last two decades. It is well known that there is at present no law in this country to prevent anyone from compounding any mixture he chooses to make, active or inactive, and selling it as a cure for any disease, backed by testimonials written by himself or by unknown physicians, provided he avoids the drugs scheduled under the Dangerous Drugs Regulations. Anyone can prepare and sell new drugs, without proper preliminary tests, using, as Lord Horder recently described it, the public as his 'guinea-pig'. Deliberately misleading labels and descriptions can be attached to any fancy product without any risk of prosecution for fraud. To add to all these, false and misleading advertisements extolling the virtues of preparations which do not exist and making highly exaggerated claims are daily encountered. In fact, all sorts of trickery and fraud are rampant in the drug market in India. The harmful effects of such nefarious practices to the public are too well known to the practitioner, but I am afraid are not sufficiently appreciated by the public in general. The enormous damage done to the health of the people by such traffic in spurious drugs can be readily appreciated even on a cursory examination.

THE REMEDY

But what can be done to put an end to such a deplorable state of affairs? It must be said to the credit of the medical and pharmaceutical professions that they have been fully alive to the seriousness of the situation which has arisen and have made creditable attempts to put an end to it. It will be recalled that as a result of insistent demand from all quarters, the Government of India in 1930 appointed an *ad hoc* committee—the Drugs Enquiry Committee.

Of this committee, I was appointed the chairman and this gave me the opportunity of carefully investigating the whole question of drug adulteration and spurious drug trade from every point of view. I realized from the very beginning that organization of the profession of pharmacy on proper lines was an essential prerequisite of any scheme for the control and restriction of adulterated and spurious drugs in the Indian market. In the report of the Drugs Enquiry Committee you will find a scheme for putting the profession of pharmacy in this country on a solid foundation. The pharmacists are the persons who directly deal with the drugs. They are, in fact, the custodians of drugs; they are the people who prepare and compound medicinal preparations and on their efficiency depends the purity and effectiveness of the medicaments. If there is no healthy and effective co-operation from this class, no satisfactory solution of the problem of drug adulteration will be found.

LEGISLATION TO CONTROL DRUGS AND PHARMACY

With this idea in view, the Drugs Enquiry Committee suggested the enactment of legislation to control both drugs and pharmacy, either by a combined Drugs and Pharmacy Act, or by a Drugs Act and a Pharmacy Act separately as may be found convenient. If a separate Drugs Act and a separate Pharmacy Act are enacted, these should be passed simultaneously and should operate concurrently. The committee also recommended that the legislation should be *central* embracing the whole of India in its scope. Further progress has, however, been slow since April 1931 when the report of the Drugs Enquiry Committee was submitted to the Government of India, owing no doubt to the very complicated nature of the task. It was therefore a matter of genuine satisfaction to everybody concerned when the Central Government, as a first step in the direction of the much needed drug control, established the nucleus of a Central Drugs Control Laboratory—the Biochemical Standardization Laboratory—at the All-India Institute of Hygiene and Public Health in 1937. Such a laboratory is, of course, essential in order to evolve definite 'norms' or standards for conditions existing in this country, in order of medicinal preparations in the market. This laboratory has now functioned for about a year and a half and has accumulated a large amount of data regarding the

quality of the drugs in use in this country by making a systematic analysis of medicinal preparations from all parts of India, both those manufactured in the country and those imported. Standards are also being worked out suitable for the climatic conditions prevailing here, but the legislation that can enforce such standards has to be enacted before this unit can be of any practical use.

IMPORT OF DRUGS BILL

An imperfect piece of legislation under the name of 'Import of Drugs Bill' was introduced in the Central Legislative Assembly and went to the Select Committee stage in October last, 1937. It would appear from the statement of objects and reasons accompanying the Import of Drugs Bill, that the manufacture, storage and sale of drugs, as also the control of pharmacists and pharmaceutical education, were essentially for provincial governments to deal with, that the Government of India were precluded on technical grounds from undertaking the necessary legislation, covering all aspects of importation, manufacture, storage and sale of drugs without the permission of the provincial governments concerned. Strong protests against this piece-meal legislation were expressed by the representatives of the drug industry all over India as also by the representatives of the pharmaceutical profession. In its issue of 21st March, 1938, the leading daily paper of India, the *Statesman*, in an editorial pronounced the Import of Drugs Bill as 'a very inadequate measure of defence against the evil it aims at overcoming' and remarked that 'what the Government of India is doing cannot be regarded as action as a whole, for the Bill deals only with imports and importers, a limitation that will certainly not put an end to adulteration but will put honest importers at the mercy of the dishonest manufacturers or distributors in this country'. The *Indian Medical Gazette* also made a plea for instituting 'action as a whole', as recommended originally by the Drugs Enquiry Committee. In fact it was clearly felt on all sides that any piece-meal legislation would defeat the object for which Indian public opinion has been agitating for such a long time. It no doubt augurs well for the future of the Indian Drug Industry and all connected with it, that the Select Committee was adjourned *sine die* after expressing the opinion that the proposed legislation is only a half measure and to be of real benefit to the country, it must be substituted by a more comprehensive legislation embracing all-India within its scope on the lines of the recommendations contained in the report of the Drugs Enquiry Committee.

The Central Government had their difficulties, as under the new constitution it cannot undertake such a legislation without the explicit consent of the provinces. Opinions of the provincial governments were, therefore, invited with regard to this important question. It is pleasing to note that most of the provinces have not only agreed to the enactment by the Central Legislature but some are even contemplating passing their own legislative measures to control manufacture and sale of drugs within the area under their jurisdiction. All legal difficulties and the question of jurisdiction between the central and provincial subjects have thus been settled and it may be confidently hoped that there will be no further delay in placing the All-India Drug and Pharmacy Control Legislation on the statute book in the near future. A complete legislation covering both drugs and pharmacy will undoubtedly remedy the crying need of this country in the matter of drug control. A representative body such as yours which is vitally interested in this question should do all that is possible towards the attainment of this object. The Government of India, I feel sure, will be only too glad to give due consideration if you can present your case to them.

BUILDING UP A PROFESSION OF PHARMACY

Lastly, I wish to impress on you, gentlemen, that the changes necessary for the building up of a profession of pharmacy on sound lines cannot be effected at once.

Time, hard work, and patience are needed but there is no reason to be pessimistic. With the aims and objects of the association always before us and with the active co-operation of members drawn from the ranks of manufacturing pharmacists, pharmaceutical chemists and members in active drug trade, we can and should be able to develop a unique organization which will work in unison towards promotion of the interests of ethical drug trade and stand solidly against all sorts of base and nefarious practices such as drug adulteration, price cutting, tampering with quality, etc. It is quite possible for the association to develop a code of ethics and to foster a feeling of good-will amongst all who are directly or indirectly interested in drugs from the academic and scientific point of view and from the point of view of public utility. It is reassuring to see that there is already some evidence of a greater interest being displayed in this direction among all concerned and I may confidently hope that the problems, though difficult, will ultimately be satisfactorily solved. If pharmacy has been able to attain its rightful place in other countries, it is not impossible for it to attain a similar position in India if only you have the will to do it. I have every hope that this association will be able to organize and carry out the important work of up-lift with utmost zeal and energy.

It only remains for me to express my sense of deep appreciation and gratefulness to those who have worked on behalf of the association during the past year. I am particularly indebted to my friend, Prof. B. N. Ghose, who carried on the duties of the President while I was away in England and who has never grudged his co-operation whenever approached. To my former pupil and now my co-worker, Dr. B. Mukerji, the General Secretary, and to Mr. P. Das, the Organizing Secretary, I am grateful for the many ways in which they have served as official representatives of the association and have contributed to the well-being of the association. I know that wherever they have gone they have made friends for us and have clearly demonstrated the advantages to be gained by making these broader contacts. The members of the council have been very helpful, as have also those who have given freely of their valuable time to committee work.

In conclusion, I thank you once again for the great honour you have done me.

R. N. CHOPRA, C.I.E., K.H.P., M.D.,
S.E.D. (Cantab.), F.R.C.P. (Lond.),

BREVET-COLONEL, I.M.S.,
President, Bengal Pharmaceutical Association.

SUMMARY OF TUBERCULOSIS NEWS FOR THE MONTH OF SEPTEMBER 1938

I. *Carlo Forlanini institute scholarship*.—In response to an invitation from the International Union, the King George Thanksgiving (Anti-Tuberculosis) Fund invited applications through the provincial anti-tuberculosis sub-committees and the principals of the medical colleges for the award of six scholarships for the study of tuberculosis at the Carlo Forlanini Institute, Rome. The fund committee approved two candidates for these scholarships, and information has now been received that one of the candidates, Dr. B. S. Ramana, B.Sc., M.B., B.S., officer-in-charge, Anti-Tuberculosis Clinic, Mysore City, has been finally selected by the executive committee of the International Union for a scholarship tenable from 15th November, 1938, to 15th July, 1939.

This is the third occasion on which a nominee from India has been selected for this foreign scholarship, the previous awards having been made in 1933 and 1934.

II. *Medical post-graduate course in tuberculosis*.—The King George Thanksgiving (Anti-Tuberculosis) Fund has decided to hold a medical post-graduate course in tuberculosis at the Mayo Hospital, Lahore, from 14th November to 10th December, 1938. Tuberculosis specialists and medical superintendents of some of the tuberculosis sanatoria in India will deliver

lectures on various aspects of the subject, in addition to practical demonstrations, etc.

III. *Tuberculosis clinic at Arrah.*—A tuberculosis clinic has been started at the local Sadar Hospital, Arrah. A new site for an independent tuberculosis clinic has been selected by the provincial tuberculosis officer. The construction work will start shortly.

IV. *H. E. the Marchioness of Linlithgow's Appeal for the King-Emperor's Anti-Tuberculosis Fund.*—The seventeenth list of subscription to H. E. the Marchioness of Linlithgow's Appeal for the King-Emperor's Anti-Tuberculosis Fund issued by the Honorary Treasurer shows that Rs. 52,51,477-3-9 have actually been received up to 18th August, 1938.

THE TRANSACTIONS OF THE MEDICAL COLLEGE REUNION. NINTH SESSION, 1937-38

THE Annual Reunion of past and present students of Calcutta Medical College is an event of considerable interest to the members of the medical profession in Calcutta. A number of scientific meetings and demonstrations are held during each session, and papers mostly of interest to general practitioners and medical students are read at these meetings. In their *Transactions* the papers read during the ninth session of the Reunion are collected.

The *Transactions* is divided into six sections, viz, general, the sections of medicine, tuberculosis, surgery, and midwifery, and the students' section. The first section contains, besides an introduction dealing briefly with the history of the Calcutta Medical College Reunion, the important speeches on general subjects, delivered during the session. Most of these speeches deal with the problems of medical education—undergraduate and postgraduate—a subject of vital interest to the profession and to educationists, particularly at the present time. The medical curriculum consists nowadays of highly complex and advanced specialities of which little was known thirty years ago. This leaves relatively less time for the students to study the cases in the wards and the out-patients' departments, and to learn everyday surgical and obstetric technique. In the speeches of Major-General P. S. Mills, I.M.S., Surgeon-General with the Government of Bengal, and Lieut.-Colonel T. C. Boyd, I.M.S., are to be found practical suggestions as to what sort of training should be given to the students, so that they may turn into good general practitioners. The first principle of teaching institutions in India should be to turn out good general practitioners, for the general practitioners are the mainstay of the profession and on them the medical relief of the public mostly depends.

Most of the articles published are well written and the subjects chosen are of great interest to the profession. But some of the papers such as those of oscillometry, the nature of toxin, the studies of enzymes, and on the ergot preparations will be appreciated mainly by specialists and research workers on the respective subjects.

It is difficult to choose any paper for special mention, but in the section of medicine, the article on the treatment of malaria, which removes many misconceptions regarding the synthetic anti-malarials, and those on sulphanilamide and on diabetes will be read with great interest by the general practitioners. In the section of tuberculosis, Dr. P. K. Sen draws attention to after-care of the tuberculous patient, an important subject to which sufficient attention has not been paid in this country before.

In the section of surgery the papers dealing with the treatment of empyema in children and on the management of compound fractures are worthy of special mention.

In the section of midwifery, the article on the treatment of anæmia in pregnancy, in which Colonel P. F. Gow has given the records of ten cases in which specific treatment in the form of iron or liver, or both combined, had failed to produce any improvement but the patients responded to repeated blood transfusions, is

important from the point of view of practical obstetrics but of little interest to the hæmatologist.

The format of the *Transactions* is very satisfactory. There are a few printing mistakes but compared with similar publications in India it is particularly free from them. In the students' section a record of academic achievements of the students might have been included as well as the records of activities of the athletic and dramatic sections of the students' club. However, the originators of the idea of publishing the *Transactions* and the scientific sub-committee of the Reunion who carried it through so successfully are to be congratulated on their first effort. It is a high class and instructive publication which students, old and new, of the Medical College and other practitioners will find of great interest and practical value.

THE BRITISH JOURNAL OF RHEUMATISM*

THE cases for and against specialist journals have many times been stated in these columns.

Despite the dangers associated with the segregation of any subject in a specialist journal, a time comes in the life of a branch science when the question of the publication of a journal of its own has to be faced.

The case in favour of this particular journal as presented by the originators is as follows:—

'Rheumatism, although a term incapable of definition, is nevertheless useful in the designation of a group of affections which, although connected with and sometimes changing into each other, yet differ considerably in their respective assemblages of symptoms and methods of treatment.

Its prevalence has long been regarded as a serious menace, not only to industrial efficiency but to the general well-being of the nation. The actual facts regarding the extreme seriousness of its incidence only became known as the result of an enquiry instituted by the Ministry of Health about thirteen years ago.

It is a matter of no small wonder that up to the present no journal devoted entirely to the study of rheumatism in all its aspects has made its appearance. It is, therefore, judged that a wide welcome awaits a paper which, being published in complete independence of any institution or particular viewpoint, can bring all schools of thought together within its covers and present a survey of the progress made in every field of investigation.

The general practitioner wishes to know what the consultant or the man who specialises in rheumatic complaints thinks about this or that question, while the consultant has a great deal to learn from the general practitioner; also the gynaecologist, the dentist, psychiatrist, orthopaedic surgeon, pathologist and radiologist have each a contribution to make to the stock of general knowledge. How can the exchange of ideas on these lines take place in the absence of an adequate medium?

It is to supply this urgent need for a journal to deal with the problems which are cropping up every day that *The British Journal of Rheumatism* is being started.

Contributors will be drawn from those working in every phase of rheumatism in this and other countries, and the editorial staff will be glad to receive original papers, descriptions of clinical cases, and similar material.

It will appear quarterly at first and will contain about half a dozen articles on various aspects of the rheumatic diseases by well-recognized authorities. All writers will be requested to pay special attention to the treatment side of whatever they are dealing with. Each issue will include a leading article. Books will be reviewed and interchange of views by correspondence will be encouraged. The fullest information will be supplied about post-graduate instruction.

* *The British Journal of Rheumatism*. Published quarterly by Messrs. Baillière, Tindall and Cox, 8, Henrietta Street, London, W.C.2. Annual Subscription:—12s. 6d. Post Free. Single copies:—3s. 6d.

From time to time, special numbers dealing with perhaps one branch of the subject will be published; for example, a number might be devoted to gout, another to osteo-arthritis or rheumatoid arthritis, and so on.

It is hoped that all those working in the field of rheumatism will co-operate to help to make *The British Journal of Rheumatism* a useful publication and a worthy representative of British medicine.

Our only criticism of the above case is, Will the average practitioner be able to afford to purchase this journal, only one of a large number of specialist journals all dealing with one or another of the subjects about which 'he wishes to know what the consultant and specialist thinks'?

For the journal itself we have nothing but praise. The first number contains a foreword by Lord Horder and articles by a number of well-known British writers, Sir Leonard Hill, Sir William Willcox, Dr. Leonard Findlay, Dr. A. H. Douthwaite, Dr. C. B. Heald, and many others.

The quality of the articles is what one would expect from physicians and writers of this calibre, and the format of the journal is excellent; one of its great qualities is its lightness.

We can strongly recommend this journal to all those interested in the subject, and wish it the success it deserves.

DIGEST OF TREATMENT*

THE 'digest' habit is very firmly rooted in America. Few apparently have time to read the real thing, and therefore they purchase and read a 'digest'. Medical literature is so voluminous that it is scarcely possible for one man to read even the titles of the articles in journals published in the English language alone, and certainly no one has the leisure to read through one-tenth of such articles. This 'digest' is therefore very welcome.

The idea of the journal is not of course original, but, what is more important, it has been carried through very satisfactorily. The format of the journal is good—it is small and handy but the print is easy to read. The articles are well chosen and the condensation has been carried out judiciously; few articles cover more than three pages but all essential details are given. So far most of the extracts have been taken from British or American journals, but there are a few from German and other foreign journals rendered, of course, into English.

To a practitioner who wishes to extend the scope of his reading we can certainly recommend this journal.

TENTH INTERNATIONAL CONGRESS OF MILITARY MEDICINE AND PHARMACY

THE forthcoming International Congress (10th) of Military Medicine and Pharmacy will be held in Washington from 7th to 15th May, 1939. Invitations to participate have been sent to every country by the President of the United States and already acceptances have been received from several countries. A full scientific and social programme has been arranged and will shortly be mailed to all the countries to which invitations were sent. A large registration is hoped for and every effort will be made by the committee in charge to make the Congress an attractive one to those participating. General Charles R. Reynolds, the Surgeon-General of the United States Army, will be the President of the Congress. Registration is open to all officers of the medical services of the Army, Navy, Air and Colonial services, National Guard, territorial forces and public health service, whether active or reserve. Colonel Harold W. Jones of the Army Medical Corps is Secretary-General. The Secretarial Office is at the Army Medical Library, Washington, D.C.

* *Digest of Treatment*. Published monthly by Messrs. J. B. Lippincott Company, London (16, John Street, Adelphi, W.C.2). Yearly subscriptions:—25s. Post free. Not sold separately.

BOMBAY BIRTH CONTROL CENTRE

THE Secretary, Birth Control Research Committee, Vile Parle, informs us that the number of people who visited and sought advice at the Birth Control Centre, 166A, Vincent Road, Dadar, Bombay, conducted by the Birth Control Research Committee of Vile Parle, during the quarter ending 15th September, 1938, was 605 out of which 393 were males and 212 females. The total number from the beginning was 1,240.

THE INTERNATIONAL PHYSICIAN'S LUNCHEON CLUB

THE International Physicians' Luncheon Club of New York extends a most cordial invitation to physicians visiting New York to be honoured guests at an excellent international luncheon, at the same time offering the services of the members of the Club for any information they may desire.

While guests are not requested to make speeches, any useful information they wish to give informally will be greatly appreciated as fostering medical progress and international goodwill among physicians from all over the world. Luncheon is served at the International Medical Centre, 135, East 55th Street, New York, every Tuesday punctually at 1 o'clock and is over about 2 o'clock.

Physicians are kindly requested to inform the Club of their presence not later than 9 a.m. Tuesday by telephoning Wickersham 2-7900, or writing International Physicians' Luncheon Club, 135, East 55th Street, New York.

TRUSTEE OF THE RANCHI EUROPEAN MENTAL HOSPITAL

THE Surgeon-General with the Government of Bengal has been re-appointed as a trustee of the Ranchi European Mental Hospital, with effect from the 1st September, 1938, representing the Province of Bengal.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following students are declared to have passed the L.T.M. Examination, Session 1938.

Passed

(Arranged in alphabetical order)

Aaron Devasagayam, L.M.F., private practitioner.
Abdur Rahim, L.S.M.F., in charge, Rural Dispensary, District Lyallpur.
Parma Nand Awasthi, L.S.M.F., private practitioner.
Rajendra Nath Barah, L.M.F., private practitioner.
Bhagwan Das, L.S.M.F., private practitioner.
Chaman Lal Bhatnagar, L.C.P.S., private practitioner.
Jagadindra Nath Bhattacharjee, L.M.F., Medical Officer, Gopalpore Tea Estate, Jalpaiguri.
Gopal Chandra Bhowal, L.M.F., Assistant Medical Officer, Sessa Tea Estate Hospital, Dibrugarh.
Kali Charan Chakravarty, L.M.F., Assistant Medical Officer, Paneery Tea Estate, Assam.
Nitya Ranjan Chakravarty, L.M.F., Honorary House Surgeon, S. K. Hospital, Mymensingh.
Sushil Ranjan Choudhury, L.M.F., private practitioner.
Chapala Nath Chowdhury, L.M.F., Honorary Medical Officer, Bogra District Board.
Sudhangsu Kumar Das, L.M.F., private practitioner.
Lila Das Gupta, L.M.F., Honorary Clinical Assistant, Campbell Hospital, Out-Patients' department.
Rihani Ganesh Datta, L.C.P. & S., private practitioner.
Vithal Govind Deshpande, M.B., B.S., Assistant Surgeon, B. B. and C. I. Rly., Ajmer.
Faqir Chand, L.S.M.F., I.M.D., Government of India.
Khawaja Nasir Uddin Ghori, L.S.M.F., S.A.S., Police Hospital, Ajmer.

Sidheswar Gupta, L.M.F., private practitioner.
 Wazir Chand Jolly, L.S.M.F., private practitioner.
 Govind Prasad Kapoor, L.S.M.F., private practitioner.
 Benoy Bhushan Kar, L.M.P., private practitioner.
 Faqir Chand Khandpur, L.S.M.F., private practitioner.
 Jagdish Chandra Kharabanda, L.M.P., private practitioner.
 Prabh Diyal Khatri, L.M.P., private practitioner.
 Satya Pal Khosla, L.M.P., private practitioner.
 Sudhanshu Kumar Kundu, L.M.F., Resident Medical Officer, Katalguri Tea Estate.
 Joginder Singh Lamba, L.S.M.F., private practitioner.
 Nil Kanta Lodhi, L.M.F., Assistant Medical Officer, Patlecheria Tea Estate, Assam.
 Broja Gopal Misra, L.M.F., private practitioner.
 Jatindra Nath Mukherjee, L.M.F., Medical Officer, Jagatnarin Charitable Dispensary, Singur.
 Sukhendu Bikash Nandy, L.M.F., private practitioner.
 Benoy Krishna Nayak, L.M.F., House Surgeon, Burdwan Fraser Hospital.

Kalendri Prasad Nigam, L.S.M.F., private practitioner.
 Moreshwar Govind Pendse, L.M.P., private practitioner.
 Shambhoo Nath Saksena, L.M.P., L.P.H., Medical Officer of Health, Municipal Board, Amroha, District Moradabad.
 Sadashiv Sitaram Sapre, L.M.P., private practitioner.
 Gaupat Narain Saxena, L.S.M.F., private practitioner.
 Baidya Nath Sen Gupta, L.M.F., private practitioner.
 Bhubon Mohon Sen Gupta, L.M.F., Demonstrator of Anatomy, Ronaldshay Medical School and Radiologist, Fraser Hospital, Burdwan.
 Kashi Nath Shukla, L.M.P., Sub-Assistant Medical Officer, Nagpur District.
 Shiva Swarup Varma, L.S.M.F., private practitioner.
 Aileen Beatrice Vining, M.D., L.M.C.C., L.M.S., Medical Officer, Women's and Children's Hospital, Pithapuram.

Treatment of Ulcerative Colitis with Aluminum Hydroxide and Kaolin

By J. B. EYERLY, M.D.

and

H. C. BREUHAUS, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. 109, 17th July, p. 191)

ONE of the oldest remedies brought down to present-day medicine is kaolin (aluminum silicate). It is one of the chief products of the erosion of igneous rock and therefore is a common constituent of many soils and is classified as a silicious earth. Rich deposits of high grade kaolin are found in parts of the United States and also in the Orient, where it is mined chiefly for use in pottery and was used very effectively in the treatment of Asiatic cholera many centuries ago.

Both Walker and Braafldt were impressed by the great usefulness of this product in the treatment of the 1919 epidemic of cholera in China. In giving it both by mouth and by rectum it proved to be one of their most useful aids in bringing about a great decrease in mortality. Walker in discussing the rationale of kaolin concluded that its action was twofold. First, there is a mechanical action, because large numbers of bacilli are enclosed and carried off but are not killed. Second, by adsorption the kaolin takes up toxins. Braafldt also studied the action of kaolin in both normal and pathologic conditions. He concluded that it carries down large numbers of bacteria from fluid mediums if it is kept in motion. The latter consideration is important because kaolin, although it has some colloidal activity, has a tendency to settle out of a liquid medium and thus its large surface area for adsorptive purposes is lost. When kaolin settles out from suspension, a firm, tenacious, claylike mass results (bolus alba) which may lead to serious faecal impaction in the rectum. He also found that various pathologic bacterial toxins were neutralized. He emphasized the proteolytic action of these bacteria and observed that when kaolin is taken by mouth for a period of from ten to thirty days in doses of from 1 to 2 ounces (30 to 60 gm.) a change in flora to an aciduric type may be accomplished. *B. welchii* was practically eliminated from the stools in these experiments. It is interesting to note that Dragstedt found kaolin as useful as a high lactose diet in preventing thyroparathyroidectomized dogs from going into tetany.

Kaolin is a common constituent of many soothing powders, chiefly by virtue of its inert, highly adsorptive property. Hektoen and Rappaport found it useful

in cases of diphtheria, applying the dry powder to the nose and throat at intervals of two hours. They explained its action as a physical one in that practically all pathogenic bacteria were removed in from three to four days. In severe pharyngitis they obtained excellent results by having their patients swallow one-third teaspoonful four or five times per hour during the day.

Aluminum hydroxide is somewhat similar to kaolin but has greater colloidal activity. It settles out of suspension less readily and forms a light viscid gel. Under certain conditions it is capable of acting as either a weak acid or a weak base; this property alone has made it popular in the treatment of peptic ulcer. It also has a moderate astringent action and causes a mild dryness and puckering of the mucous membranes of the mouth when taken orally. Because of the increased colloidal and astringent action, its value as an addition to kaolin readily becomes apparent.

Neuman in 1914 was one of the first to report the use of aluminum hydroxide in bringing about a more rapid line of demarcation and healing in gangrene. He accredited this to its protective power and ability to neutralize acids as well as other toxic products. Zuverkalov and Salomkin found that hog cholera virus might be adsorbed by aluminum hydroxide from blood and urine at a pH of five. By iso-electric precipitation of the protein, the virus could be precipitated but the supernatant fluid also contained the virus. They found the adsorption to be reversible in that the virus could be eluted with phosphate and aminoacetic acid (glycine). Complete adsorption could not be obtained when up to 2 per cent aluminum hydroxide was used.

Clifton reports that staphylococcus bacteriophage can readily be adsorbed by aluminum hydroxide. This too could be eluted by using a secondary ammonium phosphate solution.

Differences in the adsorption of diphtheria toxins by aluminum hydroxide are recognized. Schmidt used purified diphtheria vaccines of the same titre and noted that they were adsorbed in varying degrees by the same amount of aluminum hydroxide. Roughly, the adsorbability of the vaccine was related to the nitrogen content of the salt-free preparation, but different adsorbability was found in samples of similar nitrogen content.

Knowing that there was little doubt about the ability of aluminum hydroxide to adsorb toxins, we were interested in studying its neutralizing effect. When 1.10 minimum lethal doses of a stock diphtheria toxin was mixed with 5 c.c. of a 3 per cent aluminum hydroxide suspension and shaken thoroughly and then injected into a guinea-pig, the animal was sick on the fourth day and recovered. Any larger amount of this

toxin resulted in death of the animal within twenty-four hours. While this apparent protective action may have been due to the slowing of absorption of toxin, it may also have resulted in part from segregation of the toxin by adsorption.

The varying ability of this chemical to adsorb diphtheria toxin may be just as applicable to toxins from other sources and its neutralizing capacity thus also vary. When one deals with a toxin in the alimentary tract the situation is entirely different from that in an enclosed body cavity and, even though the toxin is not neutralized, anything that would adsorb or prevent its absorption by the body until it is eliminated would be beneficial.

It is important that the kaolin and aluminum hydroxide be as chemically pure as possible. Any impurity changes colloidal activity and may lead to disappointing results. Small quantities of alkali cause kaolin suspensions to settle out into a firm mass. On the other hand, alkali affects the mixture of aluminum hydroxide and kaolin in an opposite manner and gives a greater bulk with a firmer gel.

The normal flora of the colon is mildly aciduric, and relatively few of the proteolytic or Gram-positive organisms are seen. When proteolytic organisms preponderate and the normal intestinal action is disturbed, the re-establishment of an aciduric flora is often difficult. It seemed worth while to try aluminum hydroxide and kaolin for this purpose. Braafladt stated that by feeding kaolin alone he could remove the putrefactive organisms and produce an aciduric flora. Neither we nor Swalm were able to produce this change, though the latter was able to establish an acidophilus culture with a mixture of kaolin and aluminum hydroxide. In several feeding experiments on dogs and rats we were never able to reduce the Gram-positive organisms below 20 per cent in rats and 50 per cent in dogs.

Swalm used a kaolin-alumina mixture in treating many gastro-intestinal disorders and found that 86 per cent were definitely improved by addition of this medication to the general therapy. He stressed its local action in the lumen of the stomach and intestine through its mildly astringent and adsorptive properties and believes it to be most useful in hypermotile states.

TOXICITY OF ALUMINUM

Aluminum in minute quantities is found normally in the tissues of animals. There is little evidence that any harm results in the amounts in which it is likely to be consumed. Without question some of the more soluble forms, such as alum or aluminum chloride, are quite toxic and even fatal when taken in large quantities. Underhill and Pterman, using biscuits made with alum baking powder, found that the metal was readily absorbed and excreted in the bile and urine. When given in large doses it is chiefly stored in the liver, spleen, brain and thyroid gland. The same authors injected aluminum chloride and sulphate into rabbits and rats, producing changes similar to lead poisoning.

Seibert and Wells fed large amounts of the various forms of aluminum to rabbits and produced varying degrees of toxic changes in all animals. They concluded:

The strongest evidence, however, that the feeding of aluminum compounds in any form, including that supposed to be so insoluble and inert as aluminum hydroxide, may be harmful lies in the results obtained in the feeding experiments with large single doses of aluminum compounds. Quick responses such as decreases from two to three million in the number of erythrocytes and of as much as 20 per cent in the hæmoglobin were noted in a day or two following the injection of large doses of aluminum in the form of . . . metallic aluminum and the granular, insoluble aluminum hydroxide.

In spite of these results we feel, as others have shown, that small doses of aluminum, especially of such an insoluble form as aluminum hydroxide and kaolin, will result in no harm. Relatively large doses of both

these compounds when fed to dogs by stomach tube over a period of three months produced no untoward results. Aluminum hydroxide has been used for several years in the treatment of peptic ulcer without any evidence of toxicity. In Swalm's sixty-five cases treated with a kaolin-alumina mixture, no harmful results were noted.

To determine the effects of relatively large doses of kaolin and aluminum hydroxide when taken by mouth, two dogs were fed 2 ounces of these substances by stomach tube for six days each week over a period of three months. Dog 1 was a normal appearing male and weighed 26½ pounds at the beginning of the experiment. It was given 2 ounces of kaolin suspension between 10 and 11 each morning for six mornings a week over a period of three months. The diet consisted of a single feeding of scraps given about 12 noon. At no time was there any evidence of ill health, but occasionally a rather firm chalky stool was passed. After twelve weeks the animal had gained one-half pound and was in excellent condition. At this time the dog was killed and a thorough post-mortem examination showed no changes worthy of note.

Dog 2 was a normal appearing adult male and weighed 25 pounds at the beginning of the experiment. It was given 2 ounces of a 3 per cent aluminum hydroxide suspension and managed in the same manner as dog 1. This dog also remained normal in behaviour and appearance during the three months. It lost one-half pound but at all times passed normal stools. At autopsy no change in any tissues or organs was found except two small roundworms in the first part of the ileum.

Histologic examination of the liver, kidney, spleen, brain, heart, lungs, adrenals, stomach, small and large intestines and mesenteric lymph nodes of both these animals showed no changes worthy of note. These were stray dogs and had been in the laboratory only a few days before the experiments were begun. Such animals usually gain a few pounds when confined and put on a diet of scraps. The fact that they practically maintained their original weight is significant. Since no pathologic changes could be found, it seems quite probable that the administration of aluminum hydroxide and kaolin reduced the effectiveness of the digestive juices.

METHOD OF ADMINISTRATION

It has been customary to give kaolin or a mixture of kaolin and aluminum orally. Except for lesions in the upper gastro-intestinal tract, this method has certain limitations. Walker and Braafladt found that a combination of both oral and rectal administration was most effective. When the patient was sufficiently recovered, they gave kaolin only by mouth. Walker realized the possibility that kaolin might also take up the digestive juices and found that rennin would be adsorbed when it was filtered through a kaolin bed. Swalm also considers this factor and advises that such a mixture should not be given by mouth over too long a period of time.

In ulcerative colitis there is a raw ulcerating mucous membrane, and thus to obtain the maximum benefit from kaolin and aluminum hydroxide we give it only by rectal retention. First, the colon is cleansed with a pint of warm water. In one hour this is followed by a retention enema consisting of a 3 to 5 ounce (60 to 150 gm.) mixture of kaolin and aluminum hydroxide in from 3 to 5 ounces (90 to 150 c.c.) of warm distilled water. The patient is instructed to retain this as long as there is no discomfort. Usually one retention a day is sufficient, but occasionally two are given. In this manner, larger doses of the mixture can be brought into direct contact with the inflamed mucous membrane without previous admixture with food and digestive juices.

REPORT OF CASES

Case 1.—A white woman, aged 35, entered the hospital, 16th August, 1934, complaining of intermittent diarrhoea and blood in the stools for six years. There were from four to twenty stools in each twenty-four

hour period. There was no abdominal pain but considerable tenesmus. The patient had lost 65 pounds. The past history was essentially negative except for the usual childhood diseases.

The patient was anæmic and emaciated. The abdominal muscles were relaxed; the descending colon was palpable, firm and sensitive. A soft systolic murmur was heard near the apex; otherwise there were no physical observations of note.

The stools were liquid and contained gross blood, clumps of leukocytes and considerable mucus. No parasites were found in either freshly examined or cultured specimens. A good growth of Gram-positive diplococci was obtained in the blood agar culture.

An Ewald test meal showed 50 points of free hydrochloric acid and 75 points of total acidity.

The proctoscope was inserted without difficulty. The mucous membrane was oedematous, dark red and covered with a dirty gray tenacious exudate which, when removed, uncovered a raw, bleeding surface. No distinct ulcers were seen.

A therapeutic test with carbarsone was given without benefit. Acriflavine 1 : 3,000 irrigations were used each day for some weeks without improvement. A 15 per cent bismuth subgallate suspension in mucilage of acacia as a retention enema was given for three weeks without change. An autogenous vaccine made from the stools was given for six weeks without benefit.

The patient was then given aluminum hydroxide and kaolin retentions once a day. Within two weeks a definite improvement was noted. The retentions were continued for six months, at which time she had gained 40 pounds. The retentions were discontinued and the patient is continuing to pass on an average two normal soft formed stools each day. Proctoscopic and fluoroscopic examinations reveal a normal appearing membrane and the presence of the normal haustral markings.

Case 4.—A white man, aged 66, had been in poor health for some time before entering the hospital, 9th October, 1935, with complete urinary obstruction. An emergency cystotomy was performed. At that time the blood chemistry showed total non-protein nitrogen 97.6, urea nitrogen 66.6, creatinine 3.9. He was given a transfusion of 460 c.c. of whole blood, and twenty days later a suprapubic prostatectomy was performed. At that time the blood chemistry showed total non-protein nitrogen 53.3, urea nitrogen 22.8, creatinine 1.7. The hæmoglobin had increased from 60 per cent to 70 per cent, the red blood cells from 3,110,000 to 3,950,000, and his condition in general was greatly improved.

Three days after the prostatectomy he began to pass frequent liquid stools containing macroscopic blood, clumps of leukocytes and mucus. Methylene blue was injected into the bladder but none was recovered in the stools. On rectal examination there was no opening through the rectal wall. Proctoscopic examination up to the rectosigmoid junction revealed a red oedematous mucous membrane covered with much mucus. The mucous membrane bled readily wherever touched; no distinct ulcerations were seen. Several fresh specimens were examined and cultured on liver serum but no amœbas were found. Culture on blood agar yielded an abundant growth of *Streptococcus viridans*.

The patient was given retentions of aluminum hydroxide and kaolin once a day. After five days the medication was discontinued. The stools were formed and microscopically negative.

Case 6.—A white woman, aged 29, entered the hospital, 22nd January, 1936, complaining of diarrhoea for one year, passing from four to six liquid stools containing gross blood each day. She had considerable abdominal distress.

The past history was negative except for the usual childhood diseases.

Physical examination was essentially normal except that the patient appeared anæmic.

The stools were liquid; they contained gross blood and leukocytes in clumps. Examination of fresh and cultured specimens revealed no parasites. On Endo

and blood agar plates an abundant growth of non-hæmolytic *B. coli* was obtained.

An Ewald test meal showed 25 points of free hydrochloric acid and 55 points of total acidity.

The rectal mucous membrane was oedematous and many shallow ulcers from 1 to 3 mm. in diameter were seen. When the tenacious gray exudate was removed, a raw bleeding surface remained.

A barium sulphate enema showed a decrease both in the diameter of the descending colon and in the haustral markings.

A therapeutic test with carbarsone produced no change. Aluminum hydroxide and kaolin were given. After eight weeks the temperature was normal and a slight tendency to constipation existed. One month later she had gained 12 pounds and was passing one normal stool daily. Retentions were discontinued. Two months later there was a recurrence of diarrhoea. At that time the rectal mucosa was found to be considerably injected but no ulcers were seen. Retentions were resumed for six weeks. At present the patient passes one or two formed stools without gross blood each day. The appetite is excellent, a gain in weight is resulting and the condition in general is greatly improved.

COMMENT

In a review of these cases it is noted that the therapy employed is not unlike the various methods generally found useful in treating ulcerative colitis.

The diet must be of high caloric, non-irritating type and contain all vitamins necessary for normal health. Opium in some form is frequently used in the early stages if pain and excessive diarrhoea are present. A consistent programme carried out intelligently is essential if such cases are to be cured.

CONCLUSIONS

Investigation by others and our clinical study support the belief that the treatment of ulcerative colitis by aluminum hydroxide and kaolin mixture is rational.

The adsorption of bacteria and their products reduces irritation and decreases the absorption of toxins.

The astringent action lessens absorption and the transudate from the inflamed surfaces is diminished.

It is not toxic.

There is no admixture with food and digestive juices.

A neutral reaction in the lumen of the bowel is preserved.

No bolus nor impaction formation occurs with moderate care.

Modern Concepts of Diabetes and its Treatment

By E. M. WATSON, M.D., M.Sc. (West. Ont.),
F.R.C.P. (Edin.)

(Abstracted from the *Medical Press and Circular*,
Vol. CXCVI, 12th January, 1938, p. 28)

INTRODUCTION

THE developments of the past fifteen years have created an entirely new conception of diabetes mellitus and its treatment. Diabetes promises to become one of the major social and economic problems in the future. This prediction is based mainly upon the established hereditary nature of the disease. The following statement was recently made referring to the United States of America: 'In all probability one fourth of the population are carriers of the tendency to diabetes which they may transmit to their own offspring. We have no way at present of selecting those destined to become the diabetics of to-morrow and the next year'.

THE NATURE OF DIABETES

While diabetes presents a challenge to preventive medicine, the nature of the disease introduces an obstacle in the path of efforts towards its eradication.

In common with many chronic non-specific diseases, diabetes is not the result of a single etiological factor. Most cases of the disorder arise from the combined effects of two influences: (1) a predisposing cause, and (2) an activating or exciting cause.

The exciting cause of diabetes is often obvious, and includes such factors as infections, arteriosclerosis, obesity, emotional strain, trauma, thyrotoxicosis, and altered function of the pituitary gland. The evidence in favour of the inheritable potentialities of diabetes is incontestable. Indeed, diabetes may be regarded essentially as an hereditary tendency which is subject to activation by various precipitating factors of exogenous or endogenous origin.

THE DIAGNOSIS OF DIABETES

The diagnosis of diabetes is either very easy or very difficult. The disease is discovered almost as frequently by accident during the course of a routine medical examination as through the recognition of the typical diabetic symptoms. The most common sign of diabetes is glycosuria, but the discovery of diabetes does not necessarily constitute a diagnosis of diabetes. In association with certain characteristic clinical manifestations and especially when accompanied by ketonuria, glycosuria is pathognomonic.

In evaluating the significance of glycosuria, especially the symptomless variety, one must bear in mind that of which allow glycosuria to appear at times in the absence of an elevated blood sugar, and prevent glycosuria, at other times, in the presence of hyperglycaemia. A knowledge of the blood sugar concentration, therefore, is imperative for a proper investigation of the carbohydrate metabolism. As a working rule, the finding of a blood sugar of 140 mgm. per cent or higher in the fasting state, or 170 mgm. or more two to three hours after a meal, particularly breakfast, is diagnostic of diabetes. But a person may be a diabetic even although his blood sugar values fall below these figures.

The sugar tolerance test is a valuable aid in the detection of cases of early or mild derangements of carbohydrate metabolism and in differentiating the so-called innocent glycosurias from true diabetes. Two types of innocent glycosuria deserve mention, namely, renal glycosuria and 'lag' glycosuria.

Renal glycosuria.—Following the ingestion of 50 or 100 grams of dextrose, the individual with renal glycosuria presents a normal blood sugar curve, that is to say, the maximum elevation of the blood sugar is not beyond 170 mgm. per cent, and it has returned to the normal fasting level in two hours. The only abnormality is the coincidental occurrence of the blood sugar in the urine in detectable amounts unless the renal threshold for glucose is exceeded. Ordinarily, glucose does not escape from the blood into the urine in detectable amounts unless the renal threshold or leak point for glucose is exceeded. Normally, the renal threshold lies somewhere between 160 and 180 mgm. per cent of blood sugar, probably nearer 180 than 160. In persons with renal glycosuria, it is presumed to be below this level.

The blood sugar curves must be interpreted with caution, and all factors, especially a positive family history of diabetes, must receive due consideration. Renal glycosuria, like true diabetes, can occur in several members of a family.

'Lag' glycosuria.—The so-called 'lag' type of blood sugar curve is characterized by a sudden steeple-like rise of the blood sugar to an abnormal height, followed by an equally sudden decline to the normal fasting level again within two hours. Because the renal threshold is exceeded, there is a transient glycosuria. This type of response to the sugar tolerance test was described originally by Maclean, who applied the term 'lag' in connection therewith on the assumption that there was a lag or delay on the part of the liver in exerting its glycogenic function. Individuals so affected were thought to require a higher concentration of sugar in their blood than was usual to stimulate the glycogenic process but, when once started, this function was

adequate. Since the phenomenon is exhibited frequently by individuals whose stomachs empty rapidly it would seem that the rapid and excessive absorption of sugar from the intestine is an explanation for its occurrence.

While 'lag' glycosuria is usually considered to be a harmless anomaly, it should, perhaps, be regarded with suspicion.

IMPROVEMENTS OF TREATMENT

The general popularity of the higher carbohydrate diets for diabetics speaks for the efficacy of this form of treatment. Likewise, the therapeutic applications of standard insulin are too well known to merit special comment. The outstanding recent advance with regard to diabetes is the introduction of compounds of insulin which, after their subcutaneous injection, exert a prolonged and stabilizing effect upon the blood sugar, in contrast to the unmodified insulin, the action of which is quick, powerful, and evanescent.

Protamine insulin.—Protamine insulin was developed by Hagedorn and his associates in Denmark. It consisted of standard insulin mixed with a protamine prepared from the sperm of a fish and buffered to a reaction of pH 7.3. The compound was found to be relatively insoluble, painless on injection, and not followed by protein shock. The protamine-insulin combination disintegrated slowly in the subcutaneous tissues and the insulin was liberated and taken up by the blood stream gradually over a period of many hours.

It was evident from the numerous published reports of the clinical application of protamine insulin that it was in many instances a valuable adjunct to existing methods of treatment. In spite of the advantages claimed for the original protamine insulin, it had certain shortcomings, and it has been supplanted by a more effective preparation, namely, zinc protamine insulin.

Zinc protamine insulin.—Apparently zinc is intimately concerned with the metabolism of carbohydrates. It had been shown that the action of insulin and protamine insulin was augmented by the addition of small amounts of zinc. It is now generally agreed that zinc protamine insulin has a more prolonged effect upon the blood sugar than the original protamine insulin and it has the added advantage of being supplied in a form ready for use, without the necessity of preliminary mixture with the buffer solution. The administration of a single injection of zinc protamine insulin causes a gradual reduction of the blood sugar, the lowest point being reached 12 to 24 hours after the injection. One noticeable result of the use of this new insulin is that diabetics are permitted to start their days with a normal or low fasting blood sugar concentration, a status which was difficult to attain with the former available methods of treatment.

The principal advantage of zinc protamine insulin, however, is that it permits, in many instances, the reduction of the number of injections of insulin which are necessary to maintain optimum control of the diabetes. In this respect it is no less a relief to the parents of juvenile diabetics who had to accustom themselves, oftentimes, to the injection of a dose of insulin in the middle of the night and who lived in more or less constant fear of nocturnal reactions.

The chief differences between standard insulin and zinc protamine insulin are that standard insulin acts quickly and zinc protamine insulin acts slowly. Standard insulin is not cumulative in its effect, while zinc protamine insulin exhibits cumulative properties. These guiding physiological principles should govern the usage of the two products and their relative merits must be considered carefully before changing a patient from standard insulin to zinc protamine insulin, or before starting a new case on insulin therapy. If a diabetic is being controlled satisfactorily on one or perhaps two injections of standard insulin a day and his routine is established, there may be no good reason to switch to the new insulin. On the other

hand, the individual whose diabetes demands three or four injections of standard insulin every 24 hours has every reason to be hopeful regarding the benefits to be derived from zinc insulin.

There are no certain rules to guide one in the use of zinc protamine insulin. Many mild or moderately severe diabetics can be controlled satisfactorily with but a single injection of the substance each morning immediately before breakfast. Others with more severe grades of diabetes require supplementary injections of the quicker-acting standard insulin to accomplish the desired regulation of the blood sugar.

The zinc protamine insulin, on account of its slow mobilization in the blood stream, is often not adequate for the immediate metabolism of the carbohydrate introduced with the meals, consequently rather marked rises of the blood sugar are apt to occur. This post-prandial hyperglycemia is especially prone to develop after breakfast. The control of such undesirable fluctuations of the blood sugar may be accomplished by modifying the diet in a way that the carbohydrate value of the breakfast is reduced and that of the other meals increased accordingly. The metabolic strain may be minimized by multiple meals whereby the daily carbohydrate allowance is divided into six or seven small feedings. This is, however, a rather bothersome procedure.

A more satisfactory method is by some combination of zinc protamine insulin and standard insulin. These two types of insulin can be given together mixed in the one syringe in the morning, the standard insulin taking care of the immediate requirements until the zinc protamine insulin begins to act. This is an effective means of combining the two insulins and it is more agreeable than the giving of two separate injections at the one time. Another practice which has been found to be satisfactory in several cases is to give doses of from 10 to 30 units of protamine zinc insulin at noon, with a small dose of standard insulin in the morning and possibly in the evening as well.

Experience has shown that besides reducing the number of injections, the use of zinc protamine insulin has permitted, in many instances, a reduction of the total number of units of insulin necessary for adequate control of the diabetes.

Probably the only definite contra-indication for the employment of zinc protamine insulin is diabetic coma and clinical acidosis, but it may be used to advantage even under these circumstances, in conjunction with standard insulin, to prevent a relapse of the ketosis.

Zinc protamine insulin is not as consistent in its effects as standard insulin. Individuals with severe diabetes treated with zinc protamine insulin frequently have recurrences of the glycosuria for no apparent reason. This may be due to differences in the dispersion of the injections and differences in the vascularity of the tissues. Muscular activity also plays an important part in the regularity of the control of the blood sugar.

A change from standard insulin to zinc protamine insulin should be undertaken gradually in order to avoid the temporary relapse of the diabetes which may occur during the period of readjustment; also, to avoid reactions due to the cumulative action of the protamine insulin. It is advisable, in the light of our present knowledge, to refer the patient to a hospital for the therapeutic transition in order that proper chemical control of the situation may obtain.

In an attempt to transfer a patient from multiple doses of the old insulin to the new zinc protamine insulin, the plan suggested is to discontinue the noon and midnight doses of the old insulin and to give one-half of the total daily insulin requirement in the form of zinc protamine insulin in the morning, together with one-half of the previous morning dose of standard insulin. Also, give in the evening one-half the quantity of standard insulin which had been used formerly at this time. Subsequent adjustments can be made, according to the results of the blood and urine tests over a period of several days, in order to determine the optimum dosage of zinc protamine insulin alone,

or in combination with standard insulin, which most nearly satisfies the requirements of the individual patient.

Insulin reactions.—It is true that insulin reactions are not experienced as frequently with the new insulin as with the old insulin. But the hypoglycemic reactions which do occur as a result of the new insulin are of a severe grade and they differ in certain respects from those with which we had become familiar while prescribing only the standard insulin. The reactions caused by protamine insulin are more subtle in their development and they may occur unexpectedly, with little or no warning. The subjective symptoms are less marked and the skin will likely be dry, in contrast to the profuse perspiration which accompanies the hypoglycemia occasioned by standard insulin. Lower blood sugar levels are observed in the hypoglycemia caused by protamine insulin than in that brought about by standard insulin. We have noted the blood sugar to drop as low as 29 mgm. per cent before hypoglycemic symptoms became manifest. The gradual decline of the blood sugar permits the compensating mechanisms to operate, until finally, when an extremely low blood sugar level is reached, alarming symptoms, even convulsions, may suddenly supervene. Vomiting may occur. The reactions caused by protamine insulin are more intractable than those caused by standard insulin, and there is a tendency to relapses of the hypoglycemia following the treatment of a reaction. A common time for hypoglycemia to develop in patients who are receiving zinc protamine insulin is during the early hours of the morning.

Exercise.—Physical exercise is a recognized form of therapy in diabetes, acting in conjunction with diet and insulin. Exercise causes a reduction of the blood sugar in the patient with severe or moderately severe diabetes only if there is a sufficient amount of insulin available in the body at the time of the exercise. As mentioned by others a patient receiving an adequate amount of protamine insulin always has some insulin available in the body. It is to be expected, therefore, that exercise should exert a notable blood-sugar-lowering effect in persons who are treated with this preparation.

Physical activity, therefore, is a factor of greater practical importance with the use of the new insulin than it is with the old insulin. If variations of a patient's activities occur with any regularity and can be predicted, modifications of the treatment, as by varying the insulin dosages or the amount of carbohydrate in the meals, can be instituted to suit the circumstances, and thus prevent hypoglycemic reactions.

We do not know yet how to use zinc protamine insulin to its best advantage. Therefore, its true rôle in the treatment of diabetes cannot be stated with certainty at present.

Crystalline insulin.—Recently, a crystalline form of insulin exhibiting physiological properties rather similar to those of protamine insulin has been developed in America and studied clinically by various workers. This product is still under investigation and is not on the market.

THE MAJOR COMPLICATIONS OF DIABETES

The improvements of treatment have brought about great changes in the character of the complications of diabetes.

Diabetic coma.—Coma, which was the principal cause of death before the introduction of insulin, rarely occurs to-day, but when it does develop, still all too frequently, it is hardly ever fatal. Death from diabetic coma is as inexcusable as death from diphtheria.

The diabetic is not adequately treated unless he and his relatives are taught how to avoid coma. Therefore, the development of coma in a known diabetic, except in rare instances, is a reflection upon the individual's integrity or judgment, or upon the accomplishments of the physician. Coma may be the first manifestation of diabetes. In any case, one has

to deal with an extremely ill patient, in fact a medical emergency, and the only fair course is to have the patient removed to a hospital with all possible speed. The time intervening between the onset of the acute symptoms and the institution of treatment is most important. For every hour that the state of ketosis exists untreated, the more remote become the chances for final recovery.

The salient features of severe diabetic coma are: dehydration, ketosis, hyperglycemia, abdominal pain, vomiting, subnormal temperature, rapid pulse, feeble heart action, oliguria (or anuria), increased non-protein nitrogen of the blood and hypochloræmia.

Any plan of treatment must have as its immediate objectives, therefore, the restoration of fluids and electrolytes to the body, the rapid utilization of glucose, the re-establishment of renal function, support to the circulation, correction of the gastric malfunction, and counteraction of the shock factor.

The first step in the management of a coma case is the verification of the diagnosis of diabetic coma. As soon as this is clear, proceed at once with the administration of insulin and fluids, which are the most important items in the treatment.

Outline of treatment of diabetic coma:

1. *Insulin*:
(a) 20 units intravenously and 20 units subcutaneously.

(b) 20 units subcutaneously every half-hour until there is clinical and chemical evidence of improvement. The best guide regarding the size and frequency of the insulin dosages in diabetic coma consists of repeated blood sugar estimations.

If circumstances demand that urine specimens only must be relied upon, these should be collected at intervals of one or two hours and the rule is to give: 20 units of insulin for a red or orange test with Benedict's solution;

15 units for a yellow test;
10 units for a yellow-green test; and
No insulin for a green or blue test.

(c) Zinc protamine insulin—in view of the urgency of the situation, standard insulin should be relied on in the treatment of diabetic coma, but 50 to 100 units of the zinc protamine variety may be injected for remote effect to prevent a relapse.

2. *Fluids*—by mouth (if possible), subcutaneously, or intravenously. 1,000 to 1,500 c.c. of normal saline interstitially in the axillary spaces, repeated in a few hours if necessary. Water, clear broth (with salt), ginger ale, tea, and coffee may be offered by mouth.

3. *Gastric lavage*—for vomiting and nausea, unless the patient is in extremis, is often quite effective.

4. *Cleansing enema*.

5. *Circulatory stimulants*—a low blood pressure is a bad prognostic sign—adrenalin, strophanthin, coramine, caffeine, digitalis, blood transfusion.

6. *Hypertonic salt solution for anuria*—50 to 130 c.c. of 10 per cent salt solution may be administered intravenously.

7. *Food*—the utilization of carbohydrate by the patient is imperative to prevent the persistence or the recurrence of the ketosis. The carbohydrate must be presented in a concentrated, readily utilizable form, e.g.

(a) Glucose—not necessary in the early stages of anti-coma treatment, but should be given when the blood sugar begins to decline: (i) intravenously if necessary, 300 to 500 c.c. of 10 per cent solution, (ii) in amounts of 5 to 15 grams at intervals in orange juice by mouth if the stomach is retentive. An intake of 100 grams of glucose should be provided during first 24 hours.

(b) Resumption or establishment of diet as soon as possible; avoid by all means starvation, particularly carbohydrate starvation. Soft, bland nutrients such as gruel, junket, milk, eggs, bread, pureed vegetables, etc., can usually be started within the first 48 hours.

If the patient fails to respond to the treatment in the expected manner, re-check for possible undetected complications or associated conditions.

Cardiovascular degeneration.—Arteriosclerosis, and all its sequelæ, is the complication *par excellence* of the diabetes of the present day. Some statistics, collected recently by Joslin, indicate that the development of arteriosclerosis in diabetics is being deferred. Nevertheless, fact remains that arteriosclerosis, whether generalized or localized in the heart, the legs, or the brain, accounts for the majority of deaths among diabetics to-day.

SURGICAL OPERATIONS ON DIABETICS

Every effort should be expended to permit as little disturbance of the metabolism as possible for the surgical diabetic. In order to prevent post-operative ketosis, carbohydrate starvation must be avoided. Our practice is, except in emergencies, to give the glucose equivalent of the breakfast in conformity with the prescribed diet, preceded by the usual dose of insulin, as early as possible on the day of the operation.

Immediately following the return of the patient from the operating theatre, a sample of blood is withdrawn and the blood sugar concentration is determined at once. According to the result, insulin is or is not given. If the blood sugar be in the neighbourhood of 200 mgm. per cent, 10 units of standard insulin are injected, if it be 300 mgm., 20 units are given.

As soon as it is permissible post-operatively, the patient is encouraged to drink fluids freely. If this is not practical for any reason and especially if vomiting is troublesome, the fluid must be administered parenterally. For the first 24 to 48 hours after an operation the meals are replaced by their glucose equivalent and insulin is injected according to the requirements.

The only cases of post-operative diabetic coma which I have known were those in which the surgical programme was followed out without attention to the diabetes.

A meagre experience indicates that diabetics who are prepared with zinc protamine insulin withstand surgical intervention even better than those treated with standard insulin. At any rate, the cases which have been observed so far did not exhibit a post-operative hyperglycemia or ketonuria sufficiently marked to require the injection of the rapidly-acting standard insulin. No doubt the persistent supply of insulin within the body stabilized the blood sugar to a much more pronounced extent than we had been accustomed to observe with the standard insulin.

Sciatica and its Treatment, with Especial Reference to Epidural Injection

By GERALD SLOT, M.D., M.R.C.P., D.P.H.

(Abstracted from the *Medical Press and Circular*, Vol. CXCVI, 5th January, 1938, p 15)

Ætiology

THE ætiology of sciatica is by no means well defined. The usual causes of the diseases are allied to those which are often associated with rheumatism, viz, focal sepsis, cold, damp, trauma and muscular strain. It is true, however, that there are many cases in which none of these antecedents can be identified, and there are, too, a large number of cases in which the focal sepsis has been removed and yet no amelioration has occurred in the condition. Trauma must play a part, and I am inclined to regard spondylolisthesis as being at times responsible. That this is a factor in some cases is undoubtedly true, and accounts for the cures that have at times been effected by osteopaths in manipulating the spine. Whether this displacement occurs by traction or direct irritation, is difficult to say. The features of cases in which this has occurred are high tenderness, that is, tenderness over the lumbosacral spine and the upper part of the gluteal region. The middle part of the leg and the thigh often seem

to be immune, while the pain is referred to the foot. A convenient classification is that proposed by Professor Roger, *viz*, (1) para-sciatica, referable to an irritative contraction of the roots, *viz*, that part of the root which runs from the dura mater sheath to the plexus, the plexus trunk and branches. Para-sciatica includes the rare symptoms associated with tabes, herpes and syphilitic meningitis. (2) The second group is the symptomatic sciatica connected with infection, and in this group we have had cases in which gonorrhœa, alcohol, gout, and growths, either of the nerve or spinal cord, have given rise to the sciatic syndrome. Injuries such as those caused by falls and blows and direct injury following injections have also been associated with these symptoms. (3) In the third group we have the rheumatic sciaticas, and these can be ætiologically divided into the funicular or high sciatica, sciatica of the sacro-iliac type; here it is the plexus which is chiefly involved; and, lastly, low or neuro-sciatica, where the pain is largely in the leg or foot, and may be confined to the branch of the nerve only. In addition to these findings, there is also sciatica which resembles fibrositis. The important point is the recognition of the causation in sciatica, *viz*, the vertebral element. This factor was further emphasized by Goldthwait, who insisted on the importance of the vertebral and pelvic joints in the ætiology of sciatica, and drew attention to this form of sciatic neuralgia which follows sacralization of the fifth lumbar vertebra, due to the fact that the fifth root of the lumbosacral plexus runs between the lumbar and first sacral vertebra in the intervertebral foramen. This root is one of the chief constituents of the sciatic nerve. Rheumatic sciaticas are by far the commonest in my series, and of all the rheumatic sciaticas the lumbo- or high sciatica is the most frequent. These are very frequently associated with an arthritis of the lumbar vertebrae, or of the sacro-iliac joint, and it is only when the x-ray is taken that a disease which may not previously have been suspected is revealed. In the high sciatica the onset is sudden; Lasegue's sign or stretching of the leg does not increase it. The peroneal femoral reflex is usually absent. In the middle sciatica the ankle jerk remains, while hypotonia and atrophy of the gluteal muscles are common. In low sciatica the pain rises above the buttocks; the ankle jerks and malleolar reflexes are frequently absent, and the knee jerks are usually present.

Other causes which produce pain are a sacralization of the fifth transverse processes, spina bifida occulta. Extrusion of the intervertebral disc into the spinal cord with compression of the spinal cord and nerve roots caused by any abnormal strain or stress will also set up severe sciatic pain. This condition is extremely difficult to diagnose as the protrusion may occur at any level of the movable part of the spinal column: in the cervical, thoracic, or lumbar regions. Frequently in these cases the neurological examination is negative and an ordinary x-ray may only show narrowing of the intervertebral space. The only sure diagnostic measures are fluoroscopic and x-ray examinations, after injection of lipiodol into the subarachnoid space, the reversed Queckenstedt test, performed as an epidural injection, is really the best means for diagnosing this condition. In ordinary sciatica the pain is at first exaggerated by the injection, and then, as the anæsthetic spreads, the pain becomes relieved; but where extrusion of the intervertebral disc is present the pain becomes unbearable, and the injection has to be stopped. In such cases surgical intervention in the form of laminectomy is the only satisfactory procedure. The diagnosis of the presence of a protruding disc is not easy; the condition is usually to be suspected in patients who have pain that follows the distribution of one or more spinal nerve roots for a considerable time, and who have not been benefited by the usual conservative forms of treatment. An examination of the cerebrospinal fluid by lumbar puncture reveals a total protein content of more than 40 mg., and there is a positive reaction to the test for globulin. At times these tests may be negative, and

the reversed Queckenstedt test gives the real and only clue to the cause of the trouble. For the radiological examination, 5 c.cm. of radio-opaque oil is injected into the subarachnoid space in the lumbar region, and the excursion of the oil is studied on a tilting fluoroscopic table while the patient is in the prone, supine, lateral and oblique positions. As the protruded fragment of the disc is extradural, it pushes against the column of the radio-opaque oil on the vertebral surface, and indents or displaces it posteriorly and sometimes laterally. Complete obstruction of the oil is observed in large protrusions. A protruded disc frequently emerges through the posterior spinal ligament, after which it usually extends on one or both sides of the medial lines and presses on one or both contiguous roots, with a resulting deformity of the oil shadow. The most valuable views for demonstration of these lesions are the antero-posterior and oblique. A complete study of the passage through the entire spinal canal should be made, as more than one lesion may exist. Tumour of the cord may also be present.

In the majority of cases in our series, now well over 200, true sciatica seems to be rare, and most of them fall into the group which one would prefer to call 'the sciatic syndrome'. The pain frequently starts with a severe stab in the back, which is of a violent character, is usually one-sided, especially over the region of the buttocks and the posterior aspect of the thigh, and very often runs down the leg and into the feet. The pain is of a varying character, sometimes dull and aching, and at other times associated with sharp bouts. In objective examination various methods have been adopted: one is the detection of certain local points of tenderness, such as the external malleolus, or the external plantar nerve, and others which have been described by various writers. These points are, however, too varied and too inconsistent to be of value in diagnosis. Another method is to see whether pain occurs on stretching of the nerve, giving rise to the familiar Lasegue sign, in which an attempt is made to straighten the leg on the thigh while the patient is lying in the dorsal position; association of abduction with this movement usually increases the pain. In many of our cases, too, there has been some well-marked scoliosis and it has not always been easy to ascertain whether this has come after the disease or simultaneously with it. Sweating on one side and wasting of either the thigh or leg muscles are also frequent symptoms. Apart from this, physical examination helps little. The reflexes are variable, though usually diminished and sometimes absent. Lumbar puncture reveals no change in the cerebrospinal fluid. We have attempted to classify these cases according to their symptomatology in high and low, according to whether the pain is situated more in the calf or more in the upper thigh or back, but this has not been easy because so often the pain merges one into the other.

In group 2 we find the 'sciatic syndrome'. In these cases an x-ray examination may show osteoarthritis of the spine, sacro-iliac joint or hip. More detailed examination will reveal occasionally an enlarged prostate or malignant disease of the sacrum or rectum; while where bilateral sciatica is present the possibility of tabes dorsalis should always be taken into account. Tuberculosis of the sacro-iliac joint has been present in one of our cases, and afforded the clue to a particularly intractable pain.

THERAPEUTICS

Many of the cases in our series had had the usual treatments for sciatica, that is to say, eradication of the septic focus, massage, diathermy, and the more modern short-wave diathermy, various proceedings such as stretching of the nerve, acupuncture, and the usual analgesic drugs, such as aspirin and its various derivatives; and it was only when these had failed that the method we use has been tried. This is founded upon the fact that has been observed, that many cases of sciatica are associated with disease of the sacro-iliac joint. This can be proved in some cases

by radiological examination, while in other cases radiology shows little change, although the symptoms suggest irritation from this focus; these are: pain on jerking of the spine, tenderness over the sacro-iliac joint, tenderness on rotation. In addition to this, there is the well-established therapeutic knowledge that the stretching of the sciatic nerve in some cases relieves the pain, but not in all. The cases where the pain has not always been relieved have been those in which some scoliosis has been present.

The treatment we have used has been a combination of epidural injection and manipulation under evipan anaesthesia. The advantages claimed by this method are the rapidity of treatment, the simplicity of the technique, and the high percentage of cures obtained in comparison to other methods. The two principles of the treatment are: (1) the stretching of the nerve roots by the harmless fluid, and (2) manipulation. The patient is prepared as follows: He enters hospital either the night before or the same morning, a complete examination, including x-rays, having previously been made. First, everything must be prepared; this includes 100 c.c. of 1 per cent novocaine in sterile normal saline, a lumbar puncture needle, an infiltration syringe which fits the lumbar puncture needle closely (the type I now use is made by Messrs. Vann), evipan, and a syringe for administering this. It is convenient to have the patient lying in the left lateral position. The evipan is given by an assistant, 5-8 c.c. are usually required. Prior to administering the evipan the sacro-coccygeal foramen is identified; this can be done by running the finger down the two sides of the sacral crest, and feeling a depression bounded on the two sides by the tubercles of the sacrum. This can also be identified by running the finger up the coccyx. The needle has first to be introduced at an angle of about 70° to the skin; to enter the canal the direction has to be changed to an angle of about 20° to the sagittal plane. One can feel when the needle is in the right place; 50 to 100 c.c. of warm sterile novocaine are now slowly injected—the dose varies with the size of the patient. As the fluid goes in the resistance is found to increase; the needle is then withdrawn and the puncture sealed with an 'Elastoplast' dressing. Manipulation is now performed. This consists first in the hyperextension of the lumbar spine; the knee is placed in the hollow of the back and both legs firmly and gently pulled against it. The patient is then turned round and the knees straightened, and both legs, one after the other, are forced on the pelvis (the pelvis being fixed by an assistant) so as to stretch the sciatic nerve. It is wise to have the patient in position before the evipan, as this avoids a certain amount of moving about. On recovery, some veganin is prescribed, or, where there is severe pain, omnopon, and it is wise to have some massage the next day. A Transcutan bath is also helpful. In the majority of our cases this has been all that has been necessary, but in 20 per cent of them one treatment has not been sufficient, and a second injection has been required. The majority of the series of over 200 cases have been intractable cases which have resisted the usual methods of treatment.

In cases of osteoarthritis of the hip, of course, the manipulation is practically reduced to a minimum, although I am convinced by experience in many cases of the intractable trouble that a slight manipulation acting with the epidural injection has been most helpful to the patient. This does not apply, of course, to the cases where there has been bony ankylosis. We have been persuaded to do this in osteoarthritis because of their intractable nature, and because of the similarity of their symptoms to some cases of sciatica. While, of course, no cure can be promised in this condition, patients have frequently been very pleased with the great alleviation of pain which has resulted and the treatment can, if necessary, be repeated in six months' time. The average stay in hospital has been one day. Other methods of treatment have been:

(1) *Operative measures*.—Resection of the ilio-tibial band. This operation was described by Ober,

but the indications for it are by no means clear. An important diagnostic sign is alleged to be as follows: The patient is placed on one side, the examiner places one hand on the pelvis and grasps the patient's ankle lightly with the other, holding the knee flexed at a right angle. The thigh is abducted and extended to the coronal plane of the body. If contracture is present, the leg still remains abducted.

(2) *Pre-sacral injection* for sciatica has been described by Pendl at the Surgical Congress. Anaesthesia is obtained by pre-sacral injection in the knee-elbow position, about 2 cm. along and right on the tip of the coccyx, parallel to the medial plane and directly in the anterior surface of the coccyx and os sacrum, up to the bone of the sacrum. I have no experience of this method.

The subarachnoid injection of alcohol has been advised for the relief of some of those intractable cases of pain; this seems to be a measure fraught with some risk of permanent nerve damage, and although relief at times is obtained, I have felt that the dangers involved have not justified its use. Where, however, the pain is due to malignant changes in the vertebral column, and other methods have failed, this might be considered. Lipiodol injections have been given epidurally, but I have not seen any advantage of this over the saline therapy.

(3) *Electrotherapeutics*.—Many cases have been treated by this method. Salicylic ionization has been widely used, and at times has been followed by relief of pain, but this method should not be used in the acute stage, or when the skin is inflamed. Dielectrolysis has been described as a successful treatment but the treatment seems to be inadequate, and by no means easy to carry out. Deep x-ray therapy has been used, and a fifth of the cases were cured and a fifth improved. The early cases reacted more quickly, but then it is well recognized that early cases of sciatica frequently get well of their own accord.

(4) *Spa treatment*.—The usual spa measures used are: (a) hot sulphur water in the form of the swimming bath; (b) under-water douches, the patient lying in a bath full of mineral water for five minutes; (c) the Aix douche, massage carried out under a stream of water by two attendants. Large jets are applied by a hose which the attendant holds high on his shoulder and applies to the lower limbs of the patient; (d) the general Aix douche, which consists of a needle spray in a narrow cabin, a combination of a natural vapour and water massage. Rest is essential after all these treatments as there is sometimes a severe reaction.

Diathermy and short-wave therapy have also been used with success in some cases of sciatica. Stretching and massage is of little value in true sciatica, but is of great value in the fibrositic cellular type.

An operation has been recommended by certain orthopaedic surgeons for intractable cases, this consists of fusion of the lumbo-sacral spine, the facets of the lumbo-sacral articulation are exposed and removed, and a Hibb's fusion performed. Following this operation relief of pain has been recorded, and neurological examination later has revealed return of motor and sensory function, but it is clearly a severe operation which should be held in reserve for only the most drastic cases.

Therapeutic Abortion and the Law

(From the *British Medical Journal*, Vol. II, 30th July, 1938, p. 225)

THE true physician's only desire is to do his best for his patient. His problem is often to choose between two evils: the possible ill effects of his treatment, and the probable consequences if he does nothing. The gynaecologist sees many pregnant women who, if they go to term, will probably suffer some harm. This may be slight, or so grave that it will almost certainly cause death. In many of these cases he is convinced that an abortion is in the best interests of the patient. His choice, however, is complicated by the knowledge that

if he terminates pregnancy he will destroy a potential life, and also that the law forbids abortion in some circumstances. Many doctors have for a long time been anxious to know exactly what the law allowed them and did not allow them to do. They found one answer only. The Offences Against the Person Act, 1861, Section 58, said that a person who 'unlawfully' used an instrument with intent to procure the miscarriage of a woman committed a felony for which he could be punished with penal servitude for life. They asked the meaning of 'unlawfully' and were told that it had never been defined, either by Parliament or by a judge, but that the law almost certainly allowed the termination of pregnancy for the purpose of saving the mother's life. When they discussed the subject among themselves, they found wide variations of opinion on what the law was—apart from much wider variations of opinion on what the law ought to be. They felt anxious and insecure, and a strong movement grew up among them to have the law clarified.

At the same time, a number of lawyers who had paid special attention to the problem were aware that the law was vague, but felt convinced that this very vagueness was a good thing. They realized much better than the doctors the essence of the English legal system: a man may do anything which is not expressly prohibited by law; and where authority is lacking the law is written in the hearts of the people, to be interpreted by the judges. The undefined word 'unlawfully' allowed the authorities to give the medical profession, whom they knew to be with very few exceptions not only responsible but conscientious, a free hand to decide for themselves what was lawful in therapeutic abortion. The lawyers were content, in other words, to assume that an abortion was carried out lawfully when a doctor performed it in good conscience, after careful thought and observation and under proper conditions, for the substantial benefit of the patient. They felt that, so long as the law refrained from saying what a doctor could do, the question of what he could not do need not arise so long as he acted *bona fide*; he could be left outside the sphere of criminal law and practice altogether, and the police could devote their energies to detecting and prosecuting the people against whom the statute was directed—namely, the professional abortionists, lay or medical, about the unlawfulness of whose activities there was no possible doubt. This attitude, however, did not allay the anxiety of medical men, and the situation was resolved last week in an English court of law.

Mr. Aleck Bourne has for some time been among the chief of those who have desired to know clearly where they stood under the law. He is a leading obstetric surgeon with keen clinical and psychological insight. He felt that in some cases, to do his best for his patient, he must perform an abortion. He also felt that the true interpretation of the law must allow abortion where it was in the best interests of the patient, and he formed the resolution to take the first suitable opportunity of having the legal position made clear. In this country a legal ruling can only be obtained in relation to a particular case, whether it be a civil action or a criminal prosecution. He was therefore prepared to take the extreme course of risking his liberty, life's work, and reputation by submitting to a criminal prosecution in which the Crown would differ from him on the interpretation of the word 'unlawfully'. As it happened, when the suitable occasion arose he was barred by a promise of secrecy from actively presenting himself as a sacrifice, and it is understood that the Crown moved on information which he had not supplied. A girl less than fifteen years of age was assaulted by some soldiers and raped under as revolting a set of circumstances as could be imagined. She became pregnant and was taken to see Mr. Bourne, who admitted her to St. Mary's Hospital for observation. He had a strong bias from the beginning in favour of an abortion, but he did not perform it until he had satisfied himself, by tests and observation, that the girl would in all probability, if she had gone to term, have suffered grave and lasting nervous damage which would

have expressed itself in psychoneurotic and physical illness perhaps for the whole of her life. Though he acted openly, he did not consult any of his colleagues, his reason being that in such cases he was accustomed to act as the 'second opinion' himself. He was charged under Section 58 of the Act of 1861 with unlawfully using an instrument with intent to cause miscarriage, and the case turned on the interpretation for the first time of the word 'unlawfully'.

The trial took place on 18th and 19th July at the Old Bailey before Mr. Justice Macnaghten, and will long be remembered as one of the most remarkable that has ever taken place, even in the Old Bailey. The accused was treated throughout with admiration and respect; his motives were regarded with what must have been almost unanimous approval. It was less a criminal trial than a co-operative effort by judge, jury, counsel, and witnesses to create law out of strong but ill-defined feeling. The foundation was laid by the judge after the Attorney-General, Sir Donald Somervell, K.C., had closed the Crown case: he defined the word 'unlawfully' by importing a phrase from the Infant Life Preservation Act, 1929. That Act was passed to prevent the killing of a child in the short interval when it is capable of being born alive and therefore comes outside the law of abortion but has not yet acquired an existence independent of that of its mother and therefore cannot in law be murdered. Section 1 of that Act contains a proviso that no person shall be found guilty of the offence of child destruction unless it is proved that the act which caused the death of the child was not done in good faith for the purpose only of preserving the life of the mother. The learned judge held that this proviso expressed what had always been the law in regard to abortion and was implicit in the word 'unlawfully' of the 1861 Act. He therefore ruled that the question for the jury would be: 'Has the prosecution proved to your satisfaction, beyond reasonable doubt, that the act which Mr. Bourne admittedly did was not done in good faith for the purpose only of preserving the life of the mother?'

No one doubted Mr. Bourne's good faith, but he himself admitted that he had not acted to save the girl from immediate death. The next step in the case was therefore to determine the meaning of the phrase 'preserving the life of the mother'. There was no doubt that the girl's health would almost certainly have been gravely injured. In fact, the Attorney-General greatly clarified the case by admitting as much at the end of his closing speech. He said, 'I do not minimize the possible mental effects of which Mr. Bourne and the other doctors spoke. The question is whether those mental effects, grave as they are, justify under the law the termination of pregnancy'. In answering that question the judge used words which will probably be quoted for a long time to come as a statement of the attitude which the law requires of the doctor who performs a therapeutic abortion. He said, in effect, that no line can be drawn between danger to life and danger to health; that no doctor knows whether life is in danger until the patient is dead; and that if on reasonable grounds, based on adequate knowledge, after consultation with colleagues, a doctor forms the opinion that the probable consequences of the continuance of pregnancy would make the woman a physical or a mental wreck, then he is not only entitled, but it is his duty, to perform an abortion. In saying this his Lordship was—most fortunately—saying that the law and the physician's duty are in harmony. To preserve a woman's life, he implied, is not merely to save her from death; it is also to save her from illness which would destroy so much of her life that it would hardly be worth living. With this view the jury agreed, as is shown by their verdict, and it is now the declared law until it is corrected or modified by the Court of Criminal Appeal in some other case.

The trial *Rex v. Bourne* has therefore ventilated the whole subject of therapeutic abortion and produced a statement of the law which substantially allows the conscientious medical man to do what he has been doing already. But the law, hitherto vague, has now

been clarified, and after the Ministry of Health's Inter-Departmental Committee on Abortion (the Birkett Committee) has issued its report it may be clarified still more.

Treatment of Narcotics Addiction

'FALLACY OF CURES'

(Abstracted from the *Annual Report, Central Narcotics Intelligence Bureau, Egyptian Government, 1937, p. 85*)

IN the Annual Report for 1931 of the Central Narcotics Intelligence Bureau a note on treatment for narcotics addiction by the assistant director of this bureau drew attention to the danger of so-called 'cures' which were, in fact, not cures at all but merely temporary de-narcotization of basically unstable and abnormal persons. Figures from a report made by the Mayor of New York in 1930 by seven professional doctors together with their observations and deductions were quoted to show that there is no evidence to confirm claims for any such thing as a 'cure' or a 'specific' for drug addiction.

The intervening years have produced no challenge to this conclusion: on the contrary it has everywhere been supported and confirmed by professional medical men as opposed to 'quacks' who have specialized in the treatment of drug addicts and addiction.

The latest confirmation is to be found in the Annual Report for 1936 on Traffic in Opium and Other Dangerous Drugs published by the Bureau of Narcotics of the United States of America Treasury Department.

The Narcotics Educational Association of Michigan, which sponsors and controls a farm for the treatment of drug addicts, makes the following remarks:—

'It is our present opinion—after years of close observation—that in the main no one becomes addicted to narcotic drugs except only those who may be best described as "emotionally unstable and personally inadequate" and that, with very few exceptions, those who are "emotionally stable" have very little to fear in the way of drug addiction.

In other words, in a vast majority of instances drugs such as morphine are the means of escape from the realities of life indulged by unstable persons really wishing to escape those very realities. This is true of essentially all those who appealed to the association for help.

An employment bureau and probationary follow-up department was theoretically designed to provide after-cure care for returned patients, whose "habit" had been broken at the association farm. But it did not take into consideration what then was presumably unknown, *i.e.*, that the returned patient, though "cured" of his addiction, was still emotionally unstable and personally inadequate, and certain to remain so. He may have given every evidence of a favourable reaction while in the favourable environment of a farm, but found himself utterly incapable of successfully coping with the unfavourable environment of our urban centres.

The use of the word "cure" is highly erroneous and improper in that no cure—in the commonly accepted sense of the word—is known to medical science. That is, no "medicine" is known which will "cure" one addicted to the use of narcotic drugs without his consent or against his will.

It would appear that during all these years the directors of the association had suffered from one grand delusion, *i.e.*, that drug addicts were "ordinary folks like themselves" who had become addicted. And, if only they could be "cured" of that addiction, they might again resume the status of useful citizens. The fact remains that at least a considerable, though unknown, percentage of all drug addicts are not "like other folks" but rather are members of an emotionally unstable and personally inadequate group for whom little of permanent character or of social value can be accomplished.

One director, who has served on the board a great many years, states emphatically "that he does not recall one single instance in which a returned cured patient who visited our meetings remained a cured patient". Those addicts who, a committee of physicians have determined, have not rehabilitated successfully at the termination of their convalescent adjustment period, should be promptly transferred into a colonization period. Colonization should be indeterminate, not less than three years, and may be for life.'

In addition to the above, the State Narcotics Hospital at Spadra in the State of California furnishes details and figures of eight years' operation in the care and treatment of drug addicts, thereby enabling a special committee set up by the State Senate to report as follows:—

'California was the first State to build and operate a hospital for narcotic addicts, and there were no records available of the experience of the few private and municipal institutions of that sort. Governor Young said: "I regard this as a test-tube experiment, we can later modify or expand it".

Now, after eight years of operation, we at last understand the problem before us, and we know what we must do to solve it.

We have discarded and washed our hands of the incurable addicts who have recurred to the use of narcotics after the most thorough, painstaking course of treatment known to medical science. These incurable addicts are at liberty on the streets of our cities, spreading drug addiction among their associates and most of them following criminal pursuits in order to obtain the 4 or 5 dollars they must spend daily for their supply of narcotics.

We must provide, in addition to our hospitalization facilities at Spadra, a farm for incurables, where recurred addicts may be committed for an indeterminate period of from 5 to 15 years, at the discretion of the medical superintendent.

We know that two or three years is too short a time to ameliorate the injury wrought in the character of the addict by his addiction. It may be that the period of 5 or 10 years is not enough. We do not yet know the answer, but we do see very clearly that the 5-to-10-to-15 year commitment for the recurred addict is the only possible solution. This plan should succeed unless the disintegration of character is irreparable. In that case we know that the cost of segregating these incurables on a narcotic farm for a very long period will prove much cheaper than permitting them to enslave and degrade others and provide a lucrative market for international narcotic smugglers and our American illicit traffickers.

We must not make a retreat in our warfare against the spread of drug addiction. We must continue to advance and to defend our State against the invasion of a subtle and sinister army of destruction. The Senate Interim Narcotic Committee will introduce a bill at the next session of the legislature providing for the creation of a farm for the segregation of recurred, incurable addicts for an indeterminate period of 5 to 15 years.

To the objection that the solution of the problem of drug addiction will be an added burden upon the taxpayers, we reply that the direct and indirect cost of crime resulting from drug addiction at present is much heavier than would be the cost of segregating incurable addicts on a narcotic farm for a long period of time.

Drug addiction is seldom cured after incipient stages. Various theories have been advanced on this subject: many persons have claimed that drug addiction is incurable; others contend that it is merely a disease for which a remedy will be found; panaceas have been tried and have invariably failed.

During the past eight years of experimentation at Spadra your narcotic committee has refused to accept or promulgate any conclusions. Now however, in view of the records of our narcotic hospital, supplemented by our knowledge of statistics gathered by Dr. Somel

The absorption of mineral salts, especially calcium, is enhanced by the acidification of the upper part of the small intestine and the quick breaking down of the acid renders the lower gut alkaline and furthers the production of a normal intestinal flora.

Acidified milk is a poor culture medium for bacteria and will keep well, even in hot weather.

Finally, because the acidification renders the digestibility equal to that of breast milk, there is no need to use anything but whole milk; consequently the feeds are easier to make up, they have a higher caloric value, and therefore there is less likelihood of underfeeding. Smaller volume feeds are required, with less gastric distention, lessened liability to vomiting and, because of the high caloric value, there is seldom any necessity to feed at less than four-hourly intervals even with small underweight babies.

Lactic acid is chiefly used as the acidifying agent, being added in the proportion of half drachm to the pint of milk.

There is, however, quite wide choice of acids, and any of the following may be used:—

Lemon juice	..	3 drachms	to the pint
Orange juice	..	1 ounce	" " "
Acetic acid	..	1 drachm	" " "
Citric acid	..	2 grammes	" " "
Hydrochloric acid	..	4 oz. N/10 HCl	" " "

None of these has any advantage over lactic acid.

If preferred, bacterially cultured milk may be used. *Streptococcus acidilactici*, *Bacillus bulgaricus* and *Bacillus acidophilus* are equally good, especially when the milk is homogenized before being inoculated.

Using lactic acid, the standard formula is prepared as follows:—

B. P. lactic acid, one drachm for each quart of milk (or two drops to the ounce if the feeds are made up individually). The acid is first diluted with water (about one ounce of water for one drachm of acid) and then added slowly to the milk, *which must be cold*, the mixture being stirred continuously. With the addition of the last few drops of acid the milk will become finely and uniformly curdled. The sugar is then added in the proportion of three ounces to the quart and the mixture heated to body temperature before being offered to the infant. It is important not to heat the mixture too much or the curds will

conglomerate and the feed will not flow through the teat.

In using this acidified formula it is essential that the hole in the teat be enlarged sufficiently to allow free passage to the fine curds. (Enlargement is easily carried out with a red-hot needle.) During the feeding the bottle must be shaken at intervals to ensure an even suspension of the curds and prevent blocking of the teat.

As has been said, the feeding interval will normally be four-hourly, with four or five feeds in the 24 hours according to circumstances. The quantity necessary will be determined by the infant's expected weight. The customary allowance is 50 calories per pound of such expected weight, and the formula here described yields 30 calories per ounce. Thus for a three-month baby, who should weigh 12 lb., 12×50 or 600 calories are necessary per day. These will be provided by 20 ounces of the formula, which may be given in five feeds of 4 oz., or four feeds of 5 oz., according to the infant's size.

Dried or evaporated milk may be used equally well as the basis of the formula, and acidified after reconstitution with the required quantity of water. The use of dried milk has the advantage of enabling the percentage of solid matter in the feed to be increased (by using more powder), thus increasing the caloric intake without adding to the volume of the feed; often a very useful procedure in feeding premature infants.

The complete formula is also available in dried form under the designation 'Modified Lacidac', which has been in use as a most satisfactory routine feed in hospital and private practice during the last nine years.

Summary

Whole milk acidified with lactic acid and with 10 per cent glucose added is a most satisfactory routine feed for babies. It is especially valuable for underweight and marasmic babies and for premature infants.

Details of the preparation of the formula are given.

Apart from a very small percentage of cases (considerably less than 1 per cent) in whom lactic acid milk causes vomiting, and who are found on investigation to have an unusually high gastric acidity, the dictum that any infant fed on this formula who does not thrive is suffering either from an infection or from a congenital anomaly has been fully borne out.

Reviews

THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE.—Under the General Editorship of Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., M.D., D.Sc., D.C.L., LL.D. 1938. Butterworth and Company, Limited, London. (To be completed in 11 volumes.) Sold in complete sets only. Cash price, Rs. 25 per volume. Also available on the instalment system at Rs. 10 per month. Price, Rs. 26-8 per volume. Only available from Messrs. Butterworth and Company (India), Limited, Calcutta. Volume IV. Pp. xxiii plus 600 plus 50

THIS volume commences with 'diarrhoea' and concludes with 'endoscopy of the rectum'.

There is a general article on diarrhoea by Sir Arthur Hurst, and two shorter chapters, on flagellate diarrhoea and on hill diarrhoea, by Dr. N. Hamilton Fairley. Dr. Fairley takes the view that the pathogenicity of the flagellates is unproven; for the treatment of giardia infection he emphasizes the high protein diet, but he also mentions the rather dangerous procedure of de Rivas, lavage with hot glycerine and magnesium carbonate solution; in fact the impression gained is that he is not writing with the authority of personal experience. (The omission of any mention of atabrin is natural, as attention has only recently been called

to its action on flagellate infections.) On the other hand in his chapter on hill diarrhoea he seems to be writing with more assurance, though he is on difficult ground on account of the extreme uncertainty regarding the ætiology of this clinical entity. There is a fourth chapter, devoted to diarrhoea in infancy and childhood, by Dr. W. B. Ellis.

The chapter on epidemic dropsy is contributed by Colonel R. N. Chopra. He gives a concise but very complete account of this disease, so important to the people of the eastern half of this peninsula. It is the inclusion of authoritative articles of this kind that place this encyclopædia in a class by itself as a standard book of reference for the worker in the tropics.

The chapter on bacillary dysentery is by two workers with wide experience in tropical medicine, though mostly in a different field, Major-General H. Marrian Perry and Lieutenant-Colonel A. G. Biggam. The chapter is an excellent one, but, if we have a criticism, it is that, for a book of this kind, they have taken up too much space in discussions on bacteriology, including bacteriological technique, and have even gone as far as outlining the method of preparation of anti-dysenteric serum. Their short reference to bacteriophage in treatment is guarded, to the extent of being definitely discouraging. They say there is no acceptable statistical evidence of its value.

Other important and interesting chapters in the volume are on dietetic deficiency diseases by Dr. Helen Mackay, eczema by Dr. Arthur Whitfield, electro-diagnosis by Dr. E. P. Cumberbatch, and ear diseases by Mr. Lionel Colledge.

The same high standard of authoritative writing is evident throughout this volume.

THE NEW INTERNATIONAL CLINICS.—Edited by G. M. Piersol, M.D. Volume I. New Series 1. (Old 48th.) 1938. (Published quarterly.) J. B. Lippincott Company, Philadelphia and New York. Pp. iv plus 322. Illustrated. Price, 50s. for four volumes. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. The annual subscriptions to the series (issued quarterly) is Rs. 33-8

We are pleased to see the reappearance of these quarterly International Clinics. Many useful and important contributions have appeared in this series, the format of which is very convenient for the personal or institution medical library.

The first number contains some useful articles on a variety of subjects, for example, the treatment of wounds, vitamin-A deficiencies in adults, pneumothorax in the treatment of tuberculosis, newer interpretations of gastric mucosal functions, skin diseases from an emotional standpoint, normal blood pressure, and intestinal obstruction. There are a few 'clinics', that is to say articles written around illustrative cases, which are very instructive from a practical point of view. Finally, there is a 'review of medical progress', the subject chosen being 'Biliary stasis and decompression'.

The writer of the article on gastric mucosal function is obviously very much intrigued by Greenspon's theory of the aetiology of pernicious anaemia, but, either the paper was written some time ago, or he is unaware of recent work in which it has been shown that some of the experiments on which this theory rested could not be repeated by other observers. The same writer uses the word 'hypotheate' in the meaning 'to frame a hypothesis'. We are a long-suffering race and allow those who have the privilege of using our language to take appalling liberties with it, but the line must be drawn somewhere. The word 'hypotheate' has an entirely different meaning, namely 'to pledge or mortgage' (the 't' is silent, *please*, Doctor Morrison), which it had before Queen Ann came to the throne of England, when Maryland was a not very flourishing English settlement, Baltimore was the name of a noble English family, and grass grew where the town of Baltimore stands to-day, and it has retained the same meaning ever since. The word 'hypothesize', meaning 'to frame a hypothesis', has been in the English language for more than 200 years.

There is one contribution which the reviewer considers might well have been omitted, 'Treatment of amebic dysentery by means of intracolonic heat, by Dr. Damaso de Rivas'. In the interests of our cerebral arteries, we will control ourselves and simply say that it is well below the high standard of the majority of the articles in this useful series.

TEXTBOOK OF NUTRITION.—By J. A. Nixon, C.M.G., M.D., F.R.C.P., and D. G. C. Nixon, M.B., B.S., M.R.C.S., L.R.C.P. 1938. Oxford University Press, London and New York. Pp. xi plus 219. Illustrated. Price, 7s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

'NUTRITION' is very much to the front in medical practice at present, and we have been given a very large number of books on the subject during the last few years. The authors of the book under review consider that an apology is necessary for adding to their number. Though the apology is not very convincing, we consider that the book has certainly justified itself, which is a far more important point.

The book is written primarily for the medical student and practitioner, but it should prove useful to the sanitarian, the non-medical dietitian, and the

social worker. Emphasis is laid on the physiological, clinical and economic aspects, and the chemical aspects of the subject are purposely neglected.

The subjects dealt with are the physiology of digestion and metabolism, assessment of the state of nutrition including height and weight tables, food requirements, the choice of foods including very adequate food tables, diet and income, diet in relation to disease production, disease prevention, infection, work and physical efficiency, nutrition in disease and in lactation, and the effects of cooking.

We have a few minor criticisms to offer. The sentence 'In pernicious anaemia liver or a preparation of hog's stomach is an indispensable item in dietetic treatment. Recent observations indicate that liver extract is more potent if injected' is to say the least of it somewhat naive, in the year 1938. In places, the authors' arithmetical sense appears to be distinctly shaky, *e.g.*, they say that one quart of milk contains 160 grammes of protein; they possibly mean 160 calories derived from protein.

In their chapter on diet and disease production, they are very emphatic about the complete lack of evidence for the statement that meat-eating causes cancer. It is a most interesting study in mass suggestion; the assertion that meat causes cancer is made so frequently by food faddists and other cranks, usually accompanied by blatant misstatements, such as, 'as is universally recognized' or 'as has been proved' that a large number of people really believe that some association between meat-eating and cancer has been scientifically proven.

We consider that the book is a valuable addition to the medical literature of nutrition, and is one that will meet the requirements of the practitioner admirably, providing him with a well-balanced introduction to the study of nutrition and a ready reference book for looking up important facts and figures that no one can hope to, or should attempt to, memorize.

ADVANCES IN THE THERAPEUTICS OF ANTIMONY.—By Prof. Dr. Phil. Nat., Hans Schmidt, and Dr. Med. F. M. Peter. 1938. Georg Thieme, Publishers, Leipzig. Pp. x plus 257, with 10 diagrams. Price, RM. 18

ANTIMONY has earned for itself a unique place in the history of therapeutics. It has always managed, to use a modern expression, to get 'into the news', and has displayed an unusual ability to stir human passions; it has been lauded to the skies as a cure for all ills, and it has been banned by parliamentary edict; it has saved the lives of hundreds of thousands, and has been a favourite medium of the murderer; it has brightened the eyes of Jezebel, and it has helped to empty the stomach of a surfeited Nero. It has also made a complete slave of one of the world's great chemists, Professor Hans Schmidt, but it can with equal truth be said that it has been completely mastered by him. For many years Professor Schmidt has lived and thought of nothing but antimony; in his home he is surrounded by antimony in the hundreds of forms in which it occurs in nature, and in his laboratory he has toiled day and night, like the alchemists of olden times in their search for the elixir of life, to find the most perfect preparation of antimony, so that to-day the shelves around his laboratory walls are lined with hundreds of different chemical combinations of this element.

Unlike those of the alchemists of old, Professor Schmidt's efforts have been crowned with success and he has prepared antimony compounds that can be tolerated by the human organism in doses that a few years ago would be considered unbelievably large, and yet that have a parasitocidal power many times greater than the old pharmacopoeial preparations. The greatest successes of antimony have been in protozoal and helminth infections of man and animals, in leishmaniasis, bilharziasis, and trypanosomiasis, but in many other conditions, *e.g.*, granuloma venereum, it has proved of undoubted therapeutic value.

The present volume is not a chemical treatise but a record of the successes and the therapeutic limitations of antimony in its multifarious forms.

The largest section of the book is entitled 'Clinical experience in human medicine', other sections are 'Clinical experience in veterinary medicine', 'Tests in experimental infections', 'On the synthesis of antimony preparations', and 'Pharmacology'.

The book was published in German last year. This English edition is very welcome; it is an important contribution to general therapeutics, but more especially to therapeutics in the tropics.

A TEXTBOOK OF HISTOLOGY.—By A. A. Maximow and W. Bloom. Third Edition. 1938. W. B. Saunders Company, Philadelphia and London. Pp. xv plus 668, with 542 illustrations. Some in colour. Price, 30s.

PROFESSOR MAXIMOW'S is a name that will figure in the histological textbooks of many generations as that of a man who was responsible for some of the most important advances in the closely allied sciences of cytology and histology during the first quarter of the present century; that he died before completing his textbook on histology will be considered by many nothing short of a tragedy. However, the book which Dr. William Bloom has produced from Professor Maximow's material is, in the reviewer's opinion, quite the best textbook available to-day. That this opinion is not unique is suggested by the fact this textbook is now in its third edition.

The first point on which we should congratulate the present author is that the bulk of the book has been increased only by a negligible number—six to be exact—of pages. This is a great achievement, more especially as, we are informed in the preface, 42 new text-figures have been added.

We have not compared the present and the last edition section by section, but in most chapters there has been considerable revision and references made to important new work. For example, in the chapter on the spleen Taliaferro's work on monkey plasmodium infection has been utilized to explain the functions of the spleen and some of his illustrations included.

In the chapter on the blood forming and destroying tissues there is a good coloured plate of cells from a stained smear made from human bone marrow, which include the pathological megaloblasts seen in pernicious anaemia.

It only remains for the reviewer to repeat his opinion that this is the best textbook of histology available to-day.

MALARIA IN CEYLON: AN ENQUIRY INTO ITS CAUSES—THE THERAPEUTICS AND OTHER MEASURES USED DURING THE EPIDEMIC OF 1934-35, WITH RECOMMENDATIONS FOR THE PREVENTION OF FUTURE EPIDEMICS.—By C. L. Dunn, C.I.E., D.P.H. 1937. Baillière, Tindall and Cox, London. Pp. vi plus 57, with 4 maps and 5 graphs. Price, 6s.

THE epidemic of malaria that occurred in Ceylon in 1934-35 was one of the most widespread and devastating outbreaks of recent times. This epidemic affected nearly 2 million people and collected a toll of over 100,000 lives. It cost the Government over 5 million rupees and in addition the strain of organizing one of the biggest campaigns for the treatment and cure of the sick.

Colonel Dunn who had an opportunity to visit the island at the time of the epidemic and to study first hand the conditions prevailing there has set forth his observations in this excellent report. He has discussed the history of malaria in the island, its physiography and climatology, the causes of the present epidemic and the therapeutic and other measures used for controlling it, in a clear and lucid manner. He has himself collected a vast amount of data which he has analysed. The significance and value of his data are enormous. His section on the therapeutics of malaria is worthy of special mention. On the whole this is a valuable

contribution and ought to be read by everyone interested in malaria. It gives an insight into the ways and means that ought to be adopted for controlling malaria when it breaks out on an extensive scale.

TEN MILLION AMERICANS HAVE IT.—By S. W. Becker, M.S., M.D. 1937. J. B. Lippincott Company, Philadelphia and London. Pp. 220. Price, 6s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 4-8

THIS is a book on syphilis meant for the use of the general public. It narrates in a vivid and interesting way, and in simple non-technical language, the ravages caused by the disease in America. It forms part of a campaign that has recently been started in that country for educating the people on the dangers of the disease and for inducing sufferers to resort to treatment early.

In the book special stress is laid on the necessity for considering this disease as in no way different from any of the other infectious diseases. This indeed is the correct view and should be accepted. There is no meaning in considering venereal diseases as a just punishment for the sin committed. An enormous amount of harm has been done already in the past by branding these diseases as a mark of an immoral person and that attitude has indirectly forced the sufferers to hide their disease as far as possible and to resort to secret and inefficient treatment by quacks; this has also encouraged the wide dissemination of infection.

Although the disease is mostly contracted by a voluntary act on the part of the adult individual that is no reason why the state and the public should look down upon an infected person and shirk helping him to get rid of his trouble. Both the public and the state must admit that they owe a duty to the healthy; if so by neglecting the sufferers they are failing in their duty to the healthy. It is high time therefore that the present attitude of the public towards syphilis and the venereal diseases was changed and the sufferers treated in a sympathetic and humane manner.

Every facility should be provided for the diagnosis and cure of the disease at public expense. Only by adopting such a course will this disease be stamped out from our midst. The book on account of its championing the above views is worth reading. Syphilis is as much a problem in India as in the West. The indifference and apathy shown to the control of this disease in India is regrettable. What is stated to be the need in America is also true of India. Therefore the book is specially recommended for study by the general public in India.

K. V. K.

SYPHILIS AND ITS TREATMENT.—By W. A. Hinton, M.D. (Boston). 1936. Henry Kimpton, London. Pp. xvi plus 321. Price, 15s.

IN this book Dr. Hinton has set forth his experience gained in the laboratory and in the clinics at Boston. The book consists of 321 pages and gives a fairly detailed account of the clinical, laboratory and therapeutic aspects of syphilis. Although there are many books written on syphilis this is certainly a valuable addition to them. Most American books are full of illustrations. In this one illustrations are conspicuous by their absence and yet the book will be found useful by students and practitioners.

K. V. K.

MUIR AND RITCHIE'S MANUAL OF BACTERIOLOGY.—Revised by Carl H. Browning, M.D., LL.D., D.P.H., F.R.S., and Thomas J. Mackie, M.D., D.P.H. Tenth Edition. 1937. Oxford University Press, London. Humphrey Milford. Pp. x plus 996. Illustrated with 212 illustrations in the text and 6 coloured plates. Price, 20s. Obtainable from Oxford University Press, Bombay and Calcutta

ON the retirement of Sir Robert Muir from participation in the revision, the original authorship of this well-known textbook of bacteriology has come to an end. For more than forty years 'Muir and Ritchie' has

been recognized as one of the standard books on bacteriology and has been used widely, both by medical students and post-graduate workers. The present edition has been thoroughly revised and brought up to date. New knowledge and new methods of investigation have been incorporated, and many of the illustrations have been replaced by photomicrographs. The tenth edition of this well-known book fully maintains the high reputation of its predecessors and we have no doubt it will be as popular with medical students as the previous editions.

C. L. P.

NOTES ON BACTERIOLOGY AND CLINICAL PATHOLOGY FOR NURSES.—By Herbert Rogers, M.D., Ch.B. (Bristol). 1938. H. K. Lewis and Company, Limited, London. Pp. vii plus 40. Price, 1s.

THIS little book has been written to assist nurses preparing for the examinations required by the General Nursing Council and to create an interest in the pathological investigations carried out on their patients. The first half of the book consisting of 16 pages is devoted to the classification and the study of bacteria, fungi, protozoa, and animal parasites, and the second half to clinical pathology and the methods of collection of pathological specimens. The author has succeeded remarkably well in giving a simple and a clear account of the nature of bacteria and other human parasites, a study of which will help the nurse to understand the meaning of the various laboratory investigations carried out on patients and will lead to an intelligent co-operation between the wards and the laboratory.

C. L. P.

AIDS TO BACTERIOLOGY.—By W. Partridge, F.I.C. Revised by H. W. Scott Wilson, B.Sc., B.M., B.Ch. (Oxon.). Sixth Edition. 1938. Baillière, Tindall and Cox, London. Pp. vii. Plus 300. Price, 5s.

THE sixth edition of this well-known member of the *Aids Series* has been thoroughly revised. The classification, as recommended by the Society of American Bacteriologists in a slightly modified form and which has been generally accepted by the majority of English bacteriologists, is used throughout this edition. This is a distinct advantage as it must lead to a uniformity in nomenclature and a clearer understanding of different genera. It is regrettable, however, that in the adoption of the new nomenclature the abbreviations used for the genus *Bacterium* and the genus *Bacillus* have not been differentiated and in the abbreviated form stress is not laid on the great differences between these two genera.

This book is of immense value to the student not only for revision purposes, but it will help him in the understanding of the subject when it is used in conjunction with one of the larger textbooks and with his lecture notes. There is a remarkably large amount of information including the important recent contributions to bacteriology in a readily accessible form, which will be of interest and value to the medical practitioner and also to the medical bacteriologist who desires to refresh his memory on any particular subject.

C. L. P.

A SYNOPSIS OF PHYSIOLOGY.—By A. Rendle Short, B.Sc., M.D., F.R.C.S., and C. L. G. Pratt, M.A. (Educ.), M.Sc., M.D. Third Edition. 1938. John Wright and Sons Limited, Bristol. Pp. 325. Illustrated. Price, 10s. 6d.

THIS small book is an admirable collection of up-to-date information on physiology. The chapter on chemistry will be of great help to students. The subject-matter is well written and not monotonous to read. It is a very suitable book for students for quick revision before their examinations. It will also be a useful book to practitioners for quick survey of the subject. It is trusted that the book will meet an eager demand.

P. D.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY.—By W. A. Newman Dorland, A.M., M.D., F.A.C.S., Lieut.-Col., M.R.C., U. S. Army. Eighteenth Edition. 1938. W. B. Saunders Company, Philadelphia and London. Pp. 1607. Illustrated. Price, 30s. (plain). 32s. 6d. with thumb Index

It is perhaps not quite the right place to raise this protest, but why is it that no British publishing house will undertake to give us an English medical dictionary? America is supplied with some excellent ones of which the book under review is one of the best examples. The compilers have gone a long way towards meeting the wants of the British reader and in most instances have given the alternative English spelling, but why should the British reader, for words beginning *hæmato-*, have to see those beginning *hemato-*. It makes it an up-hill fight for editors in the Empire, outside Great Britain, to maintain correct English spelling in their journals.

It is three years since the last edition appeared. It is an alarming thought that it has been necessary to add definitions of 3,000 new words, and that as a result the text has had to be increased by sixty pages. However, the words have been brought into use and we must be able to look them up when we meet them for the first time. A little saving of space has been made by contracting the posological tables without limiting their usefulness.

'To be of permanent value a medical dictionary must cover modern literature and this calls for frequent and constant revision. The editor believes that in this new and enlarged edition the *American Illustrated Medical Dictionary* will continue to prove its usefulness to practitioners and students.' We are quite sure that it will, and can unhesitatingly recommend it.

A GUIDE TO ANATOMY: FOR STUDENTS OF MEDICAL GYMNASTICS, MASSAGE AND MEDICAL ELECTRICITY.—By E. D. Ewart. Fourth Edition. 1938. H. K. Lewis and Company, Limited, London. Pp. xii plus 342, with 102 illustrations including 39 plates. Price, 12s. 6d.

THIS little volume is intended to serve the needs of students of medical gymnastics and massage, and as such is a guide to anatomy in a restricted sense. The book consists essentially of two broad divisions, e.g. (a) osteology (section i); (b) soft structures (sections ii, iii, iv and v) with an introductory section before each division giving, in a brief outline, the fundamentals of the nature of structures to be described in the following chapter or chapters.

The author has constantly kept in view the needs of his special class of students and consequently laid stress upon those structures which are directly concerned with this special mode of treatment. The subject-matter has accordingly been arranged in order of importance, viz. bones, articulations, muscles, and then nerves and vessels.

In this brief account, every part of human anatomy has been included but unfortunately old terminology has been used. One would wish that the muscles and nerves were more elaborately illustrated, not only for the purpose of examinations but also for subsequent professional utility. Thus, muscles of the foot are important for examinations, as will be seen from the questions in the appendix, and also to chiropodists and masseurs but no diagrams of the muscles of the sole of the foot are given. Similarly, a diagram of the neurone would enable the students to understand the constitution of the nerve better than its very short description. Some of the figures in half tone would be better understood, if replaced by simple line drawings, e.g., figure 39, depicting the back muscles. The value of the book as a guide, would have been enhanced further, by a more careful selection of structures for illustrations. Some of the sketches of surface anatomy and nerve plexuses might be replaced, without affecting the purpose of the book, by appropriate diagrams of structures which are more directly concerned with massage.

On the whole, however, the book covers the requirements of the syllabus of the chartered society of massage and medical gymnastics, and if more attention be paid to illustrations, the book should prove a suitable guide to those for whom it has been written.

AIDS TO PRACTICAL NURSING.—By M. Houghton, S.R.N., S.C.M., D.N. (Lond.). 1938. Baillière, Tindall and Cox, London. Pp. xii plus 307. Illustrated. Price, 3s. 6d.

This will be a very useful book containing some very excellent hints for the student nurse, and as a reference book for the trained nurse.

It is very concisely put together, each chapter providing most interesting and exciting reading for the student who is anxious to learn as much as possible.

Particularly are we impressed with the last chapter which deals with the 'preparation of apparatus'; this is so often forgotten in nurses' textbooks. Miss Houghton has explained each instrument so efficiently and in such a simple way that the most junior student cannot fail to follow her every action necessary to set up each piece of apparatus.

We most sincerely recommend this book as an invaluable possession for all student nurses.

E. M. C.

Abstracts from Reports

SIXTY-NINTH ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH, UNITED PROVINCES, FOR THE YEAR ENDING 31ST DECEMBER, 1936

THE STATE OF PUBLIC HEALTH IN THE PROVINCE AND HISTORY OF CHIEF DISEASES

General health of the province.—The death rate in 1936 in these provinces from all causes showed a decrease of 2.17 as compared with the figures of the preceding year, the rates per mille of population for the two years being 22.61 and 24.78, respectively. A comparative statement showing the death rates from certain important diseases is appended below. The decrease during 1936 was noticeable under all heads except injuries and all other causes. The year 1936 has shown low death rates under all heads except smallpox and respiratory diseases as compared to decennial averages.

disease but females were comparatively less affected than males. The disease was more prevalent among Muslims than among Hindus.

It was found that the recovery rate in cases treated in hospitals was more promising than in cases treated at residences. It is essential that people should realize the danger of the disease and come forward immediately for treatment in hospitals.

Beri-beri or epidemic dropsy.—There were 118 deaths in urban areas and 27 in rural areas, i.e., a total of 145 deaths during the year compared to 380 deaths in the preceding year.

Like last year the disease again appeared in somewhat serious form in Benares city, where the active symptoms appeared mostly amongst the old cases. A few new cases were also reported from Dasaswamedh and Bhelupura wards. The disease was mainly confined to the Bengali community. Ninety-two deaths were reported from Benares alone against 304 in the previous

Chief causes of mortality	Death rate per mille for 1935	Death rate per mille for 1936	Average death rate for preceding ten years 1926 to 1935	Increase or decrease as compared with 1935	Increase or decrease as compared with decennial average
Cholera ..	0.21	0.14	0.60	— 0.07	— 0.46
Smallpox ..	0.54	0.30	0.22	— 0.24	+ 0.08
Plague ..	0.47	0.15	0.72	— 0.32	— 0.57
Fever ..	19.20	17.60	18.44	— 1.60	— 0.84
Dysentery and diarrhoea.	0.38	0.34	0.36	— 0.04	— 0.02
Respiratory diseases.	0.95	0.89	0.77	— 0.06	+ 0.12
Injuries ..	0.41	0.44	0.44	+ 0.03	..
All other causes	2.61	2.75	2.77	+ 0.14	— 0.02
All causes ..	24.78	22.61	24.29	— 2.17	— 1.68

Cerebro-spinal meningitis.—The incidence of cerebro-spinal meningitis was low this year. There were 236 deaths from this cause compared with 756 in the preceding year. Of these, 207 deaths were reported from towns and 29 deaths from rural tracts.

Out of 439 towns, cases were reported only from 37. Mortality was most marked in the towns of Agra (51), Cawnpore (38), Lucknow (19), Meerut (15), Allahabad (12) and Muttra (11) while in the remaining 31 infected towns the number of deaths reported did not exceed 8.

The incidence of the disease in rural tracts of districts was very low. Mortality was reported from only 12 districts and the number of deaths reported did not exceed 8 in any case.

The majority of the cases occurred in persons between 10 to 35 years of age. Children under one year and persons over 55 years were the least affected. It was noticed that all communities were susceptible to the

year. In other infected towns and rural tracts of districts the number of deaths reported did not exceed 8 in any case. The disease has not yet been declared notifiable.

Malaria.—In 1936, malaria was responsible for 751,712 deaths as against 813,591 deaths in 1935 and the death rates for the two years were 15.53 and 16.81, respectively, while the recorded death rates from all causes for these years were 22.61 and 24.78, respectively. Malaria was responsible for about 70 per cent of the deaths registered from all causes.

Reporting under malaria is extremely defective and under the present system of reporting, particularly in rural areas, most of the fever cases are registered under this head. It is difficult to ascertain the direct mortality from malaria, but there is no doubt that mortality from this cause is certainly very large and forms a considerable proportion of the total number of deaths from all causes. Apart from the direct loss

due to deaths from malaria, it has also a marked indirect action in lowering the vitality of the sufferers and making them susceptible to contract other diseases. According to the figures supplied by the Inspector-General of Civil Hospitals, United Provinces, 1,497,346 patients were treated in all classes of dispensaries for malaria in the United Provinces during the year 1936 as compared with 1,174,745 patients in 1935, showing an increase of 322,601 patients in 1936. This increase is due to the epidemic outbreaks of malaria in 29 districts of the province during the autumn caused by unusually heavy rains and consequent flooding of the large rivers. These figures by no means represent the true index of malaria in the province and are only a fraction of the total sufferers from this disease. The figures given above with regard to deaths and sickness from malaria, however unreliable they may be, indicate that of all diseases malaria is the greatest problem of the country and anything done to fight this scourge will be a distinct economic gain to the State.

SCHOOL HYGIENE AND MEDICAL INSPECTION OF SCHOOL CHILDREN

The detailed examination of boys was conducted in 151 out of 161 Anglo-vernacular schools in the larger municipalities where whole-time officers are employed. The history sheets were filled for 20,500 boys, out of 54,000 on roll. Out of 508 primary and vernacular schools 175 were visited for 'ordinary' examinations, and out of 69,000 boys 15,000 were examined. About 3,000 boys were examined as 'special cases' and 7,000 were re-examined. These examinations were additional to a large number of parade inspections.

The percentage for all the main defects was over 71 in urban areas, if it is assumed that the defects were uniformly spread over all the boys and no boy had more than one defect in him. This figure for rural areas was over 38. It has also been calculated that roughly 28 per cent of boys had one defect, 11 per cent two defects and another 4 per cent more than two defects in urban areas so that there were not less than 43 per cent defectives to share all defects. These figures for rural areas were 18 per cent, 5.7 per cent and 2.8 per cent, respectively, giving a figure of 25.5 per cent defectives to share all defects. It may be remarked that the defect complex more or less remains, as the improvement in the health conditions found in schools has to be determined greatly by influences such as health education and home environment.

Anæmia.—Anæmia associated with the enlargement of spleen is due to malaria and in five years it has shown a marked fall from 3.5 per cent to 0.7 per cent in urban areas and from 7.2 per cent to 3.8 per cent in rural areas. The figures from anæmia due to other causes were comparatively small, although in 1932-33 the school health officer, Agra, reported that every seventh case of anæmia was due to intestinal parasites.

Skin disease.—The dirt diseases of the skin in urban and rural areas were 3 per cent and 3.4 per cent, respectively. The figures for rural areas showed a marked reduction as compared to 9 per cent originally and this is due to the activities of the Junior Red Cross movement in the districts.

Diseases of eyelids (Conjunctivitis and granulations).—In urban areas the incidence of these diseases was 5 per cent and in rural areas it was 6.5 per cent.

Effect of milk on poor nutrition.—The scheme of the free supply of milk to ill-nourished and poorer boys was tried in Agra, Lucknow, Cawnpore, Allahabad and Benares, where the central school dispensaries are situated. The school health officer of Cawnpore reported that each boy was given a quarter seer of milk in the middle of each working day in 10 schools, and monthly records of weight were kept and 150 boys profited by this arrangement. Although the data are meagre it is noteworthy that there was on an average an increase of 2.7 lb. in weight per head in three months' time compared with the average of 1.0 lb. of the controls, i.e., a net gain of 1.7 lb. per head. In one school the milk was discontinued after three months and a fall in the average gain was noticeable, the gain

being only 0.2 lb. above the average of 1.0 lb. of the controls.

In Lucknow the results of feeding on pasteurized milk in 14 schools on the same principle as in Cawnpore were worked out and showed gain in weight.

Encouraged by these results eight milk clubs were started in schools in Lucknow where the boys got milk from the Government military dairy farm on payment.

A free meal scheme was also carried out in one of the primary municipal schools of Lucknow and the same set of boys was fed by turns on whole milk, separated milk, gram, *moong*, soya bean and parched wheat and it was noted that the gain in weight was most marked when the boys were fed on milk or separated milk.

In Benares where pasteurized milk was supplied free to 290 boys with a total of about 21,000 meals of a quarter seer of the milk, over 90 per cent showed a marked increase in weight, the gain being greater among those who were less nourished.

Pasteurized milk in the same quantity as elsewhere was supplied to 252 boys in Allahabad.

REPORT OF THE SUDAN MEDICAL SERVICE FOR THE YEAR 1936

Yellow fever.—Survey work has been continued as follows:—

(1) The examination of liver sections from fatal cases of pyrexia of obscure origin. The tissue is obtained either by viscerotomy or at post-mortem examinations.

During the year 16 livers from all parts of the country have been examined histologically, but in no instances were the changes suggestive of yellow fever.

(2) Mouse protection tests.

(A) A series of sera was collected from the natives of the Eliri district of the Nuba Mountains, and forwarded to Dr. G. M. Findlay of the Wellcome Bureau of Scientific Research, London, for mouse protection tests.

The results were as follows:—

Of 27 sera from Eliri 12 (44 per cent) were positive and 15 (56 per cent) were negative.

Of 18 sera from Lafufa 5 (28 per cent) were positive and 13 (72 per cent) were negative.

Of 5 sera from Nyaro 3 (60 per cent) were positive and 2 (40 per cent) were negative.

Of 38 sera from Kau 30 (79 per cent) were positive and 8 (21 per cent) were negative.

Of 31 sera from Heiban 3 (10 per cent) were positive and 28 (90 per cent) were negative.

Of 39 sera from Gulfan 8 (21 per cent) were positive and 31 (79 per cent) were negative.

The results indicate that there has been a widespread infection with the virus of yellow fever throughout the Nuba Mountains during the last 20 years, the youngest individual in whom a positive was obtained being 12 years of age. Careful investigations, however, have not so far discovered any clinical cases of yellow fever. The results at Kau are particularly interesting where almost 80 per cent of the population have positive sera, but where there is a complete absence of any history of jaundice or other suggestive clinical condition. The evidence at present is that the infection is entirely subclinical, but a permanent dispensary has been established at Kau with a view to obtaining as completely as possible a medical history of the population throughout the year.

Another interesting point, which it is hoped to investigate more fully, is the striking difference in the percentage of positive sera in adjacent and apparently similar districts.

(B) During the year the mouse protection test has also been carried out on the sera of a number of cases of obscure febrile jaundice. Of 25 cases examined two, one from Malakal and the other from Medani, have given positive results. As the sera of these cases were not examined at the onset of the illness, these results are of little significance, the available evidence suggesting that they were due to some previous infection.

(C) Results of idouse protection test with animal sera.

Monkeys—14 *Cercopithecus aethiops* and 1 *Cercopithecus phyrhonoris* have been tested. The latter was negative, and of the former one was positive and 13 negative. Unfortunately it was not possible to determine the original habitat of the monkey whose serum was positive.

Cows—Sera from 13 cows from Khartoum, White Nile and Western Kordofan have been examined. Those from Khartoum and the White Nile were negative, while of those from Kordofan 2 out of 4 were positive both of which came from areas where positive human sera have been found previously.

Investigations are being continued on these lines, and extended to include other species of wild and domestic animals.

ANNUAL REPORT OF THE MYSORE STATE DEPARTMENT OF HEALTH FOR 1936

THE state of public health was satisfactory in the year under report. A decline in the incidence of plague was observed, and, as compared with the previous year, a big fall in the mortality from smallpox was registered. Cholera, which had been forecasted by the department months in advance, showed a small rise towards the end of the year, and adequate measures were undertaken to prevent its spread. The total mortality during the year amounted to 96,278 deaths, giving a death rate of 14.31 per mille of population; and the reported births numbered 1,36,569 with a birth rate of 20.31, the death and birth rates in the previous year being 14.54 and 20.45, respectively.

Studies made during the year have shown that cholera is likely to spread into the State from outside, and therefore in an effective control of the outbreak of this disease it will be necessary to give protected water supplies to the villages within a belt of about 10 miles along the frontiers. Action has already been taken in this connection and Rs. 2,600 has been sanctioned under the rural water supply scheme for sinking wells in 8 such villages.

The statistics of malaria deaths collected during the year show definitely that nearly a third of the deaths reported are due to malaria. It is important therefore that immediate steps should be taken to relieve the situation. In this connection, it may be noted that the District Board, Shimoga, distributed about 20,000 quinine pills in badly-infected villages at a cost of Rs. 500. But many of the sufferers are without any sort of treatment either because of distance from the nearest dispensary or for want of helpers to fetch the medicine. Anti-mosquito measures in villages will take money and time and it is obvious that free distribution of quinine should be immediately undertaken among the needy. The distribution could be made by the village *panchayets*, the revenue department through the revenue inspectors and the health department through the sanitary inspectors and vaccinators.

The scheme for the experimental control of malaria in 10 villages in the Irwin Canal Area sanctioned in 31st January, 1935, with the co-operation of the Rockefeller Foundation for a period of one year, was sanctioned for a further period of one year financed solely by the Government.

On a co-operative basis between the Government and the Rockefeller Foundation, the Government sanctioned the organization of a health training centre at Closepet, the entire cost being met by the Government after a period of five years.

A committee was appointed to examine the question of correct registration and compilation of vital statistics in Mysore State and the statistics of maternity and child welfare. The committee have submitted their report to Government for consideration.

Health exhibitions on a large scale were organized on the occasion of the Health and Baby Week in Bangalore city in May. It is proposed to make such exhibitions

a great success in future with the addition of models on the various aspects of public health work.

The League of Nations Commission for Rural Health visited Mysore, Nagenhalli, Mandya and Closepet in the latter part of the year and saw the progress made in rural health and malaria control work.

Maternity and child welfare.—Dr. Jean M. Orkney, Director of Maternity and Child Welfare Bureau, Indian Red Cross Society, New Delhi, visited the State and saw the activities of welfare centres in Mysore and Bangalore cities and in a few rural areas.

Government have approved of four types of maternity homes:—

- (i) Maternity home for a village.
- (ii) Maternity home for a village combined with quarters for a midwife.
- (iii) Maternity home for a village combined with a child welfare centre and quarters for a midwife, and
- (iv) Maternity home for a village combined with a child welfare centre and quarters for a midwife and a dispensary.

Baby weeks were held during the year in 43 places excluding Tumkur district under the auspices of the Red Cross Society, the village *panchayets*, the district boards and municipalities. The organizer attended 12 of these as against 16 in the previous year. Baby weeks, when held, should serve the purpose of evaluating the working of infant and child welfare centres working during the previous year and focus the attention of the general public in health matters.

A number of special circumstances combined to make the year 1936 an exceptionally busy one. In the first place, there was the distribution by the Government of the whole of the Silver Jubilee Fund, added to which was the munificent donation of Rs. 25,000 by Her Excellency Lady Willingdon for an anti-tuberculosis dispensary. In the second place, the year witnessed the commencement of the Government's drive for village improvement in selected villages, the promotion of maternity and child welfare work being one of the principal items of this programme. In the third place, there has been quite a remarkable wave of enthusiasm for the work of the kind on the lines of the programme that was worked out in 1935, and donors and other promoters of schemes for maternity homes and similar buildings are coming forward in such numbers that it has put quite a strain on the staff to organize and adjust the claims of the various competing schemes.

Health education.—During the year 165 cinema shows were organized, as compared with 178 in the previous year, and approximately 88,000 persons attended these shows. The Publicity Officer in charge explained the films in Kanarese.

A film on leprosy prepared with local settings under the auspices of the State Leprosy Relief Committee was handed over to the department for demonstration in different parts of the State. It is proposed to purchase a new film on maternity and child welfare from the Public Health Department, Madras Presidency.

As in previous years a Health Stall was put up at Mysore in connection with the Annual Swadeshi Exhibition and the Dasara Exhibition. Similar stalls, on a smaller scale, were also put up at the Health and Baby Shows at Mandya and Mugur. In connection with the Health and Baby Week in Bangalore city in May, a Health Exhibition was organized representing the activities of the various sections of the department.

Health training centre.—The activities of the Health Training Centre at Closepet began in May with the co-operation of the Rockefeller Foundation.

The Health Officer was deputed to Ceylon for a month during November and December and in his absence Mr. S. Ramachandra Rao was in charge of the Centre.

The area of the Centre comprises 113 square miles with a population of 50,673 distributed in 72 main and 63 dake villages in five divisions.

The sanitary inspectors, during the year, paid 1,909 visits to their villages at the rate of between 1 and 2 visits per village per month.

As part of public health propaganda, the sanitary inspectors gave 4,202 talks on various health topics to a total audience of 53,460 persons, the average attendance being 13. It was found difficult to get the people to attend these talks and the usual method of talking to the groups that collected around the staff during their visits to the villages had to be adopted. It will be possible to organize systematic lectures in future with the attraction afforded by the magic lantern.

Chlorination of all the wells in the area was started in October and all the 1,273 private and 177 public wells were treated with perchloron by the end of December. It is proposed to chlorinate the wells once every quarter.

To collect whatever information was available and to see to what extent these figures were dependable were two of the problems that had to be attended by the staff at the outset. The procedure adopted is as follows: In order to estimate how many occurrences actually miss being reported, the sanitary inspectors undertake an intensive itineration of all the villages during the second week of every month, collecting the detailed information regarding births and deaths through personal enquiry. After having thus collected the information independently, they check the patels' registers and note down the number of occurrences that have escaped entry.

In the last five months of 1936, 314 out of a total of 913 births (or 34.4 per cent) and 138 out of a total of 452 deaths (or 30.5 per cent) were missed by the patels.

Vital statistics.—During the year, a special committee was appointed by Government for examining the question of improving the registration and compilation of vital statistics in Mysore State. The committee considered the various aspects of the problem and have submitted their report to Government for orders.

As indicated in the previous report, the figures returned under the following causes, for the second year of reporting, show definitely that the registration of vital occurrences by the agency of the patels is not unacceptable:—

Causes	Deaths in 2nd year of reporting (1936)	Deaths in 1st year of reporting (1935)
Malaria ..	29,995	24,643
Typhoid ..	4,856	4,071
Consumption ..	4,892	4,510
Leprosy ..	870	714
Child-birth ..	2,128	2,205
Drowning ..	865	779
Snake-bite ..	163	154
Rabies ..	68	54

Although somewhat incomplete, these figures may be taken to indicate their relative magnitudes so far as the State is concerned. The fact that so few deaths have been reported as due to leprosy and rabies, both in 1935 and in 1936, shows beyond doubt that the statistics reported by the patels are, and can be proved to be, not untrue.

THE NAIR HOSPITAL DENTAL COLLEGE, BOMBAY: FOURTH ANNUAL REPORT, 1936-37

THIS report records another year of steady progress in every respect. More students are being taught, further equipment has been added and the number of patients treated has risen from 8,554 to 9,727 in the course of the last year. This college appears to be now firmly established and as the years pass its value to Bombay in particular and India in general should become evident as in training dental surgeons it is producing a type of professional man of which there are all too few in India at present.

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1936*

VOLUME I

Public health.—The provision of a sanitary environment forms the foundation on which alone the superstructure of public health can safely be built. The supply of wholesome water, efficient removal and disposal of refuse and nightsoil, the suppression of nuisances, public cleansing, improved housing and the inspection of food supplies—these are some of the basic requirements of a community if it is to maintain a reasonable standard of health.

There can be little doubt, that, if local bodies devoted the necessary funds towards the provision and maintenance of protected water-supplies, they would obtain more than an adequate return in terms of better health for the populations under their care.

The provision of markets and slaughter houses and their sanitary supervision form an important function of local authorities, both urban and rural.

Even where markets of a reasonably sanitary standard are in existence, the local authorities concerned frequently fail to prohibit the sale of food in unauthorized places and take no steps to prevent food contamination.

Rural health centres serve the purpose of testing out methods of rural health administration and of arriving at probable estimates of cost, while they also afford excellent opportunities for the field training of public health workers and students.

But rural health problems cannot be solved by public health measures alone and no scheme for rural development can be considered adequate unless it provides for a many-sided attack on the physical, social, economic and educational aspects of village life. The suggestion is, therefore, made that a Rural Development Council should be formed at the headquarters of each province, with a district council for each district.

Adulteration of food is another matter of considerable importance, which calls for attention. Unfortunately, however, in most provinces, no food adulteration act is in force in rural areas and, even in urban areas, where legal provisions exist, their enforcement leaves much to be desired. In some places, 50 per cent or 60 per cent of the samples taken were found to be adulterated, whilst, with respect to individual articles, the percentage was even higher.

A school medical service is one of the most important parts of public health administration. Experience all over the world has shown that the provision made for the health of the school child, by periodical examination and the correction of defects, has proved to be a sound investment in respect of betterment of the national health.

In some provinces attempts have been made to supplement the diet of poorly nourished school children by the free supply of milk or of midday meals, but these have been tried in very limited areas only.

In order that mal-nutritional defects—now known to be common—should be corrected and that systematic medical care of school children should be taken, rapid development of school medical services on an adequate scale is urgently required all over the country.

Central health board.—Experience has indicated the necessity for continued co-ordination of effort, not only for the exchange of ideas, but also for the formulation

*The annual report of the Public Health Commissioner with the Government of India for the year 1936, Volume I, is now on sale with the Manager of Publications, Civil Lines, Delhi. It is also obtainable from Provincial Government Book Depôts and from private booksellers who stock Government publications.

With a view to facilitating its purchase by local bodies, health officers, medical officers and private individuals a specially reduced price of rupees two per copy, inclusive of packing and Indian postage, has been fixed for this publication.

of reasonably uniform lines of development. To serve these purposes a central consultative body, the Central Advisory Board of Health, was formed last year, on which are represented the Health Ministers of all the provinces assisted by their principal health and medical advisers. The machinery for co-ordinating public health work in India has thus been established and it may be anticipated that the coming years will witness increasing progress in every phase of public health activity.

Mortality.—Of a total of nearly 6,400,000 deaths or 23 per mille in British India in the year 1936, which is the latest year for which consolidated figures are available, approximately 160,000 or 0.6 per mille were from cholera, 105,000 or 0.4 per mille from smallpox, 13,000 or 0.05 per mille from plague, 3,600,000 or 12.7 per mille from 'fevers', 280,000 or 1.0 per mille from dysentery and diarrhoea, 490,000 or 1.8 per mille from respiratory diseases, and 1,730,000 or 6.1 per mille from other causes.

Plague.—Deaths from plague during the year were the lowest on record since 1896 when plague first came into India. Of the provinces, the N. W. F. Province, Delhi, Orissa, Assam and Ajmer-Merwara were completely free of the disease, the United Provinces was the worst affected, recording about 56 per cent of the total mortality in British India.

Cholera.—Cholera mortality also fell during the year by about 57,000. The decrease in incidence was common to most provinces, the important exception being Bengal where the mortality was 1.5 per mille or 25 per cent higher than that of the previous year.

India, however, unhappily still continues to live up to its evil reputation of being the important world reservoir of cholera infection.

Provincial public health staffs have generally done good work within recent years in the sanitary control of the numerous fairs and religious festivals, which are held all over the country. Whilst previously it was common for explosive outbreaks of cholera to occur at these centres and to be followed by widespread infection, the elaborate precautionary measures now generally in force have largely been effective in preventing dissemination of the disease from these dangerous foci.

Smallpox.—In the Philippines, the rigorous enforcement of vaccination has been followed by the almost complete elimination of the disease. 'After vaccination of the inhabitants of the six provinces in the vicinity of Manila, which had an annual mortality of 6,000 from smallpox, the deaths from this disease were reduced to insignificant numbers. In Manila, with a population of over 250,000, not one death from smallpox occurred in a period of seven years. More than 10 million vaccinations were performed between 1905 and 1915 without loss of life or limb, showing that vaccination in itself is practically unattended with any risk.'

India recorded over 100,000 smallpox deaths during 1936. Among the individual provinces, Bengal reported the largest mortality, deaths numbering about 46,000 or 44 per cent of the total recorded in British India. Compared with 1935, the increase was as high as 800 per cent.

Only about 49 per cent of infants available for vaccination in British India were successfully vaccinated during the year. This figure indicates how much remains to be done and when it is noted that in Assam, Bengal, Bihar, Orissa and Madras the percentages are as low as 22 to 37, it is evident that the vaccination staffs of these provinces have still got a large leeway to make up, but unfortunately no public health department is sufficiently manned to enable it suitably to deal with the whole of the population under its control.

Further, vaccination is compulsory only in about 75 per cent of the towns and in less than 50 per cent of the rural areas and the enforcement of law leaves much to be desired even in compulsory areas.

Fevers.—'Fevers' were responsible during the year for nearly 56 per cent of the total mortality. It no doubt mainly consists of deaths from malaria, but it

also includes large numbers of deaths from other diseases in which fever is a prominent symptom.

Malaria.—An estimate is made that the annual deaths from malaria in British India total 1½ millions and that about a hundred million persons suffer from this disease each year. During the past decade, cholera, smallpox and plague, the three infectious diseases which generally attract most notice, were together responsible for about 357,000 deaths each year, a figure which is less than one-third of the annual toll of life taken by malaria.

No satisfactory general method of bringing malaria under rapid and effective control in rural areas at a cost within the means of the people has, however, been evolved in any malarious country in the world, as the Director of the Malaria Survey of India remarks. The policy to be adopted must therefore be directed to such amelioration of conditions as may be practicable rather than to expensive methods of control, and with this end in view, every effort should be made, in the first place, to encourage the consumption of quinine.

A special grant of Rs. 10 lacs was given in 1935-36 by the Government of India to the Indian Research Fund Association mainly for anti-malarial work.

It is estimated that India's probable annual requirements of quinine for the purpose of effective mass treatment amount approximately to 600,000 lb. Her present consumption is only about a third of this quantity, of which nearly 110,000 lb. are imported and 90,000 lb. are produced in the country. Any cheapening of the cost of quinine is, therefore, dependent on a considerable expansion of India's production.

Tuberculosis.—There is strong evidence that tuberculosis, particularly of the pulmonary type, has markedly increased within recent years in certain areas. The most urgent need is the provision all over the country of a chain of tuberculosis clinics where skilled treatment and advice can be obtained from trained staffs of medical officers, nurses and home visitors, increase in the number of beds in hospitals and establishment of sanatoria for tuberculosis cases and the institution of tuberculosis colonies and settlements at a later stage.

No national effort on these lines and of the magnitude necessary for this country can be successfully undertaken without the fullest co-operation of the people, of the provincial governments, local authorities and voluntary agencies.

Leprosy.—In India, the incidence of the disease is highest along the eastern coast of the peninsula and in the western parts of Bengal. From the eastern belt of high prevalence the disease gradually diminishes in incidence to the north and west, until a fairly wide area of comparative freedom from the disease is reached, comprising the northern half of Bombay Presidency, including Gujarat, Rajputana, the western portion of the United Provinces, the Punjab, the N. W. F. Province, Sind and Baluchistan.

Within recent years, a considerable expansion of treatment activity has resulted from the provision of leprosy clinics in different parts of the country, but whilst present methods of treatment are of undoubted value in a proportion of cases, the leprosy problem cannot be solved by treatment alone.

Cancer.—If more reliable data were available, the prevalence of cancer in India would be found to be little different from that of Western countries.

Though no definite campaign has so far been planned, radium is available in four or five institutions, including the Lady Hardinge Medical College, New Delhi, the Radium Institute, Patna, Bihar, the Chittaranjan Seva Sadan and the Bengal Cancer Institute, Calcutta, and the Barnard Radiological Institute in Madras.

Maternity and child welfare.—Maternity and child welfare work has made notable advances since its inception as a national movement in India in 1918, but there are still large gaps in the services, particularly in the field of obstetrics, which must be filled before material improvement in the health of the nation can be assured.

Sufficient information is now available, as the result of special inquiries, to show that maternal mortality in India is probably five or six times as high as that of England, and when it is remembered that a high death rate implies a correspondingly high rate of sickness, the extent of suffering and invalidism which child-bearing causes in India can well be imagined.

Apart from beds for abnormalities arising during pregnancy, labour and the lying-in period, beds are also required for women whose domestic surroundings are unsuitable.

Increasing numbers of women are now seeking admission to hospitals for confinement, and this demand is being met to a certain extent by the establishment of maternity homes, which are often unsatisfactory from the point of view of equipment and skilled attendance. The movement is, therefore, not without risk, and some control of the standards and methods of these institutions would seem to be necessary if the lives of mothers are to be suitably safeguarded.

Maternity and child welfare schemes are based on a system of home visiting, of ante-natal and post-natal clinics and centres, where infant and pre-school child consultations are conducted and classes can be arranged for the mothers. Each year shows a diminution in the number of so-called welfare centres staffed by untrained workers. The primary objects of maternity and child welfare work are to educate parents in the nurture of a healthy race and to prevent disease, and these objects can be achieved only by the employment of trained health workers.

The trained health visitor is the vital unit in any maternity and child welfare scheme, just as home visiting is the basic service for which she is responsible.

The contributions hitherto made by voluntary organizations and individuals have been of great value, but a stage has now been reached when responsibility for the training of workers and the technical direction of the work should be assumed by governmental departments.

Research activities.—A study has been made for the last four years, and is still in progress, of the organism responsible for cholera, and considerable advance has been made with respect to the identification of the true cholera organism as distinguished from various related organisms found in tanks, rivers and other water supplies all over the country. These investigations have been in the nature of a co-ordinated study in which a number of different laboratories took part and a second form of attack is being made on the problem through field enquiries.

Another important line of study has been that of the rôle of the fly in the causation of cholera. Work on this subject is still in progress in more than one province.

Researches have also been carried out on the problem of malaria. Along with other subjects these included (1) study of the life-history of malaria-carrying mosquitoes, (2) testing of the value of certain anti-malarial drugs, (3) investigation of the conditions under which transmission of the disease takes place, (4) malaria surveys, (5) malaria control experiments in different groups of villages and (6) investigations into the causation and cure of the dreaded condition known as blackwater fever, which is frequently associated with hyperendemic malarious regions.

A serum for the treatment of plague patients has been prepared and is now under field trial. The results so far obtained have been quite hopeful, but further research is required before it can be said that a new weapon has been found for the fight against this disease.

The causes underlying the recrudescence of plague after periods of freedom from infection have been under investigation, present conditions providing a favourable opportunity for such studies in view of the comparatively low prevalence of the disease.

Field studies with cyano-gas have been going on for some time.

Work done in the different laboratories have covered a very large field and has included such widely different subjects as the action of snake venoms, drug addiction,

filariasis, cancer, trachoma and epidemic dropsy, to mention only a few.

Hospitals and dispensaries.—The number of hospitals and dispensaries of all classes in British India during the year was approximately 6,900 and the average population served by each institution is nearly 41,000. Whilst the average population served by each institution in urban areas reached the maximum of 20,000 in Delhi Province, the corresponding number of rural areas was as high as 124,000 in the U. P. and 104,000 in Bombay Presidency. These figures indicate the urgent need for an extension of rural medical relief.

Correspondence

A GAS MASK FOR POST-MORTEM WORK

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—To those whose lot it is to perform post-mortem examinations on decomposed dead bodies in the hot damp weather it may be of interest to hear that I have found a gas mask of great value in this type of work. It affords complete protection against all foul-smelling gases and permits of a thorough examination in circumstances where ordinarily such examination would be almost unbearable due to foul odours.

The gas mask used has been purchased from the Chief Ordnance Officer, Allahabad Arsenal, for Rs. 17-5-6 plus freight and is the Regulation Army Respirator Anti-Gas Mask IV.

To my knowledge a gas mask has not been used for this purpose before nor is it mentioned in any of the commonly used textbooks on jurisprudence in this connection. This is the justification for sending in this note.

Yours, etc.,

S. AHMAD, M.B., B.S. (Punj.),
F.R.C.S. (Eng.), L.R.C.P. (Lond.),
CAPTAIN, I.M.S.,
Civil Surgeon.

SITAPUR,

23rd August, 1938.

ANAHÆMIN IN TROPICAL MACROCYTIC ANÆMIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In a paper entitled 'Anahæmin in Tropical Macrocytic Anæmia' published in your July issue of this year, Napier and others refer to my review of the work of Dr. Lucy Wills and her co-workers (1937) which showed that in the nutritional macrocytic anæmias of monkeys the more highly purified liver extracts might be less efficacious than the less purified ones. The quotation ends as follows in inverted commas, 'In the reviewer's experience no clinical evidence of this danger is at present available...' It is unfortunate that the rest of the quotation was not given in the paper and that it was not made plain that my remarks referred to Addisonian pernicious anæmia and not to tropical macrocytic anæmia. The insertion of the remaining lines of my review in the 1938 *Medical Annual* makes this plain, for it continues—'Since, the improvement in the blood and central nervous system changes of his patients with pernicious anæmia has been as great and as quickly and easily produced with the recent highly purified preparation anahæmin as with the less purified preparation campolon'. This is the opinion also of Murphy of Boston who uses the highly purified extract made by the Lederle Company in 1 c.c. doses, and by Ungley of Newcastle and other leading hæmatologists in this country. This statement does not deny the possibility that the less highly

purified preparations might be more efficacious in tropical macrocytic anæmia.

Dr. Napier is working on a very valuable problem in trying to separate the large group of tropical macrocytic anæmias into smaller divisions by means of the therapeutic test. The difficulties are obviously great as judged by the variable and inconsistent responses which are reported in the different cases. It is difficult to compare different liver extracts with one another unless they are both used on a single case because of the variable response which individuals show to treatment. Another difficulty lies in reckoning what should be considered comparable doses of the different liver extracts to be tested; for instance, in case 8 conclusions are drawn in regard to the increased activity of campolon compared to anahæmin when the patient received only 2 c.c.'s of anahæmin as compared to 20 c.c.'s of campolon. Probably the same criticism is applicable to case 9, but unfortunately the number of days on which 4 c.c.'s of campolon was given is not stated.

Lastly, I would draw attention to the fact that batches of anahæmin were placed on the market last year which were of low potency. Some of our cases of pernicious anæmia showed little or no response to 2 to 4 c.c.'s of anahæmin. I understand that the potency of anahæmin at present on the market is extremely high. If therefore Dr. Napier and his colleagues had been so unfortunate as to use a batch of anahæmin of poor quality, this would be another factor in making it difficult to assess the comparative value of different liver extracts in the treatment of tropical macrocytic anæmia.

Yours, etc.,

L. S. P. DAVIDSON, B.A., M.D.,
M.R.C.P., F.R.C.P.E., F.R.S.E.,

Regius Professor of Medicine,
University of Aberdeen,
Practice of Medicine Department.

FORRESTERHILL,
22nd September, 1938.

[We are very pleased to get this opportunity to apologize for what we now see to have been an unjust criticism of Professor Davidson's review of Dr. Lucy Wills' work. The apology is not on account of the incompleteness of the quotation in question; in this matter we had no intention of misleading the reader. The paper Professor Davidson was reviewing was mainly concerned with experiments in nutritional anæmia of monkeys and the arguments in this paper were mostly applied to tropical macrocytic anæmia by analogy, but what we had overlooked was that Dr. Wills and her collaborators had specifically suggested that there might be some cases of pernicious anæmia 'which would either not respond to anahæmin or make a poor temporary response, but would respond to the cruder preparations such as campolon'. This of course makes Professor Davidson's remarks both relevant and necessary.

Another point he raises is in connection with the different dosages. We ourselves drew attention to this weakness in our conclusions. However, other workers have shown that very much smaller doses than we gave, as low as 25 milligrammes, will produce a reticulocyte response in pernicious anæmia. We did not give more than 200 mgm. because at that time our supply of anahæmin was very limited. In case 9 to which he refers, he is correct in assuming that a large total dose of campolon was given (this is clearly shown in the chart which is drawn to scale), but the early reticulocyte response indicated that it was the first or possibly the first two injections that produced this effect.

The last point that he raised was gone into very carefully by myself personally in London when I visited the laboratories of the manufacturers. Our supplies were obtained directly from the agents in India and there seems little chance that any of the samples were of low potency. Further, our findings have been confirmed subsequently by Drs. Wills and Evans.

The manufacturers have generously given me a further larger supply of anahæmin to continue this work. This has enabled us to give larger doses with the result that in a number of cases we have obtained a sharp response, comparable to that hitherto obtained with campolon, though we have also confirmed our previous observations regarding its failure in certain other cases, even when large doses are given.

L. E. NAPIER, J

CONGENITAL ABSENCE OF EYEBALLS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—A girl of 3 days age has been brought to me, as she never opened eyes since birth. I find that the eyeballs are absent. This is a very rare case of congenital absence of eyeballs. This may please be published for record.

Yours, etc.,

ABDUL AZIZ, M.B., B.S., P.C.M.S.,
Assistant Surgeon.

SHAHPUR,
22nd August, 1938.

CHLOROFORM AS A LOCAL ANÆSTHETIC

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Using chloroform as a local anæsthetic, I have done about 40 tooth extractions including the digging out of stumps by elevators and the use of the gum lancet, and also opened a few abscesses on other parts of the body. The results have been uniformly good, indeed almost dramatic in some instances for the patient, the onlookers and the operator. The object is achieved in an incredibly short time with but little pain and hardly any other effects.

The method is as follows:—

A piece of lint soaked in chloroform is wrapped round the tooth and gum, or applied to the abscess for about 2 or 3 minutes. This secures sufficient anæsthesia for a quick operation. Those who have used the syringe and one of the novocain preparations for local anæsthesia know how patients dread the 'poke'. Indeed the operation of securing anæsthesia is more painful than the actual extraction or the incision. This is understandable because the tissues are inflamed all round and the slightest touch, and much more a jab, is exquisitely painful. Patients would prefer general anæsthesia, if they were convinced that there would be no danger to life and no after-effects; this is my personal feeling too as a patient. In addition I consider the effects of hypodermic anæsthesia are erratic, varied, and in general unreliable.

How chloroform acts when applied in this method of local anæsthesia I do not know. It seems to me that it acts as a local cellular poison paralysing the end-plates. I have found that ether similarly applied is not nearly so effective; indeed its effects, if any, are evanescent and its use painful, probably due to the contraction of the muscular coat of blood vessels preventing access of the anæsthetic to the end-plates and causing pain by local syncope. Ethyl chloride acts like ether but is more unpleasant.

I am of opinion that unless 'nerve block' is secured by the use of syringe and novocain local anæsthesia by their use is bound to be untrustworthy and painful because it depends entirely on luck for striking the end-plates. Beginning with hypodermic or intra-dermal anæsthesia I have had on many occasions to resort to general anæsthesia. Perhaps, my technique for the production of local anæsthesia by the syringe was faulty.

There is one thing, however, which may tend to take away a little from the usefulness of the method now advocated. Is it not possible that 'suggestion' has played some part in the success that has attended my cases? My first few cases, on whom I used chloroform in this way, may have been exceptionally strong men, quite impervious to pain, and who would not have winced, even if no anæsthetic had been used. Firmly

convinced myself, it may be said, by auto-suggestion, I tell my patients that they will have no pain. The experience of others may determine if 'suggestion' plays a part in the successful results obtained. The speed with which the operation is performed seems to me to be a very important element in the use of this method of local anaesthesia. It would almost appear as if I depend mostly on suggestion and speed.

However produced the anaesthesia has been good and it is considered the method is worthy of further trial.

Yours, etc.,

G. B. S. CHAWLA,

MAJOR, I.M.S.,

Officiating Commanding, Combined
Indian Military Hospital.

LANDIKOTAL,
10th May, 1938.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL W. H. HAMILTON, C.B., C.I.E., C.B.E., D.S.O., K.H.P., to be Officiating D. M. S. in India. Dated 11th August, 1938.

The services of Major-General N. M. Wilson, O.B.E., K.H.S., are replaced at the disposal of the Government of Madras, with effect from the forenoon of the 17th September, 1938.

Colonel C. A. Wood, M.C., to be Officiating A. D. M. S., Peshawar District. Dated 6th August, 1938.

Colonel F. F. S. Smith to be Officiating D. D. M. S., Northern Command, in addition to his other duties. Dated 11th August, 1938.

Lieutenant-Colonel B. Prasad to be O. C., I. M. H., Alipore. Dated 10th August, 1938.

Lieutenant-Colonel J. E. Ainsley reverted from civil employment, on 3rd August, 1938, from Central Provinces.

Lieutenant-Colonel M. S. Joshi to be O. C., C. I. M. H., Landikotal. Dated 14th August, 1938.

Lieutenant-Colonel W. P. Hogg, D.S.O., M.C., an Agency Surgeon, is employed as Chief Medical Officer and Inspector-General of Prisons in Baluchistan, with effect from the forenoon of the 22nd August, 1938.

The services of Lieutenant-Colonel B. H. Kamakaka, M.C., are replaced at the disposal of His Excellency the Commander-in-Chief in India, with effect from the forenoon of the 22nd August, 1938.

On return from leave Lieutenant-Colonel H. Chand assumed charge of the Office of Civil Surgeon, Sialkot, on the 21st September, 1938.

Lieutenant-Colonel J. H. Smith, on return from leave, was appointed Civil Surgeon, Maymyo, from the forenoon of the 27th September, 1938, *vice* Major R. McRobert transferred.

Lieutenant-Colonel J. Findlay was appointed to officiate as Inspector-General, Civil Hospitals, Burma, from the 27th September, 1938, forenoon, *vice* Colonel N. S. Sodhi who proceeded on leave.

Lieutenant-Colonel I. S. Nalwa was appointed Officiating Inspector-General of Prisons, *vice* Lieutenant-Colonel J. Findlay.

The services of Lieutenant-Colonel R. C. Clifford, M.C., D.S.O., are placed at the disposal of the Chief Commissioner, Delhi, for appointment as Civil Surgeon, New Delhi, with effect from the 15th October, 1938.

Lieutenant-Colonel J. M. R. Hennessy, Civil Surgeon, on return from leave, is re-posted to Jubbulpore.

On return from 8 months and 1 day's leave (29 days' leave cancelled), Lieutenant-Colonel A. H. Shaikh is posted to Bareilly Central Prison, *vice* Major G. D. Malhoutra.

Major S. D. Gupta to be Specialist in Radiology, Deccan District. Dated 4th August, 1938.

Major M. K. Kelavkar, M.B.E., is appointed Assistant Director-General, Indian Medical Service (Stores), with effect from the forenoon of the 28th October, 1938.

Major W. Scott, on return from leave, is posted as Civil Surgeon, Amraoti.

The Notification placing the services of Major H. W. Mulligan at the disposal of the Government of Madras is hereby cancelled.

Major R. McRobert was appointed Civil Surgeon, Prome.

Major V. S. Rao Pandit was posted to the charge of the Rangoon Central Jail, in place of Lieutenant-Colonel I. S. Nalwa.

Major G. R. M. Apsey, on return from leave, was appointed Civil Surgeon, Akyab.

The services of Major G. D. Malhoutra, Superintendent, Central Jail, Bareilly, have been transferred from the Jail Department to the Medical Department. He has been posted as Civil Surgeon, Shahjahanpur.

The Secretary of State for India has appointed the undermentioned officers to the Indian Medical Service (Civil), with effect from the dates specified against their names, and they are placed at the disposal of the Government of Burma from the same dates:—

Captain S. W. Allinson. Dated 17th April, 1938.

Captain J. G. Stonham. Dated 18th May, 1938.

Captain W. W. Laughland to be Officiating Mental Specialist, Southern Command. Dated 12th August, 1938.

Captain V. E. M. Lee, reverted from civil employment, on the 19th August, 1938, from Central Provinces.

Transferred to civil employment

Captain L. Feinholz on 6th August, 1938, as Surgeon to H. E. the Governor of Bombay.

Captain W. B. Stiver on 28th August, 1938, to Bihar.

Captain E. Parry was transferred to military employment in Burma, with effect from the 28th August, 1938.

Captain D. K. L. Lindsay, on return from leave, was appointed Civil Surgeon, Shwebo.

Captain V. Srinivasan, Civil Surgeon, Jubbulpore, is transferred to Bilaspur.

LEAVE

Colonel N. S. Sodhi was granted 4 months' leave from the forenoon of the 27th September, 1938.

Lieutenant-Colonel A. J. D'Souza is granted 10 months' leave, from the 1st October, 1938.

Major R. A. Wesson, Civil Surgeon, Moradabad, has applied for 2 months' extension of leave, in continuation of 8 months' leave previously granted to him.

Major G. J. Smith was granted 7 months and 15 days' leave, from the 2nd September, 1938.

Major E. S. S. Lucas, Civil Surgeon, Agra, proceeded on 4 months' leave, with effect from 3rd September, 1938.

Major H. W. Farrell, an Agency Surgeon, is granted leave on average pay for 6 months combined with study leave for 4 months, with effect from the afternoon of the 17th September, 1938.

Major F. M. Collins, Acting Principal and Professor of Surgery, Medical College, and First Surgeon, King George Hospital, Vizagapatam, is granted leave for a period of 8 months, with effect from the 17th November, 1938, or date of relief, whichever is later.

Major E. G. Montgomery, Civil Surgeon, Dacca, is granted leave for 15 months, with effect from the 23rd October, 1938, or from any subsequent date on which he is relieved.

Captain J. P. J. Little proceeded on 10 months' leave, from the 8th September, 1938.

PROMOTION

Captain to be Major (Provl.)

A. K. Gupta. Dated 15th July, 1938.

Captains to be Majors

V. E. M. Lee. Dated 1st August, 1938.

G. B. W. Fisher. Dated 2nd August, 1938.

E. P. N. M. Early. Dated 6th August, 1938.

W. McAdam. Dated 6th August, 1938.

G. F. Condon. Dated 15th August, 1938.

V. Srinivasan. Dated 25th August, 1938.

Dated 1st December, 1938

H. S. Smithwick.

D. Tennant.

D. P. Mitra.

N. J. U. Mather. Dated 18th September, 1938.

B. S. Sandhu. Dated 26th September, 1938.

W. Laurie. Dated 8th June, 1938, with seniority from 10th September, 1937.

RETIEMENT

Lieutenant-Colonel H. G. Alexander. 16th August, 1938.

Lieutenant-Colonel E. H. V. Hodge, C.I.E., 28th August, 1938.

Lieutenant-Colonel H. K. Rowntree, M.C., 22nd September, 1938.

RELINQUISHMENT

On the expiry of his tenure of office, Lieutenant-Colonel W. M. Will will relinquish his post as Assistant Director-General, I. M. S. (Stores), with effect from the forenoon of the 28th October, 1938, and proceed to Bombay to assume charge of the Government Medical Store Depot, Bombay.

Lieutenant (on probation) G. K. Beatty relinquishes his probationary appointment, with effect from the 2nd August, 1938.

RESIGNATION

Captain C. L. Ash resigns his commission, with effect from the 26th June, 1938.

DISCHARGED

Captain A. G. Khan from 26th August, 1938, for ill health.

Notes

HISTIDIN AND VITAMIN C

LATELY, Bauke published a résumé of his experiences during a period of three years with Larostidin-Redoxon therapy in 120 cases of peptic ulcer. The treatment of all these patients consisted of two courses of 20 to 25 injections of Larostidin 'Roche' in which 50 to 100 mg. of Redoxon 'Roche', a vitamin-C preparation, per ampoule were dissolved.

The results of this therapy were scrupulously controlled; only cases in which cicatrization could be proved by means of x-rays were considered as cured. The presented statistics read as follows: 35 per cent of all patients were cured after the first course of treatment, 35 per cent after the second, and the remainder, about one-third of all cases, experienced relief of the acute ulcer syndrome such as bleeding, emaciation, anaemia, etc., cicatrization however did not occur.

Bauke concludes from his observations that the Larostidin-Redoxon treatment is superior to the other forms of therapy, but that it is not always able to replace surgical treatment. In these refractory cases, in which it is necessary to resort to surgery, the submission of the patients pre- and post-operatively to a Larostidin-Redoxon course is recommended in order to ensure favourable conditions during the operation and to prevent relapses. In all these cases, at least for a period of two months after the treatment, alcohol, nicotine, pungent condiments, etc., should strictly be avoided.

SHORT-WAVE DIATHERMY

We have received a small brochure on the subject of short-wave therapy from Messrs. Malgham Bros. of Bombay (26, Old Custom House Road) which they will send to any practitioner interested in the subject, on request.

Short-wave diathermy differs from conventional diathermy. With conventional diathermy, the current

passes directly to the part under treatment through electrodes in direct contact with the body. With short-wave diathermy, electrode contact with the body is not necessary, obviating a direct flow of conductive current from the electrode to the part being treated. Treatment consists of bringing the body or part, not into intimate contact with electrodes but into a so-called field between highly insulated electrodes. How this field is produced and the various methods of application are described in the brochure. The term 'ultra-short' is sometimes applied to wave lengths less than 10 metres.

Short-wave diathermy, in contrast to conventional diathermy, has the advantage of more uniformly heating the protected and isolated tissue; insulated electrodes are used, which do not require intimate contact; the danger of burns is reduced to the minimum and can be obviated by proper technique. In brief, short-wave diathermy is a distinct advance, with few exceptions affording everything attainable by conventional diathermy and permitting applications wholly impossible with the older method.

This brochure gives the theory and practice of short-wave therapy and clinical suggestions for the treatment of certain specific conditions. It provides interesting and very informative reading.

ILFEX X-RAY FILMS

We have received from Messrs. Ilford, Limited, a pack of Ilfex x-ray films with a request that we should test them.

These films were used in the x-ray department of the Carmichael Hospital for Tropical Diseases attached to the Calcutta School of Tropical Medicine, and gave complete satisfaction in every way. The films were used without an intensifying screen. They gave fine detail, the contrast was good, and the exposure time was short.

We have no hesitation in recommending these films.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

FOLLOW-UP OF A MASS TREATMENT WITH INJECTABLE ATEBRIN

By A. T. W. SIMEONS, M.D. (Heidelberg)
Bombay

IN March 1936 (*Indian Medical Gazette*) I reported on a 'blanket' treatment for malaria covering a mill area in the Southern Deccan with a total population of 5,600 souls, all of whom received two injections of atebtrin. The two injections were followed up by 0.01 g. plasmochin simplex on three consecutive days. No further treatment was given. The district was highly malarious and at the time of the mass treatment, which was completed in nine days, the malaria incidence was of epidemic magnitude.

The relapse rate for the following six months was given in the paper and appeared surprisingly low. Similar experiments carried out during the Ceylon epidemic of 1935 on a much smaller scale, and not so carefully controlled, showed equally satisfactory results, and it was therefore very fortunate that in the mill area results could be carefully watched over a period of 2½ years. The measures adopted after the 'blanket' treatment were as follows:—

(1) Intensive propaganda was carried on in the village to bring every fever case to the doctor. This propaganda was successful because the villagers all knew that two painless injections would bring instant relief of all symptoms of malaria. 'Every concealed fever case is a menace to all; every concealed case might make them all as ill as they were before the treatment, etc.'

(2) Every new case of malaria was treated at once with two injections of atebtrin (no plasmochin).

(3) No quinine whatsoever was dispensed.

(4) Simple anti-larval measures, such as oiling of pools in the river-bed during the dry season, were done, the local carrier being *Anopheles culicifacies*.

The chart gives the monthly malaria incidence for 2½ years prior to and 2½ years after the 'blanket' treatment. In the second half of the chart the black part of the blocks represents the number of re-injections, and the white part the number of injected new-comers, including a few cases from outside villages which have availed themselves of the mill dispensary. The black and white parts together give the total number of cases treated every month.

In the chart every re-injection has been registered as a 'relapse' although obviously a large number of these so-called 'relapses' are reinfections, particularly as it was noticed that most of these 'relapses' occurred after leave to the native village. But even leaving this point aside and registering all re-injections as relapses,

the results are much better than clinical experience would lead one to expect, and if it is borne in mind that these figures are from a population including women and children varying around 6,000 souls, malaria can no longer be considered highly endemic, as it was for 15 years preceding the mass treatment for which reliable records exist. In fact the relapse rate is so surprisingly low that some sort of explanation of this phenomenon must be attempted.

It may be argued that the benign tertian strain in this particular area was an unusually benign one and exceptionally sensitive to atebtrin; that the rainfall in the years following the mass treatment was particularly unfavourable for the propagation of *A. culicifacies*; that the simple anti-larval measures were unusually effective; and, finally, that owing to the excellent social welfare amenities provided by the mill management, the general condition of the population was particularly good. But even taking these points into consideration the results at Gokak seem so surprisingly satisfactory that there is still room for a more sweeping explanation. Perhaps the following observations may prove helpful.

In private practice in Bombay I see many cases of *fresh* malaria picked up from all parts of India, and having seen the excellent results of parenteral atebtrin in Ceylon and Gokak I applied the same abbreviated method in these cases. The immediate clinical results were just as favourable but the relapse rate was practically 100 per cent within one to six weeks. It was therefore soon decided to follow up the two injections with a full course of tablets, followed by a full course of plasmochin, so as to get the almost immediate clinical response attainable with injections and the satisfactory relapse rate of the oral method combined. The results of this method were better but by no means as satisfactory as I have been accustomed to see with tablets only. I therefore returned to treating fresh infections by the oral method only, and relapses again became the exception instead of the rule.

The above observations on first infections are unfortunately not based on a large series of experiments; they were made on cases as they occurred in the routine of private practice. The conclusions drawn from them may therefore be misleading, but the discrepancy between sporadic first infections and epidemic malaria has struck me so forcibly that I feel justified in attempting an explanation, which may lead to further investigations by workers more fortunately placed. Thus, further experience with injectable atebtrin has led to two seemingly contradictory results.

In the highly endemic or epidemic areas in which it has been tried, the abbreviated two-injection method yields excellent results, whereas in sporadic first or fresh infections it is a hopeless failure. Particularly the observation that the combined parenteral and oral method gives

less satisfactory results than the oral method alone in fresh cases, whereas the injections alone seem to be sufficient in epidemic malaria, points strongly to an immunological factor.

It appears that immunity in malaria may be considered a sort of balance between resistance and intensity of infection. In first infections therefore the 'infection scale' is loaded and the 'resistance scale' is empty. On the other hand in persons residing in endemic areas both scales are heavily loaded and, as no treatment can completely eliminate all parasites from the body, first infections treated energetically from the onset will always have a balance in favour of the infection. This will result in a high relapse rate because the body has had no time to build up any resistance. If on the other hand the vast majority of parasites are suddenly destroyed in a case residing in an endemic or epidemic area, the balance will turn in favour of the previously acquired immunity and a low relapse rate result, even after an abbreviated treatment which would be utterly inadequate in a fresh case.

Moreover, it has frequently been observed, and was again seen during the Ceylon epidemic, that 3 to 10 days after the parasites had been removed from the peripheral circulation with atebirin, they again appeared for several days without producing any clinical symptoms and disappeared spontaneously without any treatment. I have never seen this in first infections treated at the onset of fever, where reappearance of parasites always seems to indicate a pending relapse, indicating that the final clearing of the body can only take place in the presence of a high immunity, which easily outweighs the mild infection remaining after treatment with atebirin.

Some hold that a first infection should not be treated at once with a powerful parasiticide like atebirin, others are convinced that oral atebirin does not impair the development of a resistance. While I am inclined to agree with the latter I am most emphatically of opinion that atebirin musonate, through its quick and powerful action in fresh cases, reduces the parasite count so suddenly that the body is no longer called upon to produce an immunity, and hence an unchecked multiplication of parasites recommences and ultimately results in a clinical relapse.

Exactly why atebirin tablets do not appear to interfere with the development of resistance in fresh cases, while injections obviously do, is a problem outside the scope of this paper. It can only be said at present that it has nothing to do with the quantity of atebirin given, as injections *plus* tablets appear to obstruct immunity to a greater extent than tablets only. If a high degree of resistance to superinfection has been attained through years of exposure the body appears to become quite capable of coping with the few parasites remaining alive after treatment or introduced by a mild reinfection. This I venture to suggest may be an explanation why

the 'relapse rate' or susceptibility to reinfection at Gokak as shown in the chart seems to be very slowly increasing, as resistance becomes less.

What I have hitherto experienced with atebirin musonate has led me to adopt the following principles :—

(1) In first infections that are seen from the onset of fever—tablets only, followed by plasmochin, have given me the lowest relapse rate (although clinical relief is not as prompt as with injections).

(2) In first infections that are seen after several rigors, injections are only used if cerebral or circulatory symptoms call for very

prompt action. In these cases I have found it best to give no further treatment after two injections, to wait for the next relapse, and treat this with tablets and plasmochin. All other cases are treated with tablets only, followed by plasmochin.

(3) In chronic relapsing cases living in non-endemic areas either injections or tablets may be given, followed up by plasmochin.

(4) In malaria cases residing in endemic areas or during epidemics, and therefore having a high immunity, two injections only are the

ENUMERATIVE STUDIES IN BENIGN TERTIAN MALARIA

By V. SIVALINGAM, M.R.C.P. (Edin.),
D.T.M. & H. (Eng.)

Medical Laboratories, Colombo, Ceylon

THE observations recorded in this paper were made at the Government Hospital at Watawala from December 1935 onwards. The great 1934-35 epidemic had affected the population served by this hospital. The intensity of the epidemic had waned by the end of the year 1935. Being a non-malarious district, the people had their first malaria attack during the epidemic. Thus, the cases investigated were those having subsequent attacks consequent to infection in the epidemic, and those who having escaped the epidemic itself were suffering from their first malarial attack later. Thus the cases are easily grouped into 'subsequent' and 'primary', respectively, from the histories. The hospital is situated at an altitude of 3,200 feet above sea level and the sick were drawn from places 800 to 2,000 feet above sea level.

The method

Patients were admitted and inquiry made into the previous malaria history; they were grouped into 'primary' and 'subsequent' cases. A primary case is one of less than two weeks' duration; while cases that had recurrent

(Continued from previous page)

method of choice. The results, both immediate clinical relief and relapse rate, appear to be very satisfactory, while, where large numbers of patients have to be dealt with in a minimum of time by a short-handed staff, it is technically the only possible method of rational treatment.

There is ample opportunity for experiments with the injection method of 'blanket' treatment in India, which if carefully conducted would possibly further our knowledge of how to cope with and suppress epidemics without attaching too much importance to expensive, seldom adequate and never-easing anti-larval vigilance.

Summary

(1) Two and a half years' observation of malaria incidence in a highly endemic mill area, in which a 'blanket' treatment had been carried out with two injections of atabrin per inhabitant, showed a satisfactory result.

(2) This treatment in fresh infections gave an unsatisfactory result.

(3) Fresh cases treated with two injections at onset followed by a full course of atabrin tablets and plasmochin have a higher relapse rate than first infections treated with tablets only.

(4) An immunological explanation for this phenomenon is attempted.

(5) An immunological grouping of cases is suggested and the treatment for each group outlined.

periods of illness alternating with periods of freedom from fever and had lasted for more than two weeks for the whole illness were considered subsequent; these were relapses and reinfections. No anti-malarial treatment was given. The blood was examined in both thin and thick smears for diagnosis, and the patient was watched until there was one or more paroxysms of fever. The time of onset of fever or rigor was noted and two-hourly temperature charts were kept. Then a few hours before the next anticipated paroxysm blood was secured for enumeration and for a thin smear examination. The fowl-corpuscle suspension method, as advocated by Sinton (1924), was used for the enumeration. The thin smear was examined and the different stages of the parasites were recorded. The temperature at the time of taking the blood sample was also noted, and the highest temperature attained in the subsequent paroxysm was recorded. The fowl-corpuscle suspension used contained 10,400 cells per c.mm.; one thousand fowl cells were counted in the majority of the cases.

A. Counts in primary and subsequent attacks

The primary cases generally gave much higher counts, with a few exceptions. The distribution according to numerical values is shown in table I.

TABLE I

Number of parasites per c.mm. finger blood	PRIMARY CASES		SUBSEQUENT CASES	
	Number	Percentage	Number	Percentage
Under 5,000 ..	7	32	13	47
5,000 to 10,000	2	9	7	25
10,000 to 20,000	9	41	5	18
Over 20,000 ..	4	18	3	10
TOTAL ..	22	..	28	..

It is seen that over 70 per cent of the subsequent cases showed parasite values under 10,000 whereas about 60 per cent of the primary cases showed values above this.

Sinton *et al.* (1931) investigated 54 cases of chronic infections with *P. vivax* among adult British soldiers. They divided their cases into three groups—the 'prepyrexial', the 'interpyrexial' and 'pyrexial'. Their inter-pyrexial group consisted of 11 patients and the counts in eight of these lay between 3,000 and 5,000 per c.mm. One low count (1,960) followed a pyrexia of only 99°F., while the other two were 8,000 and 9,240, respectively. This group is comparable with the cases under review, since in the majority of these the enumerations were done in the inter-pyrexial period.

Ross and Thomson (1910) made a series of counts on eight *P. vivax* cases infected in

West Africa or America and none was of less than some weeks' duration when admitted into hospital in Liverpool. Among the cases there is only one count in the inter-pyrexial interval and this is comparable to the cases listed in this paper. This case showed 9,600 parasites per c.mm. of blood.

It is therefore suggested that 10,000 parasites per c.mm. of finger blood be taken as the upper range for parasite prevalence in the majority of the 'subsequent' cases one would encounter.

B. *Relationship of parasite numbers to degree of fever*

In table II, the counts are tabulated according to temperatures. These temperatures are the highest reached at the paroxysm next to the enumeration. Hence the fever attained would depend on the parasites present; and, of these, the matured stages alone would be responsible. Tables III (a) and III (b) show the analysis of the stages of the parasites found in the thin films taken simultaneously with the specimens for counts. It will be seen that every case that had fever, with the exception of cases 6 and 10 among primary infections and cases 11, 13, 15 and 19 among subsequent attacks, showed trophozoite stages also. The ring forms present are considered to be due to the initiation of the paroxysms described in this paper, as it is well known that sporulation starts some time before the onset of the fever. These trophozoites are the precursors of the schizonts that would give rise to the paroxysms following the ones recorded here. It was noted that it was rarely indeed that parasites could be found in one stage only in benign tertian infection. The tables also

show that fever is of quotidian type, both in the primary and subsequent cases and the exceptions are few.

TABLE II
Relationship between parasite counts and temperatures

Temperature, °F.	PARASITE COUNTS

Among primary cases there would seem to be a correlation between the parasite counts and the degree of fever among different persons. The higher temperatures were, generally, found in the cases that had higher counts. No such relationship was found among the subsequent cases. The higher temperatures were as often produced by smaller numbers of parasites as they were by larger numbers.

Ross and Thomson (*loc. cit.*) found in their cases, except four without fever, a very strong, almost convincing, correlation.

Lowe (1934) investigated 37 cases of *P. vivax* infection which had had no malaria for at least one year previously and three cases of relapses. 'The results show that in infections with *P. vivax* the relation between the number of parasites and the degree of fever in different patients is not marked. Those patients with the highest counts sometimes tend to show the greatest degree of fever but there are many exceptions to this general tendency'.

Knowles and Das Gupta (1931) studied 15 cases. These were of the endemic, chronic or 'residual' type. They state that 'whilst it is generally true that high counts are associated with high temperatures, yet the correlation is only a rough one. Our evidence goes to show that in established, chronic and 'residual' infections the patients may be febrile with much lower counts. On the other hand, he may show a high parasite count when the temperature is almost normal'.

Sinton *et al.* (*loc. cit.*) consider that 'the highest temperatures recorded to occur chiefly

with the high parasite counts'. Their cases were chronic benign tertian infections.

C. The pyrogenic limit

The attempt was made to determine the minimum number of parasites that was necessary to produce fever. The cases that did not develop fever subsequent to the counts are shown in table IV.

TABLE IV
Benign tertian

		PRIMARY ATTACK		
Case		500	parasites per c.mm. of blood.	
4	1,500	"	"	"
11	3,000	"	"	"
	230	"	"	"
17	1,120	"	"	"
21		"	"	"
		SUBSEQUENT ATTACK		
Case		3,100	parasites per c.mm. of blood.	
4	410	"	"	"
10	1,670	"	"	"
24	700	"	"	"
27	400	"	"	"
	387	"	"	"
28	215	"	"	"

The lowest counts that have produced fever were found to be 930 among primary cases and 547 among the subsequent cases. In the former, rings, trophozoites and gametocytes and no

schizonts were found on two occasions blood films were examined [case 16, table III (a)], and in the latter there were ring, trophozoite, schizont and gametocyte stages [case 28, table III (b)].

Therefore, it appears that on an average a total of about 900 parasites are necessary to produce fever in primary attacks and for subsequent attacks about 500 parasites are sufficient.

According to Ross and Thomson (*loc. cit.*) 'about 200 to 500 may perhaps be taken as the usual limit'. 'The actual limit above which they become pyrogenic probably varies in different cases'. The cases studied by these observers, as pointed out before, were of some weeks' duration and would come under the subsequent group of this paper.

Therefore, it is suggested that, in persons not attacked by malaria before, the natural resistance towards invasion of the body by parasites is great and that a larger number of organisms is necessary to produce a break-down of this resistance, resulting in the first attack of malaria.

D. Do mature forms of *P. vivax* retire to internal organs?

Sinton *et al.* (*loc. cit.*) are of opinion that 'it seems probable that blood cells infested with mature parasites are more liable to accumulate in the internal organs than cells with young forms'.

Lowe (*loc. cit.*) in dealing with the parasite count in the interval between the rigors says that 'in the literature of malaria we have found no evidence which proves that *P. vivax* disappears from the peripheral blood into the internal organs on approaching maturity. The present findings suggest that they may occur, but it cannot explain entirely the marked diminution in the parasites that is found in every case in the apyrexial period between the rigors'.

A reference to tables III (a) and (b) in this paper reveals that in cases 3 and 16 in the former and cases 2, 5, 6, 12, 14, 18, 19, 22, 23 and 25 in the latter, there was an absence of the maturer forms of the parasite, namely schizonts, though fever was present in that developmental cycle. The thin films were thoroughly searched to establish the presence of these forms but without success. If maturer forms are present in the peripheral blood in a representative manner, then it is natural to expect to find them readily in the films examined. The failure to find them in the cases noted is considered satisfactory evidence that they have receded into the internal circulation.

E. Induced malaria

Observations on the numerical prevalence of parasites in inoculated malaria among general paralytics have been made by many workers. Thus Korteweg (1924), Rudolf (1924), Pijper

and Russell (1925), and Grant and Silverston (1926) have described their findings. But it is now well recognized that malaria produced by blood inoculation is not comparable to natural malaria. James (Thomson, 1930) who has had extensive experience in therapeutic malaria affirms that 'malaria caused by direct blood inoculation is a different disease from malaria caused by mosquito bites'.

Further, even malaria induced by bites of infected mosquitoes appears to behave differently from that acquired in the open country. For it has been shown (Yorke and Macfie, 1924) that malaria induced by this method in the treatment of general paralytics responds readily to quinine and a short course with that drug produces a complete cure. Whereas, it is the experience in ordinary practice that naturally acquired malaria is not so readily curable.

Therefore it is considered that the numerical prevalence of parasites in these different groups of malarial fevers is not comparable for the purposes of this paper.

Summary and conclusions

1. Fifty cases of benign tertian infection were studied by the numerical method. They were grouped into primary and 'subsequent' cases and numbered 22 and 28 respectively.
2. It was found that the counts in primary attacks were generally higher than in subsequent attacks. It is considered that 10,000 parasites per c.mm. is possibly the upper limit of the majority of subsequent attacks.
3. Among primary cases a correlation between the parasite counts and the degree of fever among different persons was found to be present. But no such relationship was seen among the subsequent cases.
4. As regards the fever threshold, about 900 parasites are found to be necessary to produce fever in primary attacks, and for subsequent attacks about 500 parasites are sufficient.
5. Evidence is adduced to show that in *P. vivax* infections, maturer stages of the parasite tend to migrate into the internal circulation.

THE USE OF COBRA VENOM IN NERVE LEPROSY

By J. S. CHOWHAN, M.B., B.S.
CAPTAIN, A.I.R.O.

and

School of Tropical Medicine, Calcutta

THE reverence with which the average Hindu regards a snake is well known. In the Hindu mythology, *Shesh Nag* is believed to have protected God Brahma, and God Shiva gave the mark of Omega on the hood of the cobra. Shiva is depicted with snakes coiling around his neck

and a snake emerging from the tuft of his hair. The snake is an emblem of the mystery of death, as well as of healing. If a snake is killed by a person there is a belief that the snake-god takes revenge on the culprit by inflicting leprosy on him at once, or in some future incarnation. Since according to mythology leprosy is a disease given in the form of a punishment to the culprit, the snake is believed to avoid biting a leper. If it does bite a leper his disease is believed to be cured at once. In the indigenous medicine, cobra venom is said to have been used with success in the treatment of leprosy. Ainslie (1826) mentioned the use of dried flesh of the harmless south Indian hill snakes, known as *Tamool* or *Malay pamboo*, in Hindu medicine, as a remedy against 'kustom' or leprosy. The

* Fever in early hours of morning and hence highest temperature unrecordable.

blood of snakes has been used in the Moham-medan medicine as a local application in leuco-derma which is believed to be a form of white leprosy. In Northern India the flesh of the cobra mixed with arsenic has been used as an external application in syphilitic rashes and other skin diseases.

Monaelesser reported that a leper suffering from plexus-neuritis felt great relief after being bitten by a large tropical spider. Labernadie (1934) and Brambilla (1935) also remarked on the beneficial effects of cobra venom in neurosyphilis, meta-syphilitic rashes, and neuroleprosy. In Brazil the rattlesnake venom is believed to be very efficacious in leprosy and in the Butantan Institute of Serum Therapy experiments are said to be in progress in this connection.

Cobra venom in nerve leprosy

During the last few years the present authors (1937) have been carrying on experiments in connection with the therapeutic uses of cobra venom and have made references to the possibilities of its being a useful agent in the treatment of leprosy, particularly of the nerve type. Lowe (1938) reports that, in India, leprosy is commonly of neuromacular or tuberculoid type. This class includes the 'macular' and their acroteric, or 'tropho-anæsthetic' varieties. In his opinion in both these types, wherever the lesion occurs, in the skin, in the cutaneous nerves, or in the nerve trunks, there occur granulomatous changes of a tuberculoid nature. It is possible that all the active 'neural' types of leprosy may be essentially tuberculoid in nature. Muir (1936-1937) reported that confinement of infection to one or more nerves is to be taken as a sign of high resistance on the part of the patient and in such cases it may remain stationary for years. In India more than half the leprosy cases belong to the resistant type of nerve leprosy. In all these cases the most important factor is the restoration and steady maintenance of high standard of health to keep the patient free from pains.

Cobra venom has already found a place in the treatment of neuritis. Macht (1936) showed that it has marked analgesic effect when injected intramuscularly, and the sensitiveness of the nerves to pain as produced by electric current is greatly diminished. The same author has further observed that its action on the pain centre in the cerebrum is not unlike that of morphine but differs from it in being slow to appear and is more lasting in effect. It does not induce sleep in the same way as that alkaloid.

Action of cobra venom on leprosy tissues

The structure of a leproma when grown in tissue culture was described by Timofejewsky (1930). When a fragment from a leprosy nodule is planted in heparinized plasma of both man and rabbits with human embryonic extract, the fibroblasts grow well generally in the first week,

and there is also an excess of macrophages with *Mycobacterium lepræ* in them even during the second and third weeks of growth. No *M. lepræ* are seen in the fibroblasts and they do not seem to affect the growth of the tissue explant. They apparently have no toxic effect on the fibroblasts.

Henderson (1931) described the histology of a leprosy nodule and considered it as a focus for the acid-fast bacilli in the endothelial cells lining the capillaries at the site of the embolism; there is œdema of the surrounding skin elements, acid-fast bacilli occur in the dilated lymph spaces and in the phagocytes (histiocytes). In the developed nodules the multinucleated giant cells are found to be uncommon. White (1931) showed that when cobra venom was injected into aseptic tissue spaces, no protective granulation tissue developed around the irritant substances. It was observed that cobra venom rather destroyed or prevented the growth of the new granulation tissue. Is it possible that a similar action may take place inside a leprosy nodule? It is well known that tuberculoids have a tendency sometimes to central necrosis and caseation. Since cobra venom has the power of tissue digestion, if it is made to reach the interior of the tuberculoid, either by local or parenteral injections, it is possible that it may help in the dissolution of these growths.

Chopra, Das and Mukherjee (1936) showed that in dilutions such as 1-60,000 to 1-80,000 cobra venom stimulated the growth of tissue culture cells, but with higher concentrations, e.g., 1-20,000, the venom produced a rapid destruction of the growing cells. The possibility that local injections of the venom into leprosy nodules may help in their dissolution has thus a rational basis. It cannot be said, however, at this stage whether cobra venom has any effect on *M. lepræ* or not. Clinical observations show that a slight but a distinct reduction of the size of nodules and macules does occur. Improvement in the sensation of the anæsthetic patches has also been observed after the use of the venom for two or three months.

M. lepræ has a fatty capsule around it. It is possible that cobra venom may be able to dissolve this capsule and thus may even be able to act on the *M. lepræ* itself. The venom has been shown to have an affinity towards dissolving the fatty and cephaline tissues, but to anticipate such reactions from it in leprosy needs further work. Chaulmoogra oil is believed to possess a lipase which acts on *M. lepræ* by dissolving its waxy capsule. If such action be at all possible, cobra venom may possibly supplement the action of the chaulmoogra oil in the treatment of leprosy. This paper has been written only to bring before the readers the possible application of snake venoms in nerve lesions of lepers. Only after an extensive trial of the venom in all types of cases of leprosy will it be possible to form an opinion whether cobra venom has any value in this disease. It has already been mentioned that the majority of the cases in

India are of the nerve type and since the venom has a special affinity for nerve tissues, its possible utility should be investigated.

Through the courtesy of Dr. Lowe we have carried out trials on a small series of patients in the Leprosy Department of the School of Tropical Medicine, Calcutta, but these are not sufficient to draw any definite conclusions. More extensive work in this connection is being carried out in some of the leprosy clinics outside. In this paper we give the results obtained in a small series.

Analysis of the cases treated

Cobra venom is being tried in all three forms of leprosy. Injectable cobra venom was distributed to various leprosy hospitals and the results obtained from some of them are given below. Everyone who tried cobra venom reported that there was a good deal of relief in the shooting character of the pain in almost every case of leprosy of the nerve type. In about 6 per cent only, there was little or no relief at all. It is curious that the patients who did not show any improvement with cobra venom did not show improvement with any other drugs either. We have personally observed marked relief of pain and general improvement in a number of nerve leprosy cases treated with cobra venom.

Injectable cobra venom was also used in the Chandkhuri Leprosy Hospital, Baitalpur, in Central Provinces, and the S. G. P. Mission Dispensary, Kagalnar Kolahapur. The present authors are grateful to the workers in the above institutions for kindly sending the details of their cases and their opinion regarding the efficacy of cobra venom in leprosy. Dr. Gass of Chandkhuri Leprosy Hospital, Baitalpur, has published his results in *Leprosy in India* (1938). He pointed out that cobra venom markedly relieves the sensation of pain and formication, and cobra venom injections have become very popular with his patients. In a number of cases, however, the relief was only temporary and in some patients there was no relief at all.

Miss Haythornthwaite of the Mission Dispensary, Kagalnar, has kindly sent us a report on 32 cases of leprosy. She observed marked and definite relief in 14 (43.7 per cent), some relief in 16 (50.0 per cent), and slight or no relief in 2 (6.3 per cent) patients (*see table*). The figures in the 4th column show the number of mouse units injected per dose every week. In some cases two courses were given, the second after an interval of three months. The patients were given intradermal injections of cobra venom once a week. Each dose was diluted with normal saline and injected by a number of punctures in the painful area. The injections were given only in cases where the pain was bad enough to interfere with sleep. The venom could not be injected more frequently as patients had to come from long distances, and some gave up the treatment of their own accord

as they felt better and did not think it necessary to have further injections. In the majority of cases the improvement was marked. Some of them had been treated with other remedies for over a year without relief in the sensations of 'pins and needles' and formication. The venom was found to be particularly useful in giving prompt relief in cases of paraesthesia of early leprosy, the sensations generally returning to normal after a course of four to six injections. Marked relief was obtained in the severe aching pain from which patients suffered during the phases of the 'reaction period'. The relief of neuritis and of sensation, such as pin pricks, occurred from above downwards and the normal sensations also returned in the same order. In almost all patients relief was obtained with four to six injections. Two to three days after the first injection, the patient felt the improvement and after the second or third injection pain often disappeared altogether. The treated cases were mostly those on which other analgesics had been already tried without success. The criteria of the cure was that the patient reported that his pain had disappeared and he did not require any more injections.

The commonest nerves involved in order of frequency are the ulnar, peroneal, posterior tibial, and median. These nerves were thickened and painful in nearly all the patients in this series. The injections relieved the severe nerve pains due to lepra reaction. In some cases injections were given locally to relieve pain of a particular part of the body, which was interfering with the sleep of the patient.

Discussion

It had been suggested that relief of nerve pain and other nerve symptoms in leprosy, after cobra venom, is due to its choline-esterase-like action (Iyengar, Sehra, Mukerji and Chopra, 1938). In those suffering from severe and constant nerve pains, there is probably an excess of acetylcholine in tissues produced by pathological over-stimulation of nerves and possibly choline-esterase normally present is insufficient to neutralize it. Since cobra venom injections relieved nerve symptoms it is possible that it acted by neutralizing the excess of acetylcholine present. It is also possible that cobra venom may itself act like choline-esterase or may have a substance of this nature present in it. The work of this nature on the study of the biochemical changes in blood in leprosy before and after the injections of cobra venom is in progress, particularly to study its effects on choline-esterase.

It is not expected that cobra venom will ever replace chaulmoogra oil, and other measures in the treatment of nerve type of leprosy, but it may serve as an additional weapon in ameliorating some of the troublesome symptoms. This is important in view of the fact as stated by Rogers (*Lancet*, 1937) that about 60 to 70 per

cent of cases of leprosy in India are of the nerve type. Cobra venom has been shown to give marked relief in a number of such nerve cases, particularly if the injections are given into the macular and anæsthetic patch. The sensations of numbness and formication are also improved.

A perusal of the table will show that in this small series, injection of cobra venom gave definite relief in about 60 to 80 per cent of out-door patients to whom the injections were given intramuscularly or intradermally in and around the area of the nerve supply. The relief of pain was observed after the second or third injection and the pain disappeared almost completely after the fifth or sixth injection. The criteria of improvement were the return of normal sensations and better sleep at night for those who complained of sleeplessness due to severe pain or uncomfortable sensations, such as tingling and formication. Muir (1936) believes that the restoration and maintenance of a high standard of health and nutrition will keep leper patients free from pains. Badger and Patrick (1938) have reported great benefit in nerve pain after a few injections of vitamin B₁ in doses of 300 international units, injected intramuscularly. The swelling and tenderness of the nerves disappeared. The present authors have used mixed injections of vitamin B₁ (Betabion, Merck) and cobra venom with marked success in a few cases of neuritis which did not improve with cobra venom alone, believing that most of these resistant cases were due to vitamin B₁ deficiency. Vitamin B and cobra venom if used together would most probably be very useful therapeutic agents in cases of neuritis of leprosy.

Some of the fallacies in the interpretation of the data are :—

(1) The relief of the symptoms were recorded as reported by the patients themselves. Most of the patients treated were villagers and uneducated persons and their statements could not always be relied upon. They usually express the relief in the terms of annas out of a rupee.

(2) In the phase of reaction there may be acute neuritis and swelling of all lesions, but these usually subside automatically within a month or two with or without any medicine.

Summary

(1) In India about 75 per cent of the cases of leprosy are of the nerve type with symptoms of neuritis, *e.g.*, pain, formication, and pins-and-needle sensation. Injections of cobra venom undoubtedly relieve these symptoms in a large number of these patients.

(2) A possibility of the curative action of venom in leprosy has been discussed because cobra venom possesses the power of destroying the newly-formed tissues. If the venom could reach the tuberculoid in certain concentrations there is a possibility that it might help to dissolve them.

Tissue culture experiments show that the growth of tissues is unaffected by the presence of *M. lepræ*. Venom destroys the newly-formed cells and may therefore act on these growths disregarding the presence of *M. lepræ*.

(3) Trials on a more extensive scale should be carried out to test the possibilities of cobra venom in nerve type of leprosy prevailing in India, by itself and in combination with vitamin-B complex.

TABLE

Cases suffering from nerve leprosy treated with cobra venom

Number	Type of leprosy	Symptoms and complications	Dose injected (mouse units)	Effect produced
1	C1 N1	Thickened nerves, aching pains and sensation of heat in arms.	1, 2 1, 3, 4, 5, 6 } = 22	Relief of pain in arms after first dose, legs second dose; intense itching and 'ants' especially nose: now relieved.
2	N2	Pain and heat in arms and legs.	1, 2, 3, 4 } = 10	Pain almost gone.
3	C1 N2	Pins and needles in arms and calves.	1, 2, 3 4, 5 } = 15	Complete relief of symptoms for a month; now pins and needles, probably due to rains.
4	C1 N2	Nerve pains below elbows and knees.	1, 2, 3, 4, 5, } = 28	Legs improving, arms less relief; relief maintained.
5	C3 N2	Nerve pains right ulnar nerve.	1, 2, 3, 4, 5 } = 38 6, 7, 10	Relief maintained four months; recurrence of ants in hands. Relief after third injection.
6	C1 N2	Nerve pains right ulnar nerve and leg (biting).	1, 2, 3 } = 6	Relief after ten days.
7	C2 N3	Severe aching (reaction phase).	1, 2, 3 } = 6	Relief immediate, asked for more as pains returned; no further pain after four months.
8	C3 N2	Cramps in hands and legs.	1, 2, 3, 4, 5 } = 36 6, 7, 8	Relief after first dose: no pains now.

TABLE—concl'd.

Number	Type of leprosy	Symptoms and complications	Dose injected (mouse units)	Effect produced
9	N1	Pins and needles in arms and legs, nerve thick and tender, no anaesthesia.	1, 2, 3 4, 5 } = 15	Marked relief; no complaints.
10	N2	Pins and needles in right leg and arms.	1, 2, 3, 4, 5 = 15	Much relief; only slight ants.
11	N2	Reaction aching	1, 2, 3, 4 = 10	Relief after first dose, slightly twitching.
12	C2 N3	Aching all over body	1, 2, 3, 4, 5 = 15	Relief after first dose; pain only in left leg, perforating ulcer.
13	C2 N2	Pins and needles and loss of sensation.	1, 2, 3 = 6	Sensations returned.
14	C1 N3	Pain, pins and needles	1, 2, 3 4, 5 } = 15	Improvement by each dose, stopped attending.
15	C2 N2	Pins and needles in arms 12 days.	1, 1 = 2	Relief; slight return in shins.
16	C3 N2	Burning pain in nose and forehead (thickened nerves).	1, 2, 3, 4, 5, 6, 7, 8 } = 36	In divided doses in the painful areas.
17	N2	Nerve pain and bullæ; heat in hand and feet.	1, 2, 3, 4 = 10	Painless, heat sensation gone.
18	C1 N2	Pain below knees, 12 days.	1, 2 3, 6 } = 12	Did not come after two doses; feeling much better.
19	C2 N2	Pins and needles; burning pains.	1, 2 3 } = 6	Much better, but returning pains due to missing these injections; did not return.
20	C2 N3	Nerve pain especially in foot (deformed).	1, 2, 3 = 6	Sensation returned arms and legs; much better, ants only on legs, not distressing.
21	C1 N3	Nerve pain	1 1, 2, 3, 4 } = 11	Sensation returned arms and legs; much better, ants only on legs, not distressing.
22	N2	Nerve pain, swelling hands and feet.	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 10, 10, 10 } = 85	Swelling disappeared, painless definite improvement.
23	N1	Nervous patient, gangrene toe.	1, 2 = 3	Attended when pains worse; did not continue.
24	C3 N2	Nodules bursting	1 = 0.05	Injection stopped to be tried again; not returned yet.
25	C1 N2	Burning legs	1, 2 = 3	Only relief for one day ants. Died two months later of intercurrent disease.
26	N2 C2	Aching from knees and elbows downwards.	1 = 1	Sensation returning.
27	C2 N3	Aching left calf	1, 2, 3 = 6	None since.
28	N1	Pain shooting down right arm.	1, 2 = 3	Relieved; no return till 15 days ago, now slight pain.
29	N2 C2	Reaction pain, formation.	1, 2 = 3	Relieved; no reaction.
30	C1 N2	Nerve pains, severe since one year.	1, 1, 2, 3 = 7	No attacks since February.
31	C2 N1	Reaction pains, arms and legs.	1, 2 3, 4, 5, 6 } = 21	Fever; no relief.
32	N1	Heat in feet, pins and needles left forearm and left hand.	1, 2, 3 = 6	Severe reaction after each injection.

Cases 1 to 14 showed marked relief.
 " 15 to 30 " partial relief.
 " 31 and 32 " no relief.

INVESTIGATION AND CONSERVATIVE TREATMENT OF THE NASAL FACTOR IN ASTHMA

By F. T. HARRINGTON, M.R.C.S., L.R.C.P. (late I.M.S.)

THE condition known as asthma is associated with a general metabolic imbalance and is never due to one factor only. I have dealt in detail with the treatment of this condition in a recent book, and this article is more in the nature of an elaboration of the chapter on nasal treatment.

It cannot be over-emphasized that the less that is done to the asthmatic nose the better. For this reason conservative treatment is to be preferred to surgical interference whenever possible. I will quote one example showing the danger of operating unless it is absolutely imperative.

A friend of mine was consulted by an asthmatic patient for the removal of nasal polypi. He cleared one nostril only, as he was well aware of the danger of doing too much. As the result of this operation the patient entirely lost all traces of asthma from which she had been a constant sufferer.

After an interval of nearly a year during which time she had had no sign of spasm, she returned to the surgeon to have the other side done.

Against his better judgment he agreed and the other nostril was treated. The immediate result was a return of the asthma in an intensified form and no subsequent treatment has been of any avail.

This is a common experience of all who have a great deal to do with the asthmatic state,

though it is impossible yet to give any satisfactory reason for it.

Bearing this in mind I will proceed to outline examination and treatments which present none of the dangers or finality of a surgical operation, inasmuch as they are constructive instead of destructive.

Replacement

The work of Proetz of America is a real advance as a means of investigating and treating conditions within the sinus. He called it 'displacement' treatment. We prefer to call it 'replacement' treatment.

By this means we can investigate the true condition of the sinuses and also the patency of their ostia.

A patient whom I was asked to see had previously been x-rayed for possible sinus trouble and the report was negative. By Proetz's method of examination it was found that none of the sinuses on the left side of the head were normal. Subsequent operation revealed the presence of a mass of polypi in the left antrum and complete blockage of the ostia of all the other sinuses on that side. As a result of this operation combined with general treatment she has been completely restored to health after some twenty years of asthma and her weight has increased from under six stone to over nine.

Proetz's method of examination consists of the introduction of lipiodol into the upper nasal passages and the subsequent production of a vacuum which when released allows the lipiodol to enter such of the sinuses as are patent. Where a sinus admits lipiodol a complete picture of the sinus is obtained. Lipiodol is as essential to sinus x-ray as barium or bismuth is to intestinal x-ray.

I cannot do better than quote Proetz's own words with reference to our knowledge of the functions of the sinuses, he says:—'We have devised dozens of more or less ingenious ways of opening these cavities, all for one purpose—to let out infectious material, which sums up virtually the whole of sinus surgery, and cannot be considered a step ahead of the elementary surgical principle of draining an abscess anywhere in the body, as practised by the ancients. Now, unfortunately very little is known about some of the more elementary matters of the sinuses. To begin with we are not at all certain as to why they exist at all. We do not know why they are normally sterile and why presently they become infected. We do not know why once infected they may readily recover or why just as often they do not. The association between signs and symptoms is erratic. Some patients suffer intensely from sinus infections which judged by an old standard of observation appeared insignificant. Others on the contrary have noses which run copiously without putting their owners to any further inconvenience than the annoyance of blowing them'.

The present writer's opinion as to why some sinuses which have been infected clear up while others do not is that the deciding factor is largely dietetic and that a diet which includes an adequate vitamin B₁ and B₂ content is an aid to spontaneous recovery.

We do know that a large percentage of sinus operations produce no improvement to the patient: in fact an operation will often aggravate the condition for which it is performed.

By far the best way of acquiring the technique of replacement is by working under the supervision of a skilled operator. To obtain such knowledge from print is difficult and unsatisfactory and the resulting *x*-rays examination likely to be inaccurate. The instruments required are :—

- (1) A special metal syringe for the introduction of the lipiodol.
- (2) A glass and rubber device rather in the nature of a breast pump, for the production of the vacuum.

These two instruments are specially made for this work.

Whether or not the nasal mucosa is to be shrunk has first to be decided.

The patient lies on his back upon a couch, with the head hanging well back over the end in such a way that the point of the chin is situated immediately above and in line with the external auditory meatus. This position is very important and must be maintained unmoved throughout the whole process. Rather less than half an ounce of lipiodol is slowly run into the nostrils from the metal syringe, dividing the amount between each nostril.

If the head is in the correct position the lipiodol will occupy the upper part of the nasal fossæ and cause no discomfort. The patient is instructed to breathe entirely through the open mouth until the completion of the operation.

The rubber bulb of the second syringe is now compressed and the glass nozzle inserted firmly into one nostril allowing no air to escape at the sides while the other nostril is closed by the operator's finger. If the bulb be released suddenly the patient is conscious of a violent shock and therefore it is necessary to produce suction rather gradually whilst the patient is instructed to swallow repeatedly until pressure is released. If swallowing under these conditions is not easy the patient may repeat the word 'kick' 'kick' 'kick' 'kick', which has the same effect.

As soon as both nostrils have been dealt with the patient is sat up and any surplus lipiodol allowed to drain away of its own accord into a dish, no effort being made to expel it. If all sinuses are patent, little if any of the lipiodol will return, assuming the technique has been correctly observed. The patient is now ready for *x*-ray, and, if the preparation has been correctly carried out, a clear insight into the actual condition of the sinuses will be obtained.

Normally, the lipiodol is removed from the sinuses by ciliary action in 72 hours and this should be observed by *x*-ray, as delay in this respect can result from pus or a general lack of vitality, either of which condition requires treatment.

The process of replacement also provides us with a valuable form of treatment when the condition within the sinuses is one of simple catarrh or a low-grade infection without too considerable pus formation and provided the ostia are patent.

The solution used for this purpose is composed of ephedrine and salt.

It is introduced into the sinuses in exactly the same way as lipiodol, but here only the second syringe is required.

The purpose of this treatment is to shrink and tone up the membranous lining of the sinuses and to promote drainage, and its effect is demonstrated by the subsequent outpouring of any pus and mucus that may be present.

By the process of replacement we have, therefore, an effective method of examining and treating conditions *within* the sinuses.

The Dowling pack

This method of treating ethmoidal infection was first brought to my notice by Burton Haseltine of Chicago some years ago during his visit to England, and I have satisfied myself in a very large number of cases that by its use we have an entirely satisfactory mode of treatment for this condition.

One of the commonest conditions, and one that is most frequently overlooked in asthma, is ethmoiditis. This is understandable, for it is not a condition which can be seen by casual observation.

Nasal examination in all cases of asthma requires good illumination and the skilled use of the naso-pharyngoscope. The significance of ethmoiditis in these cases depends on the nerve distribution and hence this area is sometimes called the asthmo-genetic zone.

As the result of irritation or pressure in the ethmoid area a stimulus passes on by means of the sensory tract from the trigeminal and enters the 'nucleus ambiguus' to continue *via* the motor routes of the glosso-pharyngeal and vagus nerves to form the naso-pulmonary reflex arc. In a highly toxic patient this may easily be demonstrated by lightly rubbing the ethmoid area with a pledget of cotton-wool on a probe, a wheeze will immediately be heard in the corresponding side of the chest.

Dowling was an ophthalmologist and he used his 'pack' treatment for certain eye conditions, such as conjunctivitis, and it still forms the most effective treatment in these cases.

Dowling used single pledgets of cotton-wool soaked in 10 per cent aqueous solution of argyrol. As the pathology lies beneath the surface, the object of treatment demands the use of a non-irritating bactericide, capable of penetrating the

mucous membrane in order to reach the cells below. Dowling discovered that argyrol fulfilled these requirements, and it has been shown that the solution is distributed far beyond the area of its application.

Here is the technique as carried out in my practice for over ten years.

Instead of a single tampon, I use a number of thin and delicate pencils of long fibre cotton. These are successively applied by means of a slender, polished and tapering steel applicator in sufficient numbers to cover the nasal mucosa all the way from the naso-pharyngeal vault and the ecribriform plate around the under surface of the ethmoidal turbinal and upward upon its outer surface to a considerable extent.

After swelling of the mucous membrane is reduced by a few treatments, the turbinal can be almost entirely enveloped by the tampons. It is desirable that the cotton be easily released from the applicator and left at the farthest point reached without crowding or friction. The economical nose specialist who uses rough, rusty, or crooked applicators often, unwittingly does an intranasal massage that leaves his patient in worse condition than before.

I understand that Dr. Hille of America has substituted a colloidal silver chloride, which he calls 'lunosol' and which he claims to be entirely bland and stainless. I am not able to express any opinion on 'lunosol' as I have not yet had an opportunity of using it.

Apart from the therapeutic value of the 'pack', it has a diagnostic use. When pus is present the plugs on removal are found to be blanched instead of dark brown.

Apart from a little watering of the eyes during the first or second treatments, the application should cause no discomfort of any kind and the plugs remain *in situ* for an hour, after which they can be removed by the patient or the operator.

Treatment is carried out daily for a fortnight, after which twice or thrice a week for a month is usually sufficient.

The nose should be cleansed with an alkaline lotion before the insertion of the plugs and gentleness is essential for carelessness will readily provoke spasm.

It is very interesting to observe the reduction of inflamed and swollen turbinates as the result of treatment and it is of further interest to note that the tendency to head colds is greatly reduced by their use.

Diastolization.—Another successful form of treatment which I have employed for some years is Gautier's diastolization. It consists of intra-nasal massage by means of dilatable rubber bougies shaped to fit the nasal fossæ. The bougies are made in five sizes and are manipulated by means of a rubber bulb and connecting tube which, on compression, force air into the bougie which becomes rigid.

This treatment is indicated in catarrhal conditions and as a means of restoring the air way

when obstruction is due to œdematous conditions. Also I use it in preference to the cautery for desensitizing the nose.

Sensitive points on the nasal septum or turbinates which when irritated produce a coughing or sneezing reflex are usually cauterized, but in diastolization one has a far more efficient and lasting mode of treatment and it is constructive where the cautery is destructive. A spongy, œdematous nasal mucous membrane associated with nasal catarrh and deafness clears up rapidly and completely.

The effect of intra-nasal massage is to restore tone to the nerves, muscles and mucosa of the naso-pharynx and adnexa.

This treatment was first carried out by Dr. Gautier of Paris and it is in regular use at his clinic (Hôpital Dispensaire); it is also practised by Professor Worms at Hôpital Val-de-Gras.

Apart from the method now to be described, treatment is carried out at these clinics by means of the vibrating sinusoidal current, but as this treatment is not directly applicable to cases of asthma it will not be dealt with here.

Before commencing treatment, the nasal respiration is estimated by means of the 'masque de peche'. This apparatus consists of a tightly fitting face mask and manometer.

The patient is instructed to breathe vigorously in and out through the nose with lips tightly shut. The mean reading is taken, and, after adequacy of nasal respiration is estimated, treatment is commenced.

The nose is first washed out with a simple alkaline lotion and dried. One of the smaller sterilized bougies is connected to the rubber bulb and passed gently into the nasal fossa to its full extent, no notice being taken of turbinates.

With the bougie in this position, it is dilated by pressure on the bulb and retained thus for two or three minutes to compress the crypts and squeeze out mucus. The bulb is then released and the flaccid bougie withdrawn to about three-quarters of its length. The actual massage now takes place by passing the bougie in and out of the nose, alternately rigid and flaccid.

This process is repeated slowly some thirty or forty times, and is completed by again leaving the bougie distended in the nose for a minute or two. On completion of the treatment a quantity of mucus can be expelled by gently blowing the nose. Again this treatment is painless except for some mild discomfort during the first one or two treatments in the case of very sensitive noses. A little care for the first few treatments and even young children tolerate it without any trouble.

A course consists of some twenty applications which are carried out three times a week, the size of the bougie increasing from time to time. Improvement in the air way is of the greatest value in the treatment of asthma though only certain cases are suitable for diastolization and experience alone will allow the operator to

decide this point. The 'masque de peche' will show the degree of improvement which results from treatment.

One should not leave the question of the nasal factor in asthma without brief reference to the use of nasal dilators as a means of improving the air way. In civilized man the nasal alæ are of little use as voluntary muscle for the purpose of dilating the nostril.

Few people appear to have the ability to dilate the nostril adequately at will with the result that through atrophy the nostrils tend to collapse, the passage of air becomes inadequate, and the mucous membrane within the nose loses tone and becomes swollen.

For the same reason it is essential during an examination of the nose to do so immediately the speculum is inserted, for after one or two breaths with the nostrils thus dilated the membrane shrinks and becomes paler.

We know what relief the asthmatic patient feels when he is told to breathe whilst both nostrils are held open.

The apertures of some nostrils appear as little more than slits which on inspiration tend to contract rather than dilate, closing the orifices still more. It is in such cases that mechanical dilatation is of great help and I have known several patients who have been able to sleep throughout the night, free of spasm simply by the use of nasal dilators.

These dilators are indicated in cases where, for some reason or another, the nasal apertures are narrow and incapable of adequate dilatation and cases where a deflected septum is causing partial blocking of one or both nostrils, and the patient refuses operation.

There are several types of dilator obtainable and I have investigated most of them, some made of celluloid and some of thick silver wire and another such as Hurst's pattern, which grips the bridge of the nose in the form of a 'pince-nez' from which by wire side pieces the nostrils are held open by spring action. The best model in my opinion is the 'Francis' dilator. It is made of silver wire, so constructed that, with the base resting low down on the septum, the intermediate arched portion holds open the nostril. It is only necessary to open the nostril at its extreme lower margin.

This dilator is made in four standard sizes although I have intermediate sizes made for me as a correct fit adds to comfort and efficiency.

Wire has the obvious advantage over celluloid of being more hygienic. After the first fitting by the doctor the patient is able to insert and remove the dilators without any difficulty. I recommend this simple procedure where there is nasal obstruction in the absence of pus and where operation is refused or postponed.

By the means that have been described it is possible to reduce nasal surgery in asthma to

a minimum. In my own practice not more than 5 per cent of cases are subjected to operation while the results obtained by conservative measures are more certain and effective. I am never as sanguine regarding the prognosis in a case of asthma when operation is inevitable as I am when the condition lends itself to one or other of the measures I have described.

No case of asthma can be completely cured whilst there remains a pathological condition within the nose or sinuses. We have however at our disposal adequate means of dealing with any nasal condition which can have any bearing on the asthma syndrome.

A word of warning must be given regarding the use of ionization in the treatment of asthma. This treatment, which can be very effective in hay fever and certain simple catarrhal conditions, would appear to offer scope for its use in asthma. Actually the reverse is the case.

Ionization in the case of asthma when any form of nasal treatment is required is a certain way of provoking spasm and should never be employed.

In conclusion, I should like to draw attention to certain new preparations which are proving of value in the treatment or prevention of broncho-spasm and which appear to have none of the ill effects of some preparations at present in common use.

For immediate control of the actual spasm, a preparation known as 'antispasmodic inhalation' is used by means of a hand inhaler fitted with a complete face mask or by means of an electric inhaler giving a continuous vapour. This preparation contains papaverine and ephedrine and I have not known it fail to control spasm within a minute or two. It has the great advantage over ephedrine injections in that the dose can be readily controlled and discontinued as soon as the spasm passes. Any question of nervous manifestations, heart-hurry, etc., are thus avoided. Tri-xanthin co. tabs. (Bencard) contain tri-xanthin and a barbiturate and are particularly indicated in cases of spasm produced by exertion. The patient is instructed to take one tablet half an hour before taking exercise and the effect is dramatic, the patient being able to take quite long walks without distress. Excellent results are said to have been obtained in certain other conditions including migraine, dysmenorrhœa, etc., but I have no personal experience of this.

Another valuable preparation is the 'anti-spasmodic suppository'. It is indicated in nocturnal asthma and its use in these cases is most effective. Peaceful sleep produces a striking improvement in the patient's appearance and well-being. I believe these preparations are now available in India and I should be glad to know the opinion of other observers as to their experience with them.

HOBBS' TREATMENT WITH GLYCERINE APPLIED TO MALE URETHRA IN GONORRHOEA

By R. L. RAYMOND,

CAPTAIN, I.M.S.

Civil Surgeon

K. K. DE, L.M.P.

and

U. SOE NYUN, L.M.P.

Shwebo, Burma

THE antiseptic treatment of gonorrhœal urethritis is very unsatisfactory. Irrigations are frequently described as being useful for their mechanical washing effects only. They may prevent backward spread by killing the organisms before they are again implanted in healthy mucosa, but this can at best only apply to the gonococcus (see below). Neither local irrigation nor oral therapy producing antiseptics in the urine can affect organisms in the Littre gland. Intravenous therapy that aims to apply the antiseptic direct to the organisms in the glands through the blood stream is more rational, but in practice is unsatisfactory. Mercurochrome and acriflavine are not sufficiently specific to kill the organisms in the great dilution in which they must reach them, *via* the blood stream. The manufacturers of Uleron claim more specific drug effects.

Of those organisms which are discharged in the pus into the urethra only the gonococcus could possibly be killed by any antiseptic, except the hypochlorites. It is difficult to find reports of experiments on the bactericidal power of drugs carried out against the gonococcus, so one cannot venture to say whether potassium permanganate has any selective action on the gonococcus. It certainly has none on the staphylococcus. Hence the large number of secondary infections where potassium permanganate is the irrigation fluid. However, we know that :—

(1) Hypochlorite solution containing 0.005 per cent available chlorine (*i.e.*, approximately eusol, 1 to 60 dilution) will kill virulent staphylococci in under one minute, whereas

(2) Potassium permanganate 1 to 1,000 and hydrarg. oxycyanide 1 to 1,000 will not kill the same organisms in over five minutes.

The inference is that if antiseptic effects are aimed at in local irrigation hypochlorite solutions should be preferred to the time-honoured potassium permanganate and hydrarg. oxycyanide.

However, once we admit that the mechanical effects are the most important, it would seem that drinking vast quantities of plain water with the subsequent frequent micturition is better than two or three irrigations a day, and without the attendant risk of causing secondary infection.

Because this washing alone is not enough and because antiseptic therapy is so unsatisfactory we have tried the osmotic effects of glycerine to coax out the organisms from the deeper layers

with the stream of bactericidal tissue fluids. Because it has proved effective in uterine sepsis, it is reasonable to suppose that it should prove effective in the similar condition of urethral sepsis, similar in that these organisms are hidden in glands and submucosa inaccessible to antiseptics by direct application. Below is appended a table to show the course of the infection in 14 consecutive cases without and 22 cases with glycerine treatment. One grain of acriflavine is added to each 5 ounces of glycerine to ensure that it is sterile. Irrigation with potassium permanganate 1 to 8,000 was done in both series, and in the glycerine-treated group the glycerine was injected directly after irrigation.

The glycerine was injected with a sterile urethral syringe with a rubber olive on the nozzle and was retained in the urethra for as long as the patient could conveniently tolerate it. The glycerine causes smarting pain in the urethra. The glycerine has been forced into the posterior urethra and bladder at times either by accident or by design—the latter in female patients—without more discomfort than was caused in the anterior urethra. The injections were given once a day, but twice a day would probably be better. The urine becomes more turbid for one or two hours after injection owing to the tissue fluids, cells and debris extracted by the glycerine. The amount injected was enough comfortably to distend the urethra.

Although in almost all cases that reach hospital the infection has already spread to the posterior urethra and although glycerine therapy is essentially that of the anterior urethra, still benefit was derived. This is comparable to the improvement in nasal pan-sinusitis when the antra only are drained. We believe that in an early case of anterior urethritis the rational treatment would be glycerine injections, forced water drinking, hot fomentations to the urethra, and protein shock to raise the bactericidal power of the blood. We would of course bear in mind proseptasine and uleron.

Our standard of cure is of course not strict, because the patient usually decides it for us by walking out of the hospital when he feels well enough and there is no discharge, or when he is bored with the proceedings.

The table, however, shows that in each group 64 per cent arrived at the stage of clear first and second urines which we may in these circumstances call a cure. Where the urine was almost clear we may call them relieved—36 per cent without glycerine and 27 per cent with glycerine. The remaining two cases, both under glycerine treatment, left hospital early with only slight improvement.

Patients who show clear urine for some time before leaving hospital were being retained for prostatic massage and passage of sounds.

The degrees of cloudiness of the urine is expressed in the table as 3, 2, 1, 0. Every cloudy

INDUCTION OF LABOUR

By G. P. CHARLEWOOD, M.B., Ch.B., M.C.O.G.

CAPTAIN, I.M.S.

Civil Surgeon, Morven, Mercara, Coorg

INDUCTION of labour during the period of viability of the foetus has been extensively practised in the past, but its use is now becoming more and more restricted. One reason for this is that the foetal mortality after induction of labour has been found to be unsatisfactory. For instance, Kleinwachter (1902) in Germany after an exhaustive study found that 78.3 per cent of babies are born alive after induction of labour, but only 60 per cent leave hospital alive and that a further percentage die in the first year because of the extra care and attention which premature babies require.

More recently, it has been pointed out that a premature child must lose the effects of the large amounts of gonadotropic and other hormones which are circulating the mother's blood at this time. A careful history in cases of hypoplasia of the uterus in adults will often bring to light the fact that the patient was a premature baby. So that, even in cases where the baby survives, one cannot be sure that irreparable harm has not been done.

Indications

(1) *Contracted pelvis*.—Induction of premature labour has been commonly employed in the past as the treatment for contracted pelvis. The results as far as the mother was concerned

(Continued from page 729)

urine was tested with acetic acid for phosphates and periodically by microscopic examination.

The urine referred to in each case is the first morning specimen obtainable. Only one case developed a complication under treatment and that was a case of epididymitis in a glycerine-treated case.

The important feature of these two series is that the average number of days in hospital in group 1 (without glycerine) was 33, which conforms pretty well to the ordinary run of venereal department wards—while the average number of days in hospital in group 2 (with glycerine) was 18, excluding two cases that left hospital without improvement within a week and which bias the figures in favour of the glycerine-treated group. The percentage of cases cured and cases relieved is almost the same in each group, so we cannot be accused of 'cooking' the figures and moreover, as we have said, the patient is usually the arbiter in this matter.

The reason then for publishing these figures is that a line of treatment that has reduced the average stay in hospital of gonorrhoeal patients by 45 per cent is worthy of record, and that, since the treatment is based on logical principles, it may be expected that these figures would be repeated.

were always good, but the foetal mortality varied from 12 to 45 per cent.

In view of the risks to the child resulting from premature induction of labour it is now the usual practice in most British and American hospitals to give a trial of labour in all cases of contracted pelvis (except where spontaneous delivery is obviously out of the question). Where the head does not enter the pelvis, lower-segment Cæsarean section is performed. This will be necessary in less than 20 per cent of cases.

Accurate measurement of the pelvic inlet by the modern x-ray method (as originally described by Boachacourt, 1900) is now widely used as a guide as to whether there is any likelihood of the head entering the pelvis, and, if so, the course labour is liable to take, e.g., occipito-posterior in the android type of pelvis (Caldwell and Moloy, 1933).

The usual method of x-ray pelvimetry is briefly as follows:—The woman is placed sitting with the plane of the pelvic inlet horizontal, i.e., sitting with her back making an angle of 58 degrees with the horizontal. An x-ray photograph is taken in this position and the patient is then removed but not the plate. A lead sheet (perforated with small holes drilled wherever parallel lines 1 cm. apart intersect similar lines drawn at right angles) is then placed in the position and plane which was previously occupied by the pelvic inlet and a second (flash) exposure is given to the same x-ray plate.

The distance between any two points on the photograph can be read off in centimetres by counting the dots, which result from the second exposure.

(2) *Albuminuria of pregnancy, pre-eclampsia, and chronic nephritis*.—These afford common indications for induction, where conservative treatment has failed. (It is worth noting that where conservative treatment has included the administration of progestin, labour will be extremely difficult to induce and, short of performing Cæsarean section, may prove impossible.)

Where the condition does not respond to conservative treatment, it is unwise to hold one's hand too long in the hope of getting a live baby, as the usual result in bad cases is a premature still-born child. Meanwhile, by postponing induction, the mother's kidneys have been exposed to unnecessary damage or eclampsia may have supervened. Cæsarean section is often the most practicable treatment.

(3) *Cardiac disease*.—In cardiac disease induction of labour is indicated where there is broken compensation which does not respond to appropriate treatment. In many of such cases, Cæsarean section with sterilization is the treatment of choice. One should always make an attempt to get decompensated heart cases into as good a condition as possible before imposing the additional strain of induction.

(4) *Placenta prævia*.—This often offers an absolute indication for induction, but is a special subject.

(5) *Postmaturity*.—The postmature child affords one of the most easily defensible indications for induction of labour. When the expected date of confinement has passed and disproportion begins to develop as estimated by the methods of Muller or Munro Kerr, labour should be induced, especially when there is a history of increasing distocia with each successive confinement. Efforts aimed at limiting the development of the foetal head by decreasing the diet, or the calcium intake of the mother are of no avail. The children born of starving mothers, as clearly demonstrated in Germany in the war, are of normal size and development. Children born of osteomalacia mothers show normal calcification and those born of anæmic mothers have normal amounts of hæmoglobin. The foetus leads a parasitic existence and takes its requirements irrespective of the mother's condition.

(6) *Diabetes*.—In diabetes induction is now rarely required where insulin therapy is thorough. The prognosis for the child remains doubtful.

(7) *Hydramnios*.—By embarrassing the respiration and heart action this may necessitate induction of labour. This is easily accomplished by rupture of the membranes. An attempt may be made to carry the woman to term by sub-umbilical paracentesis and the slow withdrawal of fluid. This procedure has proved successful at Queen Charlotte's Hospital. It is not permissible until a careful x-ray examination has failed to show any foetal abnormality.

(8) *Chorea*, especially when its onset has not preceded the pregnancy, may be so severe as to require induction of labour or abortion as the case may be.

(9) *Tuberculosis* is no longer regarded as an indication for the termination of pregnancy. It has been shown by Bridgman and Norwood (1926) that more deaths follow the artificial termination of pregnancy than where it is allowed to run its natural course. Pregnancy should, of course, be scrupulously avoided. A possible indication for induction may arise in the occasional case where the child is viable, but the mother unlikely to live to term.

(10) *Peripheral neuritis*.—When this is severe and does not respond to vitamin B, etc., it is said to constitute an indication.

(11) *Pernicious anæmia*.—When this disease has existed prior to pregnancy it is an indication.

(12) *Convenience*.—The convenience of the patient or her doctor should never be allowed to influence the decision, still less to constitute the only indication for induction. Sooner or later disaster will follow such practice and in any case the doctor lays himself open to be blamed for any untoward development whether connected with the induction or not.

It should be remembered that even the simplest induction is not devoid of danger and as such

should not be resorted to without sound indications.

Methods of induction

For patients at full term or when past term Watson's method or modifications thereof has been used with fair success for years. Several foetal deaths have, however, been reported as the result of violent tetanic contractions of the uterus following the injection of pituitary extract. More recently, cases of unexplained foetal death have occurred where the quinine has been suspected of causing the mischief. Many authorities have for this reason abandoned the use of quinine. Pituitary extract (1 c.cm.) or pitocin (10 units) may be given with safety on a pledget of cotton-wool placed beneath the inferior turbinate bone, as originally recommended by Hofbauer and Hoerner (1927). It is readily absorbed from the nasal mucous membrane and may be removed at once should the uterus contract unduly violently.

Watson's method is as follows:—At 6 p.m. castor oil 1 oz., at 7 p.m. quinine 10 gr., at 8 p.m. a large enema, at 9 p.m. quinine 10 gr., at 12 p.m. quinine 10 gr. Next morning at 9 a.m. if pains have not commenced 0.5 c.cm. pituitary extract half-hourly for six doses or until labour commences.

Œstrin (20,000 international benzoate units hourly for 10 injections) in conjunction with other methods may have the required effect, appears to be without danger, but is very expensive.

The vast majority of cases at or past term will respond satisfactorily to medical induction consisting of castor oil, enemas, intra-nasal pitocin and, where feasible, œstrin.

Earlier in pregnancy, however, the percentage of failures becomes increasingly large and more active interference may be required. Rupture of the membranes may be practised in combination with intra-nasal pitocin and will almost invariably prove successful. This method has been used for some years at the Johns Hopkins Hospital. There are, however, two definite contra-indications. Where there is a long cervix especially when associated with unabated constipation of pregnancy (showing that the patient is still under the influence of progestin) rupture of the membranes will frequently fail to bring on labour and will expose the woman to the risks of intra-partum infection. Secondly, rupture of the membranes is most indicated when the head is still floating and the child is alive, because the rush of fluid may carry the cord past the head and it may be obstructed during labour. Generally speaking rupture of the membranes will only be practicable at or fairly near term.

In cases where medical induction has failed, and where rupture of the membranes is not considered advisable, a stomach tube or better still a very thick-walled rectal tube (Goodrich

(Continued at foot of opposite page)

REPORT OF A CASE OF EARLY ACQUIRED SYPHILIS IN A PATIENT WITH TERTIARY STIGMATA OF UNTREATED YAWS

By R. V. RAJAM, M.B., M.S., M.R.C.P.

Venereal Specialist, Government General Hospital, Madras

THE relationship between syphilis and yaws still remains an unsolved problem. To the tropical venereologist, the question is really more than of academic interest. In this part of India syphilis is fairly prevalent and yaws is endemic in many of the districts of the presidency, and the medical man is frequently confronted with cases, especially in children and adolescents, in which a clear-cut diagnosis is rendered difficult or impossible. But the social and psychological importance of differentiating the two diseases looms large in the eyes of the patient.

Some hold the view that yaws is only a tropical prototype of syphilis. The *Treponema pertenue* of yaws is morphologically indistinguishable from *T. pallida* of syphilis. Many of the clinical manifestations of the two infections are identical. Both the diseases become systemic infections very early and the serological reaction of the blood is the same. They resemble one another also in the rapid therapeutic response to organic arsenical drugs and bismuth

(Continued from previous page)

Company) may be passed between the uterine wall and the membranes. This should be combined with intra-nasal pitoein, etc. Efficient pains will usually start within 24 hours. If they do not the tube should be removed.

In many cases, Cæsarean section will be considered preferable as the results are more certain and there is no delay.

Summary

Induction of labour should be avoided as far as possible because of the fetal mortality and because of the possibility of genital hypoplasia resulting from the early removal of the child from the influence of the maternal hormones.

The various indications for induction and the technique have been surveyed.

compounds. Yaws is said to differ from syphilis in the method of transmission of infection from the infected to non-infected, in the absence of congenital or hereditary infection, in the rarity of visceral, cardio-aortic and nervous system involvement, and in its strict geographical distribution between the Tropics of Cancer and Capricorn. It is argued that these differences are conditioned by climate, sartorial and other social habits of the people, and by a racial peculiarity of interaction between the host and the parasite. As put forward by Stannus some years ago, an intensive comparative study, both clinical and pathological, of the two diseases under identical conditions of climate, race, etc., is still a desideratum.

Others are of opinion that the two diseases are distinct and mutually exclusive. In favour of this is quoted the fact that, in regions (Pacific islands, Fiji) where yaws is rife, syphilis is rare. This is explained by the theory of a reciprocal immunity. The question of reciprocal immunity was challenged by Neisser, von Prowazek and Castellani, who, using monkeys in experimental inoculation, declared that neither disease confers immunity to the other. But Levaditi found that monkeys immunized for yaws do not thereby acquire immunity to syphilis, but immunized for syphilis they have a partial immunity to yaws. To develop the immunity, the length of time which the infection has persisted in the animal is considered important. It is suggested by Nicholls that there is a true immunity to syphilis in those persons who have suffered a long course of untreated yaws.

Harrison thought that the relationship between the two diseases would not be decided by the results of experiments to determine resistance to infection with the organism of yaws after previous inoculation with the organism of syphilis, or *vice versa*. It has been proved by Brown, Pearce, Chesney, Kolle and others that rabbits which have been inoculated with one strain of *Treponema pallida*, though resistant to that particular strain, can be successfully re-inoculated with a heterologous strain of the same organism. This experimental observation may as well be applied to the alleged absence of immunity between yaws and syphilis. The close similarity between yaws, syphilis, and the more recently described *Bejel* of Arabia, in their causative organisms, in their clinical manifestations, serology and therapeutic response, may be explained on the supposition that they are a group of disorders of the same family (treponematoses).

A male, aged 39 years, was admitted to the venereal department of the Government General Hospital with a penile sore and cutaneous eruptions.

Previous history.—In his 10th year the patient developed a sore at the nape of his neck which took nearly a month to heal. From that period for about 8 years he suffered from multiple recurrent ulcers scattered all over the body, but particularly on the extremities and, from his statement, it appears that he

has had no special treatment for the condition. The ulcers healed and then spread. The patient finally became a cripple. Now for the past 19 years he has not suffered from any active disease.

Family history.—The patient is a native of Cochin where yaws is endemic. Unmarried. His father died when he was 16 years old. Mother alive and healthy. He has three brothers and three sisters all alive and healthy.

Present history.—Two and a half months ago he exposed himself to the risk of venereal infection and noticed a sore on his penis 15 days after exposure. About 8 weeks after the appearance of the penile lesion he developed a rash on the skin.

Condition on admission.—An ill-nourished man of 39 partly edentulous. Patient crawls about, being unable to stand and walk. Multiple, puckered, thickened scars of old ulcers on the arms, shoulder regions, buttocks, legs and feet. Both the lower extremities are badly deformed. The skin of the limbs, especially

the legs and knees, is one mass of adherent cicatricial tissue. The bones of the legs are considerably atrophied and thin. The right foot is a shapeless mass of pseudo-elephantiasis. Both the knee joints are ankylosed in the position of partial flexion. The right hand and fingers are also deformed and scarred. The accompanying photograph reveals more than any description the state of the lower limbs.

An indurated papulo-ulcerative chancre on the anterior aspect of the coronal sulcus is partly visible in the photograph. The glands in both inguinal regions are slightly enlarged, painless and discrete. Scattered papular syphilids on the trunk and limbs. No mucous membrane or muco-cutaneous lesions. No stigmata of congenital syphilis. Dark-ground examination of the serum from the chancre showed teeming *Treponema pallida*. The Kahn and Wassermann reactions of the blood were positive. The patient was put on anti-syphilitic treatment and the chancre and cutaneous rash rapidly disappeared.

THE TREATMENT OF ANIMALS WITH ANTIRABIC VACCINE

By R. O. A. SMITH, D.T.M., I.M.D.

Officiating Director

J. P. McGUIRE, L.M.S.S.A. (Lond.), I.M.D.

E. D. STEPHENS, D.T.M., I.M.D.

and

B. N. LAHIRI

SUBEDAR, I.M.D.

(From the Pasteur Institute of India, Kasauli)

THE advisability of treating animals with antirabic vaccine either as a prophylactic measure or subsequent to exposure to infection is a matter on which directors and other workers

(Continued from previous column)

So far as I can gather, there are not many such cases published in the literature. Hanschell (1928) related two cases, one in a male West Indian, and the other in a West African negro, who were seen by him with primary syphilis and with serological and clinical evidence of old yaws. Two other cases were reported by H. D. Chambers in 1937. In the first case, a woman who had yaws ten years previously gave birth to a child with signs of congenital syphilis and had a strongly positive Wassermann reaction. The chances of the mother transmitting yaws were considered remote. It was indirectly inferred that the mother must have been infected with syphilis. In the second case the mother had yaws two years prior to the birth of the child. This child showed no evidence of congenital syphilis, except that the Wassermann reaction was strongly positive.

Summary

1. A case is reported of early acquired syphilis in a patient with tertiary stigmata of untreated yaws of 29 years' duration.
2. The patient comes from Cochin State where yaws is endemic.
3. The photograph shows the terrible crippling and deformity caused by untreated yaws. Such profound pathological changes in the soft tissues and bone are very unusual in syphilis.
4. The presence of long-standing yaws has not conferred any immunity against syphilis and the reaction to the syphilitic infection both local (chancre) and the cutaneous was moderately severe.

My thanks are due to the Director, Barnard Institute of Radiology, for the clinical photograph.

in Pasteur Institutes are not unanimously agreed.

One of the main reasons advanced against the treatment of animals is the difficulty of arranging for their proper segregation during the period they are at risk. From general observation in India it would seem that except in the case of dogs, and then only in certain circumscribed areas such as cantonments and well organized towns, animals exposed to infection get neither segregation nor treatment, the owner just trusting to luck that they may escape the disease. The lack of statistics renders it impossible to estimate the mortality from rabies among cattle and other useful domestic animals in India. Certain information on the subject can be obtained from the records of this Institute as the history cards of patients treated also record whether any animals have been bitten by the dogs who bit the patient. An examination of the cards of about 800 patients treated during 1937 shows the following number of animals having also been bitten :—

Species	Number bitten	REMARKS
Camels ..	2	
Buffaloes ..	50	Also 3 cards marked 'several'.
Horses ..	3	
Goats ..	10	Also 2 cards marked 'several'.
Oxen ..	47	" 5 " " "
Donkeys ..	5	" 1 card " "

In addition there were 20 other cards where it was stated that 'several animals were bitten', but these were not specified. It is unlikely that any of the above animals received antirabic treatment and the actual mortality among them is a matter for conjecture. There were also a number of dogs said to have been bitten by the rabid ones; the disposal of dogs exposed to infection, however, will be considered separately for various reasons.

Despite such a state of affairs no death from hydrophobia has been reported among persons treated at this Institute and its centres during the past 30 years for infections caused by horses, cows, donkeys, or buffaloes (Smith, 1937). The saliva of these species of animals has been proved by different workers to contain the virus.

Provided treatment is given when necessary it would appear that rabid cattle do not constitute a grave danger to man, but their death from the disease represents a serious loss to their owners. It may therefore be assumed that no serious contra-indications exist to the treatment of this class of animal in India. The efficacy or otherwise of the treatment could be estimated by the results obtained up to date, which are given in tabular form below.

Of domestic animals which are susceptible to the disease and transmit it freely, dogs are the

only ones that need be considered. The treatment of dogs may conveniently be divided into :—

- (1) Prophylactic treatment.
- (2) Treatment after exposure to infection.

(1) The prophylactic treatment of dogs has been recommended by the International Rabies Conference (Marie *et al.*, 1927) and there are no serious reasons why prophylactic treatment should not be carried out on a large scale in India, as is being done in certain other countries. The vaccine itself is harmless, being composed of a dead carbolyzed fixed virus. The suggestion that such treatment may result in conferring a partial immunity and, if the animal be subsequently infected, give rise to conditions like 'inapparent' or 'recurrent' rabies need not cause any doubts. No reports of such conditions have emanated from Japan or America where the prophylactic treatment of dogs has been practised extensively. Neither have they been noticed at this Institute which has carried out the prophylactic inoculation of dogs on a small scale for the past five years.

(2) The treatment of dogs that have been exposed to infection is a different matter and is dependent largely on the value of the animal and the nature and position of the wounds it has sustained. It may here be mentioned that this Institute does not recommend the treatment of any dog which has been severely injured on the head or neck. As dogs are so susceptible to rabies, the chances of such an animal escaping the infection are very meagre and the kinder fate for the dog and the safer one for the owner and his immediate neighbours is to destroy the animal in as humane a manner as possible. Provided however that satisfactory segregation can be arranged it has become the practice for this Institute to encourage owners of valuable dogs which have not been severely wounded on the head and neck to have them treated. The precautionary measures to be adopted when it has been decided to treat such animals are laid down in the pamphlet on *Rabies and Antirabic Treatment in India* (Shortt, 1933), and need not be recounted here.

The results of treatment with our vaccine are now being collected six months after the date of completion, as is done in the case of humans, and below in tabular form are given the figures up to date.

The mortality among dogs treated after exposure to infection for these two years is a little over 2 per cent, which, considering the special susceptibility of dogs to rabies, is a very satisfactory figure. Cows and buffaloes also seem to respond to the treatment very efficiently. The loss of 3 out of 17 horses, however, represents a mortality of over 17 per cent, which seems a high figure. Of the three deaths, one was an animal which sustained 5 wounds on the forehead and treatment was begun 7 days late. In the second which had 2 wounds, one on the face and the

other on the leg, treatment was begun 3 days late. The third was one of four treated in a remount dépôt. All four animals were bitten on the nose by the same rabid dog, and treatment was begun four days after they were injured. It is gratifying to note that the other three animals survived. A dog and a buffalo, presumably infected by the same rabid animal in an adjoining village, received no treatment and died of the disease.

It may be concluded from the results that the vaccine confers a considerable degree of protection against infection, and that prophylactic and post-infectious inoculation of animals will save many lightly bitten ones that might otherwise succumb to the disease.

Treatment

The vaccine recommended for the treatment of animals is prepared in exactly the same manner as that for humans, only it is stronger, and the dosage for the different species of animals has been graduated according to their weights. For the prophylactic inoculation of dogs a series of seven daily inoculations of 6 per cent carbolyzed vaccine, 5 c.cm. for dogs weighing under 30 lb., and 10 c.cm. for those above that weight is recommended. Experiments conducted in the Institute have shown that the vaccine affords very efficient protection against the Indian strains of street virus, for a period of eight months and probably longer.

The following experiment was carried out to determine the efficacy of the carbolyzed vaccine prepared here compared with one on the open market. This proprietary vaccine is said to contain 33½ per cent rabies brain and cord tissue in which the virus has been killed by chloroform. It is also stated that, while the use of the single dose as a prophylactic for dogs before exposure has been found highly satisfactory, the double dose or series of injections will accomplish more. It is unfortunate that many dog owners assume therefore that a single inoculation is all that is necessary to protect their animals. That this idea is erroneous may be concluded from the results of the experiments cited below.

Fifteen dogs divided into three groups of 5 each were used in the first experiment. One group received 5 c.cm. of Kasauli antirabic vaccine for 7 days; the second group were given one injection of the proprietary vaccine mentioned above on the seventh day of inoculation of the dogs in the first batch, and the last group of 5 were kept as controls.

Twenty-five days after the treatment the dogs were given a dose of street virus into the muscles of the neck.

It is unfortunate that one dog from each batch died before the infecting dose was given, so that four animals of each group only were available for the test.

In a second experiment 15 monkeys were treated and infected under identical conditions.

The results of both experiments are given below in tabular form:—

TABLE

Comparison of Kasauli antirabic vaccine for animals and a proprietary antirabic vaccine

		DOGS			MONKEYS		
		Infected	Died		Infected	Died	
			Other causes	Rabies		Other causes	Rabies
Kasauli vaccine	..	4	1	0	3*	0	0
Proprietary vaccine	..	4	1	3	5	0	3
Controls	..	4	0	4	5	0	2

* Two died before infection from dysentery.

The results indicate that a single dose of vaccine of the type tested composed of dead fixed virus is not sufficient to protect an animal. Hermann (1928) concluded from a number of experiments that a single inoculation of a live fixed virus as large as can safely be given is not sufficient to protect an animal.

In a country like India where no muzzling or quarantine laws are in force and the number of uncared-for and ownerless dogs is legion, efficient prophylactic immunization against rabies will afford owners who value their animals a definite measure of protection, both for their dogs and themselves.

A Mirror of Hospital Practice

EPIDERMOLYSIS BULLOSA: A CASE REPORT

By B. M. KOTHARY, M.B., B.S.

In charge, Skin Department, Windham Hospital, Jodhpur

THE rarity of this condition is my plea for reporting the case.

A boy, aged 8 years, was admitted for multiple bullæ all over the body. The whole integument was covered with whitish scars resulting from the healing of such bullæ. The duration of his complaint was about seven years, that is, since his childhood. His sister about 12 years old was also suffering from the same disease. But another, older sister never had the trouble, nor had any of their forebears for three generations ever complained of it.

The history is that the child was attacked with small-pox during his childhood and ever since then he has been suffering from this condition. He is worse in the winter, while in the summer he is slightly better. Sometimes the bullæ are as big as lemons. Slight friction, pressure or irritation tends to produce blisters rapidly, which either rupture and dry up quickly or become secondarily infected on scratching. The bullæ are painless and do not tend to run into each other.

The nails have atrophied so much that there is no suggestion of their past existence on any finger or toe. The sites where bullæ appear most frequently are those which are exposed to pressure or injuries, namely, back of knuckles and phalanges of hands, elbows, knees, ankles and waist-line. There are no abnormalities in any other part of the body except the skin. Laboratory examinations of his blood, stools and urine do not show any abnormality.

The prognosis is reported to be unfavourable. The disease persists all through life and one is incapacitated from work. On the approach of adolescence a few lucky cases have improved, however. It certainly seems to be unfavourable in my case. Treatment is said to be unsatisfactory, and I have certainly found it to be so.

Presuming the disease to be a vasomotor disturbance due to abnormalities in the epidermis, calcium orally and intravenously was tried, but it did not improve the condition. Ergot was administered for a few days, but he developed amblyopia and therefore it had to be discontinued. Protein shock therapy was also given a trial through milk injections and autohæmotherapy. Ultra-violet exposures were given for quite a good number of sittings. Endocrinotherapy with thyroid and parathyroid extracts was also given its chance. Carbolyzed filtrate from the vesicles was therapeutically used. After all, the tendency to vesicle formation still persists as badly as when the patient was admitted.

I shall be grateful for any advice or suggestions for the treatment of a case of this kind.

Finally I must thank Mr. E. W. Hayward, F.R.C.S. (Ed.), Principal Medical Officer, Jodhpur State, for permission to publish this case.

MULTIPLE PERFORATIONS OF SMALL INTESTINE WITH RECOVERY

By E. H. WALLACE

CAPTAIN, I.M.S.

Civil Surgeon, Malakand

and

AMIN-UL-HAQ, M.B., B.S.

Lady Minto Hospital

A MOHAMMEDAN boy of four years was accidentally shot in the abdomen from a distance of one foot by a playmate with a 'Diana' air-rifle of German manufacture and of 0.17 grooved bore.

Operation was commenced 3½ hours after the injury and the abdomen was entered via a 3½ inches left paramedian incision. The pellet entered the abdomen

at a point one inch to the left of the umbilicus and went through the left rectus. The course of the pellet was followed through four separate coils of the small intestine and the perforations being very small were partially closed by retraction of the muscular layers. There was only slight evidence of contamination of the abdominal cavity by faeces. The perforations were closed one by one by purse-string sutures with no. 000 catgut. On reaching the fifth coil only one entering perforation could be found. The pellet was searched for but could not be located and it was presumed that it had lodged in the lumen. Two small apertures in the mesentery were not sutured. The abdomen was closed and a small glove drain was retained for 24 hours.

The pellet was recovered from a normal motion on the third day following operation. The patient made an uneventful recovery.

This case is described to show the surprising amount of damage that a small unlicensed air-rifle can cause and, secondly, it illustrates the value of early laparotomy in gun-shot wounds of the abdomen.

FILARIASIS IN THE MIKIR HILLS

By P. N. MITRA, M.B., D.T.M.

Mawkhar, Shillong

THOUGH I have been working in different parts of Assam for the last twenty-three years, I have only rarely seen clinical filariasis. The disease is occasionally seen among people coming

from Bengal, Bihar or Orissa; but the infection in such cases was contracted outside Assam. I have seen a few cases of elephantiasis of the legs among the indigenous population but I never succeeded in recovering microfilariae from such persons and it was otherwise doubtful whether

these cases were due to filariasis. However, in the Sibsagar District, in Golaghat, I came across well-marked clinical filariasis among the Mikirs. The Mikirs live in a low range of hills, running on the south of and more or less parallel to the Brahmaputra river, extending through the districts of Sibsagar and Nowgong in Assam. These hills are covered with dense jungle and are well watered with numerous springs and streams. There are no roads or bridges in these hills and no wheeled traffic is possible. The nearest hospital is at Golaghat about thirty miles away.

Elephantiasis of the legs and scrotum and enlarged lymph glands are the types that are met with. The photograph of one case shows the enormous size the scrotum had attained. Microfilariae were searched for in this patient as well as in others. The patients were available only during the day and venous blood was withdrawn with a syringe and poured into 2 per cent acetic acid, in water. By this method sheathed microfilariae were seen many times. One specimen was sent to the School of Tropical Medicine at Calcutta, and was reported upon as follows:—'The embryos are sheathed, have a smooth body, and show distinct and clear nuclei. They measure about $250\mu \times 8\mu$. They appear to be *Microfilaria bancrofti*'. In view of the fact that the filariasis in the North Cachar Hills was found to be due to *M. malayi*, I had expected the same species to be found here also. There were no opportunities for a search for the vector. It appears that the disease is limited to the Mikir Hills because clinical filariasis is not seen among the people outside this area.

The tumour was successfully removed.

FULMINANT CASE OF ULCERATIVE ENDOCARDITIS

By A. ACHUTHAN, L.M.P.

and

M. KELU, L.M.P.

Sub-Assistant Surgeons, Central Jail, Cannanore

CONVICT no. 4741 was committed to this jail on 14th January, 1938. He was overhauled and classified III-L. (Health of convicts is classified as I-H, first class, fit for hard labour, II-M, second class, fit for medium labour, and III-L, third class, fit for only light labour.)

His condition was as follows:—

Previous history.—He had had four attacks of fever attended with shivering and pain all over the body. These attacks lasted two or three days and occurred at intervals of about a month.

Condition on admission to the jail.—The apex beat of the heart was in the normal place. There was no dilatation or hypertrophy, but there was a double mitral murmur. Nothing organically wrong was discovered in other systems.

On 25th April, 1938, he was brought to the hospital suffering from fever with rigor. Temperature was 100.4°F . Blood was examined for malarial parasites and found negative. Differential blood count showed polymorphonuclears 68 per cent, lymphocytes 30 per

cent and mononuclears 2 per cent. He was very restless. Auscultation of heart and lungs revealed no new development. Pulse was 100 per minute and thready. He was complaining of great pain in the abdomen around the navel. Focal examination revealed no sign of 'acute abdomen'. At 3 p.m. he started to pass loose watery stools with mucus in them, but no blood. Microscopic examination of stools revealed no dysenteric exudate.

All the reflexes were found to be normal. He became unconscious at about 6 p.m. Lumbar puncture was done and cerebro-spinal fluid was examined. It was clear and not under pressure. King Institute, Guindy, reported as under:—

Microscopically:—Very few cells. No cellular increase. No organisms found.

Culturally:—No growth obtained.

Microscopic examination of deposit from urine showed no red cells. The next morning he became completely unconscious. Breathing was stertorous. Temperature rose to 105°F. and he died at 6 p.m.

A tentative diagnosis of ulcerative endocarditis was made.

Post-mortem findings.—Mitral valve cusps were ulcerated and thickened having a cartilaginous feel. Nodular thickening was present on the aortic valves. Infarction was present in the spleen while lungs, stomach and kidneys showed embolic focal lesions. Unfortunately examination of brain was omitted.

Remarks

Interesting features of the case are:—

1. Very abrupt onset with shivering simulating malaria.
2. Fulminating character with death within 34 hours.
3. Apparent signs of abdominal crisis, cause of which was revealed on the *post-mortem* table, viz, embolic focal lesion of stomach.
4. Unconsciousness caused by embolism.
5. *Post-mortem* findings which left no doubt about the diagnosis.
6. There were no petechiæ on the finger tips nor tender spots in the legs.

We express our thanks to Major P. V. Karamchandani, I.M.S., Superintendent, Central Jail, Cannanore, and Lieut.-Col. S. C. Contractor, I.M.S., Inspector-General of Prisons, Madras, for permission to publish this case.

TRAUMATIC DISLOCATION OF HIP

By M. G. KINI, M.C., M.B., M.Ch. (Ortho.), F.R.C.S.Ed.
Surgeon, King George Hospital, Vizagapatam (S. India)

TRAUMATIC dislocations of hip may occur as a result of a fall from a height on an abducted hip, a heavy weight falling on the back with the hip in an abducted position or as the result of automobile accidents. 'Dash board dislocation' is the term used by American writers for dislocations that occur as a result of automobile accidents either to the driver or the companion in the driver's seat.

History of case.—In June 1930, a hydro-electrical engineer, aged 40 years, was driving a car and to avoid an accident he swerved. In spite of jamming on his foot-brake he dashed against a wall with a terrific impact. He felt the impact along the whole length of

the right leg and felt a sensation as if something gave way in the right hip joint causing him severe pain and inability to use his leg. He was lifted out of the car and carried to the nearest travellers' bungalow where first aid was given. At a district headquarters hospital without x-ray facilities he was treated for nine days as a case of sprain in the region of the hip. On the 10th day he was admitted in the General Hospital, Madras, under my care.

On admission, a swelling in the region of the right hip with adduction and flexion deformity of hip and flexion of the knee was found. Movements of the hip were very painful and could not be elicited. A real

Fig. 1.—Radiograph showing traumatic dislocation of the right hip, with fracture of the acetabular shelf.

Fig. 2.—Shows the condition of the joint eight years after reduction.

shortening of 1½ inches was found. The tip of the great trochanter was found well above Nelaton's line. The head of the femur was found in an abnormal situation on the dorsum of the iliac bone. X-ray showed fracture of the top of the acetabular shelf with dorsal dislocation (figure 1).

Treatment.—Even though the dislocation was 11 days old, a closed reduction was attempted under general anaesthesia. For 1½ hours all methods of reduction were tried and proved futile. A last attempt was made using Jones's manoeuvre by fixing the pelvis to the table, flexing the hip at a right angle and rotating it medially and resting the flexed knee on the shoulder of an assistant who was directed to push the knee upwards, maintaining an upward traction on the hip

joint while a forward pressure over the trochanter was maintained. A sudden click was heard and the hip became free in its movements. The limb was fixed in abduction in plaster for eight weeks and weight bearing was allowed after three months. In six months' time he was able to play tennis, do hill climbing and do his normal work. On enquiry, after eight years, he sent an x-ray photograph of his right hip (figure 2), and wrote 'I may mention that I feel the joint perfectly all right and there is nothing even to draw your attention to it even in strenuous games'.

Points of interest

(1) The mechanism of the dislocation is due to a motor car accident where the hip was fixed to the seat and terrific recoil of the impact was conveyed through the foot-brake pedal to the whole leg causing a strain on the hip joint which gave way after fracturing the acetabular shelf.

(2) A closed reduction even 11 days after the accident was successful.

(3) The patient has a perfectly normal hip joint, as the x-ray picture 8 years after the accident shows.

CARDIO-SPASM OF THE OESOPHAGUS

By M. G. KINI, M.C., M.B., M.Ch. (Ortho.), F.R.C.S.E.D.
Surgeon, King George Hospital, Vizagapatam (S. India)

CARDIO-SPASM as a clinical entity has become a demonstrable feature since the advent of oesophagoscopy and radiography. Rosenheim in 1895 and Rumpell in 1897 studied this condition by oesophagoscopy and radioscopy respectively. Since then various contributions have been made on the subject and nothing definite as to the cause of the condition has been found. Sauerbruch, Von Hacker and Jackson called it 'phreno-spasm' thinking it to be due to extramural constriction by the sphincter-like arrangement of muscular fibres of the diaphragm. Fleiner maintained that it was a gastro-spasm. Hurst called it 'achalasia' of the cardia due to failure of co-ordinating influence. Abel found sphincteric hypertrophy at the cardia about one or two inches above the true anatomical cardiac opening. It is generally accepted that it is found in nervous people, more commonly in females, between the ages of 20 and 40 years. It bears a resemblance to a similar spasm which occurs at the upper end of oesophagus. On the analogy of mega-colon this condition is also called mega-gullet. Reports of this condition in South India are very few though globus hystericus is commonly found. Out of 4,416 admissions from the year 1932-37 only one case has come under the observation of the writer. The following case illustrates this condition :—

A female, aged 20 years, married, was admitted on 7th August, 1933, with a history of difficulty of swallowing, duration six years. She had lost a child aged 2 years, four years prior to admission. At first she noticed slight difficulty in swallowing with slight heaviness in the chest occasionally. Later, i.e., two years before admission, she found that this difficulty of swallowing occurred at frequent intervals, particularly with solids. She used to drink large quantities of fluids with the solids. At first it helped her but later it

caused her heaviness in the chest with severe distress, relieved by a copious vomit. The quantity of vomit was sometimes more than the quantity taken. As she had lost considerable weight and as the distress became very acute, she sought admission in King George Hospital.

On admission, she was found to be short statured and markedly emaciated. Respiratory and circulatory systems were normal. She was anæmic. The act of swallowing was noted by a stethoscope on the chest after giving a fluid drink. The usual sound was not heard. After a time she vomited large quantities of fluid containing food which she had taken overnight. A screen examination was done with a barium meal which showed a pear-shaped dilatation of the lower end of the oesophagus perching on the diaphragm, with constriction at the cardiac orifice (figures 1 and 2). The effect of atropine injection showed a slight relief of spasm (figure 3). Oesophagoscopy was not done.

Treatment.—Hurst's bougies were passed down the oesophagus observing them under the screen daily for three days until 44/64th inch size went in easily. She

Fig. 1.

Fig. 3.

Fig. 2.

Fig. 4.

Figs. 1 and 2.—A barium meal picture of the oesophagus showing a pear-shaped dilatation with a narrow opening, allowing a streak of barium to flow into the stomach.

Fig. 3.—Barium meal picture after atropine injection. Fig. 4.—Shows the position of Hurst's bougie in the stomach.

was under observation for one month and discharged at the end of the period after making a screen examination with a barium meal. It showed a good functioning oesophagus and the dilatation though remarkably reduced in size was still appreciable. She felt better and began to put on weight.

The treatment of this condition is varied, but this case illustrated the point stressed by Hurst that this condition is due to incoördination and,

once this spasm was relieved, the patient's condition improved considerably. On enquiry (1937) the patient wrote saying that she has gained in weight, and had another child two years after discharge from the hospital, which died at the age of 2 years. Her difficulty in swallowing has not recurred and she is keeping perfect health.

INCISIONAL HERNIA

By M. G. KINI, M.C., M.B., M.Ch. (Ortho.), F.R.C.S.E.D.
Surgeon, King George Hospital, Vizagapatam (S. India)

AN acute inflammatory abdominal condition which becomes localized and forms an abscess requiring drainage for more than 48 hours weakens the abdominal wall and results in 'incisional hernia'. The treatment of this condition is a difficult problem. In small herniae it is easy to close the rent, and reinforce the abdominal wall by fascial suture. When the rent is big the question of reinforcement becomes difficult. The following case shows the result of use of a silver filigree for reinforcing the weakened abdominal wall in a big incisional hernia (figure 1).

Fig. 1.—Aspect of the incisional hernia in the iliac region.

A female, aged 29 years, was admitted in July 1932 for an appendicular abscess which was drained through a McBurney's incision for more than a week. She was discharged cured after a month. On 27th August, 1934, she was admitted with a big hernia at the line of incision and was complaining of pain and constipation. A gap of two inches could be felt after reduction of hernia and on releasing the pressure the hernia recurred quickly. Peristaltic waves were seen under the skin due to the movement of the small bowel. On 30th September, 1934, she was operated upon. An elliptical portion of the redundant skin stretched over the hernia was removed, the peritoneum was mobilized all round the rent, the redundant portion was excised and the peritoneum was sutured as in a laparotomy wound.

The transversalis and internal oblique muscles were brought together by two kangaroo-tendon stitches, and further strengthened by interrupted 30-day catgut stitches. A silver filigree 4 inches by 2 inches was carefully laid between the internal oblique and transversalis muscles behind and the external oblique in front. The

Fig. 2.—Radiograph showing the silver filigree in position three years after operation.

Fig. 3.—The condition of the abdominal wall three years after the repair.

aponeurosis of the external oblique was carefully stitched by the overlapping method. The abdominal wall felt perfectly firm at the end of operation. No attempt was made to investigate the appendicular condition. The wound healed by first intention and the patient was discharged cured in ten days' time.

On 6th August, 1937, she was admitted for a perinephric abscess, and it was opened below the twelfth rib by an oblique incision. On examination of the abdominal wall it was found quite firm with no evidence of recurrence of hernia. She had no pain at the site of hernial repair. She was discharged in 10 days, after taking a photograph and a radiograph showing the result of operation for incisional hernia and the position of the silver filigree (figures 2 and 3).

Points of interest in this case

(1) An incisional hernia developed after drainage of an appendicular abscess.

(2) Silver filigree which was used to reinforce the weakened abdominal wall has efficiently served the purpose for which it was used.

(3) No attempt was made to remove the appendix at the time of hernial repair.

(4) She developed a perinephric abscess five years after the appendicular abscess. In this an infection from the old appendicular site may have spread to the perinephric region along lymphatic channels. She refused any investigation of her kidney condition by pyelography.

(5) Her constipation was cured after the hernia operation.

A HUGE LIPOMA OF THE BREAST

By RAI BAHADUR DR. CHHAGAN NATH

*Assistant Surgeon, Officiating Residency Surgeon,
Mewar, Udaipur*

A MOHAMMEDAN male, aged 55, was admitted into the Lansdowne Hospital on 29th April, 1938, with a huge lipoma of the left breast.

Duration—14 years.

Length of the tumour above downwards 19 inches

Circumference round the pedicle .. 22 "

Circumference round lowest part .. 29 "

Weight of the tumour .. 27 lb. 12 oz.

The interesting feature of the tumour was its large size, so that the patient used to carry it like a child in his arms.

He was operated upon on the 30th April and the whole tumour completely removed.

The patient made an uneventful recovery and was discharged on the 10th May.

A CASE OF CONGENITAL LOCAL GIGANTISM

By P. N. MITRA, M.B., D.T.M.

Mawkhar, Shillong

A HINDU female, aged 20, was admitted in the Golaghat Civil Hospital for kala-azar. It was noticed that the second and third fingers of the right hand were much bigger than their fellows of the opposite side; the third finger was

particularly disproportionate. The enlargement involved the bones, as well as the soft parts. The interphalangeal joints did not function, so she could not flex those fingers and fed herself with the left hand. The condition was congenital.

Indian Medical Gazette

DECEMBER

DIET IN TYPHOID FEVER

'FEED a cold and starve a fever'. This is a popular fallacy that has been current since the days of Hippocrates, who gave his fever patients wine and thin barley gruel only; it is a fallacy that was shared by the medical profession until less than 100 years ago. In fact towards the end of the Dark Ages, when after that long period of quiescence physicians' minds again began to work, their first achievement in this connection was the invention of a false pathology to justify the Hippocratic teaching, and it was not until the middle of the last century that certain physicians, ignoring the half truths of the very incomplete pathological knowledge of their day and basing their teaching on clinical experience, reversed the teaching and 'fed their fevers'.

This practice has been fully justified by subsequent scientific observation; two fallacies have been exploded, namely, that free administration of food tends to raise the temperature of a febrile patient, and that the febrile patient does not absorb nourishment from the food he is given. It has been proved that ordinary light articles of diet are digested and absorbed as readily by the febrile as by the healthy patient, and that their absorption plays no part in raising the temperature.

It has been shown that the destructive effect of the toxins produced in fevers falls on the proteins; one school of thought argues from this that nitrogenous substances should therefore be given to replace this loss, another that the organism is already embarrassed by an excess of waste nitrogenous products and that proteins must therefore be withheld; probably neither is entirely right, but the present tendency is more in favour of the latter view and an attempt is made to replace the lost proteins as far as possible, not by the giving of an excess of proteins but by combining easily assimilable protein, *e.g.*, of milk, with other substances that spare proteins, namely carbohydrates and fats; fats often have a nauseating effect and the febrile patient is unable to take them except in small quantities, so that in actual practice the diet is often reduced to milk and carbohydrates.

Whilst the practice of 'feeding fevers' in general was adopted much earlier, it does not seem to have been applied to the treatment of typhoid fever until early in this century; again a misinterpretation of pathology was responsible. The pathologist exhibited the wasted intestine with the shallow typhoid ulcers and their tissue-paper-like bases, one of which had given way and brought the patient to the post-mortem room. It was a matter of surprise that

the others had stood up against the passage of even fluid food and the normal intestinal movements. The deduction is that the less food that reaches this part of the intestine, the greater are the chances that the base of the ulcer will survive; so the next patient is given milk whey and glucose, and is lucky if he gets a thousand calories a day. It has been estimated that in typhoid, metabolism is increased by 40 per cent above the normal, so that the average male adult patient's daily requirements amount to about 4,000 calories and, as he is only getting 1,000, he has to make up the balance first by living on his own fat, which is soon exhausted, and then on his muscles, including his intestinal muscle, which would otherwise have formed a firm base for a typhoid ulcer, or good support for an intestinal arteriole that has been exposed by the separation of a slough.

This is not by any means all theory, and figures have been produced which show quite clearly that in practice the chance both of hæmorrhage and of perforation are reduced considerably when a high-calorie diet is given. The high-calorie diet is the routine in the treatment of typhoid in the United States and to a less extent in Great Britain, but in India the practice does not seem to extend beyond the large hospitals, and it is not always followed in these. This is in some ways surprising as physicians in this country are usually very ready to follow any new and successful development in other countries—and not infrequently to give a lead. The first and most important cause is the fact that in India professional nursing is almost non-existent outside the large hospitals, so that, if the patient is treated in his own home, as he is ninety-nine times out of a hundred, his relatives or friends undertake the nursing. Another cause is the physician's lack of authority in the Indian household, which is a most striking social phenomenon in this country. The father of a household will not hesitate to pay large fees to get the best medical opinion, he will listen most carefully to the doctor's opinion, and he will have all his prescriptions made up, but quite frequently these are never given to the patient. It is not surprising that parenteral treatment is so popular amongst medical practitioners in India; when he has given an injection the physician does know that his patient has had at least one dose of the drug. In the matter of diet he is powerless; if the mother of the household has decided that typhoid fever needs starvation, no amount of quotation of authorities nor expositions on pathology will convince her to the contrary. Further, the patient will be on her side as he has little inclination to take any food, and even in hospital practice it is often very difficult to persuade a patient to take the diet prescribed.

The figure 4,000 calories, that was mentioned above, was based on European and American standards, and of course it would be wrong to apply it to the Indian patient, but we may say

that he should receive a diet of *at least* 20 calories per pound of his expected weight, calculated from a height-and-weight table, not of his actual weight, as, if he is already emaciated, his requirements are actually greater than if he is fat. This will put the requirements of the average Indian male adult at between 2,000 and 3,000 calories. As to how this diet is to be made up, one cannot dogmatize; not only will there be caste and religious customs but personal prejudices and idiosyncrasies to be considered. In most instances, milk will be the important item in the diet, but, on the basis of 2,500 calories, more than 6 pints would have to be taken, which is usually impossible. Many patients find it difficult to take ordinary milk and in these cases citrated or lactic acid milk may be better tolerated; variety can be introduced by substituting Horlick's, Ovaltine, or some other proprietary milk preparation. Lactose and dextrin are valuable for piling up the calories, as they are not so likely to give rise to fermentation as is glucose, and the former, not being so sweet, will be taken more readily by the patient. Whilst soups generally contain little nourishment, a well-made chicken broth will contain at least as many calories as the same quantity of milk, and, if caste considerations allow, makes a pleasant change. It is not essential that the diet should be entirely fluid when it enters the mouth; such things as biscuits, rusks and bread and butter are as fluid as milk by the time they pass through the pylorus. A little solid food of this kind will help to keep the patient's mouth in better condition. Eggs beaten up with milk can be included in the fluid diet, or given lightly cooked as a solid substance. Potatoes mashed with butter, vegetables and fruits strained through muslin to remove the coarser fibres that would form a residue, and even rice similarly treated will add variety, more calories, and vitamins. Whatever diet is given it should be carefully scrutinized to assess its vitamin content and the missing factors provided medicinally.

To persuade a patient to take his full quota of calories will often tax the good qualities of the nurse to the utmost extent, and to give him this amount of nourishment without producing diarrhoea, vomiting, tympanites, or other unfavourable symptoms will need not only skilful nursing but daily attention to the diet chart and wise prescribing on the part of the physician.

Typhoid fever in Indians is not as a general rule such a severe disease as it is in Europeans, but six weeks' starvation alone will reduce a patient's strength very considerably and necessitate a long convalescence. It should be the physician's aim to see that the patient leaves his bed at the end of his typhoid attack weighing as much as, if not more than, when he entered it. This may be difficult but it is far from impossible and it is an ideal that should be easier to achieve in this country where milder, less toxic attacks of typhoid

are the rule, in hospital practice at any rate. In the Indian home we shall not alter the traditions of generations within a few months, years, or even decades, but on the other hand we should not acquiesce silently in a practice that we know to be against the best interests of our patient. Above all it is by the example of the results achieved in hospitals that in time we may hope to make the principle of 'feeding a fever' applicable to typhoid, even in the Indian home.

FIFTY YEARS OF SYNTHETIC PHARMACEUTICAL RESEARCH*

We do not feel that we let this year close without a short reference to the jubilee of one of the world's most active centres of pharmaceutical research.

Early in 1888 the dye manufacturing firm of Friedrich Bayer and Company, as a result of some important discoveries made in their laboratories, decided to undertake the manufacture of pharmaceutical products; the first substance that they made on a commercial scale was phenacetin. This decision was undertaken at a time when the organic synthetic substances in the pharmacopœia could be counted on one's fingers. It was a momentous decision the importance of which even the most enthusiastic amongst those who made it can scarcely have foreseen. Since this date this firm has devoted itself unremittingly to pharmaceutical research; its chemists have started lines of investigation and have produced substances that have proved of inestimable value to medicine all over the world, but perhaps most of all to medicine in the tropics.

There are of course many other organizations, in Germany and in other countries, carrying out research work on pharmaceutical preparations, but few, if any, who have conducted their researches on such a large scale or who can show the same imposing list of successful preparations emanating from their laboratories.

'Aspirin', one of the early products of these laboratories, is now a household remedy, so much so that one is liable to forget that it is not many years ago since acetylsalicylic acid first appeared in the pharmacopœia. 'Salvarsan' has also almost become a generic name for the important group of arsenicals that followed its discovery and revolutionized the treatment of syphilis, and now the word 'prontosil' is suffering the same fate.

It would be no exaggeration to say that the preparations that originated in these laboratories have altered the whole outlook in tropical medicine. The antimonials alone have changed the 95-per-cent death rate of kala-azar into a 95-per-cent cure rate, and have provided an easy means of cure in numerous other serious and

* *Fifty Years of Bayer Remedies*. A book issued to commemorate the jubilee of this firm.

chronic parasitic diseases. Bayer 205 in trypanosomiasis and surra, yatren in amoebiasis, and salvarsan in relapsing fever and yaws have proved invaluable drugs to the physician and veterinarian in tropical countries. The introduction of the synthetic anti-malarials might well be considered the apex of the achievements of the Elberfeld scientists, did we not know that intensive investigation on the present and on new lines was still being prosecuted in their laboratories, so that one not only hopes for, but may confidently expect, further successes.

The principals in this firm have consistently refused to issue any of their drugs to the general medical public until they have been thoroughly tried, both in the laboratory and in the field, and for the field trials they have unhesitatingly sought the help of scientific workers in tropical and other countries, without consideration of creed or nationality.

In return we believe that in many quarters they have received the same unprejudiced co-operation from the medical profession in our common struggle against disease.

Special Article

THE INCURABLES

By R. N. CHOPRA, M.D., Sc.D. (Cantab.),
F.R.C.P. (Lond.), C.I.E., K.H.P.

BREVET-COLONEL, I.M.S.

Director, School of Tropical Medicine, Calcutta

FROM the earliest days of history, life has imposed its stress and strain upon mankind. The continual strife with the elements, the dreadful toils and dangers a man has to undergo bring about ill health and disease which may end his uncertain existence. Man is terribly afraid of death, and makes every effort to prolong life as much as possible. In order to accomplish this, the body should be kept in good working order, and if ill health supervenes it should be combated. Unceasing struggle has therefore been carried on against disease from the earliest days of man's existence. Gods and goddesses were created to protect him from evil, and deities in anger or demons were propitiated by charms and amulets. After centuries of struggle, the spirit of science dawned and with it the will to go into the exact nature of the causation of disease by experiment and research. Thus, a more rational way of fighting disease was evolved. In this struggle, workers in different ages found that they could combat certain diseases with success, while against others they were powerless; these were termed *incurable diseases*. As science progressed many so-called *incurable diseases* were conquered; what was regarded as incurable in one age, became amenable to treatment in another. Great scourges such as plague, cholera, smallpox, leprosy, etc., are all in the process of being conquered. Development of preventive methods and advances in treatment have succeeded in freeing people in the western countries from many of these pests. Because of our imperfect methods of dealing with them in India, unfortunately, they still take a heavy toll of life and leave a trail of woe behind.

Ordinarily speaking the term 'incurable' is applied to those unfortunate victims of disease, in whom treatment with all its advances is ineffective and the rate of advent of death cannot be influenced. Such diseases or conditions may be *acute* or *chronic*. An instance of the former is hydrophobia, an acute infective disease, produced by a virus which is communicated to man by the bite of rabid dog, jackal, or wolf. When once the disease is established, there is no hope of recovery, but modern research has made its onset preventable by prophylactic treatment. Other diseases in this category are galloping phthisis, the acute leukæmias, a number of infectious diseases such as advanced tetanus, pneumonic plague, fulminating meningitis, and acute poliomyelitis. In the case of this group, in spite of all efforts on the part of science, the advent of death cannot be prevented, and the sufferer is relieved from his misery in a short time.

In the chronic type of incurable diseases, however, the unfortunate victim may go on suffering and

lingering for prolonged periods. There are two main groups in this class: the first in which the disability produced is not marked in the early stages, and the individual afflicted may be able to carry on for many years, without being a burden to society. Such conditions are diabetes, kidney and heart disease, epilepsy, early malignant disease, etc. Considerable advance has been made in the treatment of these diseases during recent years, and they are rapidly becoming preventable or curable by development of techniques of early diagnosis. To the second group belong those who are permanently incapacitated from earning their livelihood and need active care by the community. Advanced phthisis, tuberculous disease of bones and joints, blood diseases such as leukæmia, nervous diseases, epilepsy, leprosy and others may be included in this group. Science is making valiant efforts to bring them under control and success has been attained in several directions. But cancer is a disease which has baffled medical science, and the problem of causation of this dread disease is still unsolved, in spite of an enormous amount of scientific research. Not only do we not know what cancer is, we do not even know to what category it belongs, whether microbic, metabolic, or degenerative. It is the stalking spectre among diseases and it is surrounded with all the horror which attaches to the incomprehensible. Medical research has made a large majority of cases of accessible cancer in the early stages amenable to roentgen rays, surgical, and radium treatment, in such a way as to render recurrence unlikely. But unfortunately many cases are not seen early enough, others are not accessible, and in these cases the end is inevitable. No one who studies the rapid progress of medical science doubts that eventually even this disease will become preventable or curable.

Cancer accounts for a large number of this group in the west, but fortunately its incidence is lower in this country. Those afflicted with it suffer intolerable pain often for prolonged periods, before death relieves them of their misery. The incurables belonging to the class of imbeciles, idiots, and those suffering from mental disorders have presented difficulties so far as prevention and cure is concerned, in fact the last-named class has showed a definite increase, on account of nervous strain imposed by life in large towns. These are adequately dealt with in most countries in asylums or mental hospitals, and science is evolving new methods of treatment for them. A visit to some of the institutions in this country will show what a large number of unfortunate people come into this category, who have no hope of ever being restored to health and who are a burden to themselves and to society.

Then there are the maimed and paralysed individuals who are the victims of congenital defects, nerve diseases, advanced leprosy, lathyrism, street accidents, venereal and rheumatic infections, filariasis, etc. A very large group in this country are those afflicted with blindness, which is so often preventable. These people

have generally suffered from diseases that have passed away but have left a terrible legacy behind. In many cases in this group the much-needed care by the community is often not forthcoming and the sufferers are left to the mercy of the elements. These unfortunate individuals account for a large proportion of the beggar class in large towns in India.

This brief review of the incurable diseases will give one some idea of the importance of this problem and what medical science is doing towards its solution. While, in many of the western countries, adequate arrangements are provided to ameliorate the lot of these sufferers, in India little attention has been paid to the problem. According to the last census report (1931), there are 120,304 insane, 230,895 deaf-mutes, 601,370 blind and 147,911 lepers in India. A very large number of the population of this country suffer from various debilitating diseases which not only considerably reduce the working capacity of the people, but many of them are totally incapacitated. The *Annual Report of the Hospitals and Dispensaries under the Government of Bengal* (1935) shows that there are 100,626 persons suffering from venereal diseases or their sequelæ, 36,281 from tuberculosis of various forms, 6,508 cases from chronic leprosy, 24,810 from malignant tumours, 4,821 from filariasis causing definite disablement, and 4,129 from mental diseases, all of the incurable type. If this is the condition of one province in India, the condition of the rest of the country may be imagined. Only a small fraction of this large group are looked after. A cursory examination of the beggar class of any of the big cities will convince one of this.

It is to be greatly regretted that no organized effort has been made to deal with the important problem of incurables in this country. The public interest should be roused, and something should be done to bring into action the discoveries of medical science towards the prevention of incurability and proper care of the incurables. Illiteracy and ignorance among the masses are responsible for the production of a large section of the incurable class. Intensive educative propaganda is needed. One has only to see what has been accomplished in some of the western countries and to know how much can be done not only to diminish the number of incurables, but also to make the life of those who suffer from incurable affections less miserable and more contented. The platform, the stage, films, radio and newspapers combined have changed the whole aspect of the problem. The same can be done in India.

The causes leading to the creation of an incurable class should be thoroughly investigated and adequately dealt with. It has been roughly estimated that 30 per cent of the maimed beggars on the streets of large towns, such as Calcutta, are drawn from advanced types of leprosy. Adequate treatment in the early stages would almost entirely eliminate this factor. Then there are a fair number of mental deficient and morons who can be easily rehabilitated if proper care and attention is bestowed on them. Homes like the 'Bodhana Samiti' have already made good progress in this connection. Lathyrism and elephantiasis could be stamped out if suitable preventive measures, indicated by medical research, are taken. About 10 per cent of the beggars are blind. Blindness may be present from birth, but more often it is produced by smallpox, corneal ulceration, venereal diseases and nutritional defects, which are all preventable in the light of modern discoveries. It has been estimated that venereal diseases which are now preventable and curable are responsible for 40 per cent of blindness in children and 60 per cent in adults. The institution of eye clinics and travelling eye dispensaries will do much to reduce this group.

As regards the measures which can be taken to make the lot of incurables happy, much has been accomplished in the west, but even the fringe of the problem has not been touched in India. To start with, no accurate information is available with regard to the number of persons suffering from chronic incurable diseases. With the exception of a few homes for Europeans and Anglo-Indians, there are few disjointed

organizations which interest themselves in this question. The Ramkrishna Mission Hospital in Benares is one of the few institutions in India where incurables are cared for, but the problem needs much wider attention. Apart from mental asylums there is a genuine need for public institutions for incurables who are unable to look after themselves.

Broadly speaking there are three types of incurable persons:—

(1) Those who require active medical aid in a hospital or infirmary.

(2) Those who need skilled nursing.

(3) Those for whom custodial care by competent attendants is necessary.

Well-organized homes and colonies should be started to deal with each of these three groups. Apart from lunatic asylums, a few such institutions exist for lepers, but these are inadequate, and there are none for other groups.

The Calcutta Corporation has recently appointed a committee to go into the beggar problem which has a bearing on this problem of incurables. It has been estimated that there are more than 12,000 beggars in Calcutta alone. Many of them suffer from incurable disease. A proposal has been put forward to start a more commodious refuge where such people can be looked after. In Bombay a similar scheme is on foot and all other towns should follow this lead. Such places could contribute substantially to their own upkeep, if the inmates were taught a number of lucrative trades. A few institutions for the blind are already in existence and are doing excellent work. It may be emphasized that the Government and municipalities can help by giving grants to such organizations, but they cannot be expected to shoulder the entire burden. The public should realize their responsibilities and come forward with donations, as is done in western countries, to help in the solution of incurable problem by promoting medical research and palliative measures.

The responsibility of the State and society is at least as great towards this class as towards the acute sufferer from disease.

Medical News

SUMMARY OF TUBERCULOSIS NEWS FOR THE MONTH OF OCTOBER 1938

1. HIS EXCELLENCY THE GOVERNOR OF PUNJAB laid the foundation stone of a tuberculosis sanatorium at Amritsar on the 19th October. This institution is the result of a handsome gift (Rs. 60,000) from a local philanthropist, towards building and equipment. The Amritsar Municipality has agreed to give an annual grant of Rs. 10,000 towards its maintenance. It is hoped that this institution will be the centre of a large institution not only for Amritsar, but for the whole of Punjab. It is understood that the donor has already promised to build another sanatorium near Dalhousie.

2. Madras Presidency observed a very successful Anti-tuberculosis Week (25th September to 2nd October) in aid of the King-Emperor's Anti-tuberculosis Fund. It was a week of extensive propaganda and education by means of talks, lectures, broadcast talks and distribution of literature, followed by brisk collection through a well-organized 'Flag Day' and 'odd anna and pie' collections through the local banks.

INDIAN MEDICAL COUNCIL

In exercise of the power conferred by clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), the Central Government is pleased to nominate Lieutenant-Colonel M. J. Holgate, O.B.E., M.B., B.S. (Lond.), M.R.C.S.

(Eng.), L.R.C.P. (Lond.), D.T.M. & H. (Lond.), I.M.S., Officiating Surgeon-General with the Government of Bombay, to be a member of the Medical Council of India, from Bombay, with effect from the 6th October, 1938, *vice* Major-General H. C. Buckley, I.M.S., resigned.

THE 29TH ANNUAL CONFERENCE, ALL-INDIA MEDICAL LICENTIATES' ASSOCIATION

THIS conference will be held at Gauhati from 24th to 26th December, 1938. The scientific section of the conference will be held on the 26th December.

The secretary points out that as this is the first of its kind to be held in Assam, and, as Gauhati is a place of religious, cultural, political, and industrial importance, large numbers of medical men and visitors are expected to attend.

Further, the conference will give ample opportunity for scientific discussion of matters of professional interest to the medical men attending.

The secretary hopes that members of the profession will contribute scientific papers to the conference and will attend.

G. S. DAS,

General Secretary, Reception Committee.

K. C. BOROOAH,

Secretary, Scientific Section, Gauhati.

[*Note.*—This notice was received after this number had been made up and we were only able to include it by excluding other matter. Even now it will not be read by many of our readers until the middle of December. May we once more protest against this practice of giving absurdly short notice of conferences of this nature?—EDITOR, I. M. G.]

The Use of Antistreptococcal Preparations in General Practice

By A. H. DOUTHWAITE, M.D., F.R.C.P.

(Abstracted from the *Practitioner*, Vol. CXXXIX, December 1937, p. 661)

THE advent of prontosil and its derivatives is of the utmost significance not only because it has profoundly altered, in a favourable sense, the prognosis of hæmolytic streptococcal infections, but also because it has established beyond all doubt that effective chemotherapy of microbial diseases is attainable. Hitherto drugs having a specific effect in destroying infecting organisms were confined to those diseases produced by non-bacterial agencies, *e.g.*, quinine and atabrin in malaria; arsphenamine in syphilis. The term sulphanilamide will be used throughout this paper to include the original prontosil and the several derivatives which are now used in its place. Only when necessary will distinction be made between the parent substance and its simpler off-shoots. This does not imply, however, that they are all of equal efficacy. That is a matter which is still the subject of study, but is not a point which affects the main purpose of this communication. The use of antistreptococcal sera will not be discussed beyond remarking that with the exception of the scarlatinal antitoxin no proof has been forthcoming of their efficacy. On the other hand, it should be remembered that the scarlatinal antitoxic serum has been life-saving in some acute streptococcal infections other than those of scarlet fever. The occasional sudden defervescence and recovery following its use in streptococcal bacteraemia and even in meningitis cannot be ascribed to chance although the uncertainty of its effects (presumably due to a high degree of specificity) has led certain writers to that conclusion. Now, however, that a drug is available which appears to be habitually lethal to hæmolytic streptococci, the use of expensive and unreliable sera with their attendant risks will no longer be considered.

DISEASES DUE TO STREPTOCOCCI

Tonsillitis and Ludwig's angina.—Acute follicular tonsillitis responds readily to sulphanilamide provided that, as is usually the case, hæmolytic streptococci are in part at any rate responsible. A high temperature, rapid pulse, headache, and enlarged tonsillar glands in conjunction with tonsillar exudate may be regarded as sufficiently indicative of the type of infection to justify giving the drug before the result of swab-culture is forthcoming. A fall of temperature by crisis within twenty-four hours is to be anticipated, but treatment should be continued for three days to avoid relapse.

Two tablets (0.5 gm. in each) thrice daily is the usual dose for an adult. If the bacteriological investigation proves to be negative for hæmolytic streptococci they should be discontinued. It is futile to administer sulphanilamide for all forms of catarrhal sore throat, and reports without bacteriological findings of recovery from sore throat in three days are unconvincing, for this is the usual recovery period.

A case of streptococcal tonsillitis, spreading cervical cellulitis, and albuminuria with casts but complete recovery under three injections of prontosil was reported. One observer records a number of excellent results following its use for septic parotitis which he met frequently in asylum work. Here again, marked improvement was seen in twenty-four hours. Others refer to patients desperately ill with Ludwig's angina and rigors cured in a few days by sulphanilamide.

It appears from the above and many other instances that the more alarming the condition of the patient the more dramatic will the effects of therapy prove to be.

Streptococcal septicæmia.—The persistence of a high and swinging pyrexia after tonsillitis in association with headache, enlargement of spleen, rapid pulse and often vomiting and diarrhoea usually indicated the presence of streptococcal invasion of the blood stream. Positive blood cultures of hæmolytic streptococci can often be made, yet the prognosis is often good and the fever abates in two or three weeks.

Recovery from its use in a case of streptococcal infection with positive blood culture and various cases presumably of true septicæmia in children cured by the drug have been reported. I have dealt with one septicæmia with positive blood culture of hæmolytic streptococcus with secondary involvement of one knee and both shoulder joints with purulent effusion. Recovery was dramatic, the fever abating in three days and the joint fluid becoming sterile in the same period. Recovery was complete in ten days.

It is cases such as these which raise hopes that the fatalities of post-mortem and operation wounds so tragically familiar to hospital workers will dwindle to insignificance under the power of sulphanilamide.

Streptococcal meningitis and infections of the ear.—The mortality from streptococcal meningitis no matter how acquired has hitherto been appallingly high. Its development as an extension of otitis media and mastoiditis was wellnigh hopeless. It is therefore of especial interest to find convincing reports of recovery following the use of sulphanilamide.

An example of a boy with suppurative otitis media who developed meningitis was reported. The cerebrospinal fluid contained hæmolytic streptococci and much pus: 10 c.cm. of the drug was injected intramuscularly daily and two tablets given by mouth thrice daily.

The temperature was normal within thirty-six hours of starting treatment and recovery was complete.

A boy with a fracture of the anterior cranial fossa developed a hæmolytic streptococcal meningitis seven days after the accident: 20 c.cm. prontosil were given intravenously and again in eight hours. The temperature fell to normal within twenty-four hours. Two tablets of prontosil album were given thrice daily for a week afterwards.

Perhaps the most striking instance was a female, aged 28, suffering from mastoiditis and streptococcal meningitis. The cerebrospinal fluid contained 3,880 white cells (79 per cent polymorphs) per c.mm. This count rose to 5,181 with a fluid pressure of 440 mm. H₂O, hæmolytic streptococci in the cerebrospinal fluid and a temperature of 105.4°F. 25 c.cm. of fluid were removed and 20 c.cm. of 0.8 per cent sulphanilamide in normal saline injected intrathecally, and 200 c.cm. subcutaneously. Twenty-four hours later the cell count was 1,026, pressure 240 mm., temperature 104°F. Starting on the fifth day of the disease, nine daily consecutive intraspinal injections of 20 to 35 c.cm. of the drug were given. On fifth and sixth days 200 and 350 c.cm. subcutaneously respectively. Orally from 4 to 6 grammes were given from the seventh to twentieth day. On the sixth day of treatment the cerebrospinal fluid was sterile and the cell count 450. The mastoid was not opened until the cerebrospinal fluid was sterile. A mastoiditis was aborted with prontosil.

Erysipelas.—There is now abundant published testimony to the value of sulphanilamide in the treatment of erysipelas.

Three hundred and twelve cases divided into groups for control purposes were reported. In these groups there was an even distribution of factors such as age, duration of disease, severity of infection and associated diseases. Ultra-violet-ray therapy was given to 104 patients; prontosil (red) to 106; U. V. R. plus prontosil to 54; scarlet fever antitoxin to 48. The average case-dose of prontosil to apyrexia was 5 gm.; minimum 1.2 gm.; maximum 15 gm. Cyanosis developed in two. These cases treated with prontosil showed better results than the controls in respect of curtailment of the duration: (1) of local spread; (2) of primary pyrexia; (3) of toxæmia. The fatality rate in prontosil treated cases was 2.5 per cent: that in controls 6.6 per cent.

A few cases treated with sulphanilamide with uniformly good results have been reported.

High mortality from erysipelas in infants under two years of age (70 to 80 per cent) existed until sulphanilamide changed the picture. It has been found that after a series of recoveries from the use of basic prontosil a batch of infants failed to respond. This is ascribed to failure of absorption of the drug, for prompt response followed the use of the HCl salt of the base.

This difficulty is unlikely to arise with the derivative preparations.

Others have treated fifty cases of erysipelas successfully with sulphanilamide and refer in particular to three patients who developed concurrently signs of nephritis in the nature of albuminuria, hæmaturia and granular casts. Recovery was complete. Another patient with chronic nephritis as a legacy from a previous attack of erysipelas developed anasarca, albuminuria of 8 per thousand, blood urea 44 mgm. and gallop rhythm as the result of a second attack. Complete recovery with the exception of 1.5 per thousand albuminuria followed sulphanilamide treatment.

One observer is unimpressed by the action of prontosil in scarlet fever or its complications or in suppurative meningitis but praises its curative effect in erysipelas in infants.

Streptococcal pneumonia and empyema.—Not the least remarkable of the uses attributable to sulphanilamide have been those of streptococcal infections of the respiratory tract.

Recovery of three children aged four years who developed a purulent pleural effusion containing

hæmolytic streptococci has been reported. The drug was administered orally. In one child the empyema was a complication of measles and broncho-pneumonia. The temperature fell by lysis and the fluid became clear in a few days in each case. No operation was therefore necessary. In one of the children acute nephritis developed and sulphanilamide was stopped in the fear of aggravating the condition. This produced a relapse in the chest lesion, so treatment was started again with completely satisfactory results. It has since been generally accepted that nephritis does not contraindicate the use of sulphanilamide.

Two cases of streptococcal empyema presenting thin pus are reported: treatment was started with prontosil tablets by mouth. Later the pus became thick and it was decided to administer 5 c.cm. of prontosil solution intrapleurally with a view to ultimate rib resection. This, however, proved to be unnecessary for in three days the pus was thinner and sterile. This is the first reference to the intrapleural route of administration.

A man suffering from broncho-pneumonia had profuse hæmolytic streptococci in the sputum. On the fifth day of the disease a turbid effusion developed at the left base. This also contained streptococci. Prontosil was given on the eighth and subsequent days for a week, the dosage being 5 c.cm. by intramuscular injection and two tablets thrice daily by mouth. On the second day of treatment the temperature and pulse were lower and fell progressively to normal by the sixth day of treatment. The effusion was absorbed in four days. Cyanosis towards the end of treatment which was continued for twelve days accompanied the orange discoloration of the skin which often resulted from the original prontosil. The paradox of a recovering patient becoming blue was at the time inexplicable but must clearly have been referable to methæmoglobinæmia.

Scarlet fever.—There is no consensus of opinion about the value of sulphanilamide in this disease. It is naturally a difficult investigation to carry out because of the comparative mildness of the disease in the present phase.

It has been reported that the number of scarlatinal patients who developed complications fell from 56 per cent in the 150 control cases to 35 per cent in the 150 treated patients. The disease was arrested in twenty-four hours in 47 cases.

Miscellaneous diseases due to hæmolytic streptococci.—From a perusal of the above it must be clear that any disease attributable to hæmolytic streptococcal infection will probably be controlled by sulphanilamide. Conditions such as cellulitis, infected wounds and peritonitis are examples.

Before leaving the subject of streptococcal infections it should be emphasized that sulphanilamide exerts its beneficial effects only when the hæmolytic streptococcus is at work (—hæmolytic according to some classifications). It has no effect on *Streptococcus viridans*, and is therefore useless in the treatment of bacterial endocarditis in the vast majority of cases. No report has yet appeared on the treatment of a hæmolytic streptococcal endocarditis. One other point is that all observers are agreed that the drug should be given for from four to ten days after defervescence in order to avoid relapse.

DISEASE NOT DUE TO STREPTOCOCCI

Following the acclamation of sulphanilamide as an effective antistreptococcal preparation it was not unnatural that it should be tried out in the most diverse diseases. Up to the present sound claims for its efficacy have been established for the treatment of meningococcal, coliform and probably gonococcal diseases.

Gonococcal diseases.—In view of the close biological relationship between the meningococcus and gonococcus and favourable results in treating diseases of the former sulphanilamide was used in gonorrhœa.

Four divided doses a day with a total of 4.8 gm. daily were given for two days, 3.6 gm. for three days, 2.4 gm. for four to eight days. No other treatment

was given. The active urethral discharge had disappeared in three cases in one day, in seven cases in two days, in two cases in three days and in two cases in seven days. Two patients gave a positive smear at twelve days. One patient failed to attend satisfactorily. One without discharge but with prostatitis and epididymitis and gonococci in the urine was clear in fourteen days.

Twelve persons with chronic gonorrhoea of one to four months' standing were treated. Ten were cured in seven to twenty-one days. No relapse up to three months. Of four subacute cases one was cured in fourteen days. In three, the second urinary specimen was clear in ten days, but the first had gonococci in it for thirty days. It is suggested that this is due to the greater vascularity of the prostatic and posterior urethra resulting in a higher excretion concentration of the drug than in the anterior urethra. Fourteen patients with acute gonorrhoea were disappointing. Cure of four in fourteen, thirty-five, ten and forty-two days respectively was reported.

Still more recently the results of treatment of 20 acute cases were stated to be disappointing.

Others challenge the above statement and refer to a hundred cases treated with good results. They gave fifteen grains of prontosil album thrice daily for several weeks if necessary, but it is noteworthy that their results were much better when this procedure was combined with urethral irrigation with potassium permanganate. Of twenty-nine patients so treated excellent results were obtained in twenty-one: there were no complications. Frequently the discharge and symptoms were relieved in three days. They report favourably also on the treatment of acute salpingitis and vulvo-vaginitis.

In a private communication I was informed of dramatic recovery of multiple gonococcal arthritis due to the use of sulphanilamide.

Prompt effect in one case of gonococcal vaginitis and two failures were observed. In one patient with ophthalmia a negative smear was obtained after thirty-six hours of treatment. It will be seen that the evidence though hopeful is still unconvincing.

Bacillus coli infections of the urinary tract.—Eighteen cases of *Bacillus coli* pyuria in children were treated with prontosil.

The breast-fed babies were given 0.1 gm. thrice daily and the dose raised for older children according to age. Thirteen of eighteen infants were cured outright in from four to eleven days. Three others relapsed but were cured with further treatment. One relapsed in spite of persistence with prontosil. One was a complete failure.

Fourteen cases of pyuria were cured in one to two weeks. Others report cure of all their cases in a few days with a dosage of 0.5 gm. t.i.d. for a week.

There was recovery in a week of eight patients with *B. coli* cystitis after previous failure with hexamine.

Sulphanilamide produces a urine highly bactericidal for most organisms infecting the urinary tract but has no effect in *S. faecalis*.

Important as these various findings are, it will be of greater interest to learn the effect of sulphanilamide on the chronic urinary infections, especially as to its value in preventing relapse.

Meningococcal meningitis.—Prontosil exerts a protective action against meningococci in mice. If sulphanilamide be given to mice immediately after infection with meningococci it protects them against one million minimal infecting doses. This protection is for groups 1 and 2. It is much less marked if the drug be administered after a delay of a few hours. Furthermore streptococci will not grow in the cerebrospinal fluid of sulphanilamide-protected rabbits. The drug, if given orally, reaches the cerebrospinal fluid in high concentration (1 : 5,000).

A case of meningococcal meningitis which had been treated with serum with no effect is referred to. After ten days of the disease with heavily infected cerebrospinal fluid a 1 per cent solution of the drug was then injected intrathecally (10 to 20 c.cm. daily). The

cerebrospinal fluid was sterile within twenty-four hours of the first dose. Recovery was complete.

Four recoveries out of seven cases of streptococcal meningitis as compared with one in fourteen of an earlier series without the drug; good results in erysipelas: no recovery from pneumococcal meningitis or staphylococcal septicaemia and excellent results in erysipelas are also reported. Five patients suffering from meningococcal meningitis were treated. One case had an injection of 0.8 per cent sulphanilamide in physiological saline intrathecally (10 c.cm. less than the amount of cerebrospinal fluid removed); two cases had intravenous injection of the same solution (100 c.cm. per 20 lb. of body weight), and the remainder had 0.6 gm. for each 20 lb. per os. Thereafter 0.06 gm. per lb. per twenty-four hours. Treatment was started on the second to the fifth day and lasted four to ten days. In all five cases the cerebrospinal fluid was sterile in twenty-four hours.

Diseases for which sulphanilamide is of doubtful value

One brief reference will be made to various complaints for which sulphanilamide has been claimed on inadequate grounds to be of benefit.

Prontosil is applied in alcohol-acetone solution or as basic prontosil in water and glycerin locally. Good results are reported in the treatment of wounds, eczema, furunculosis, epidermophytosis, erythrasma, sore throats, burns, psoriasis, and as an antiseptic prior to operations. This staggering list suggests over-statement. A limited and unconvincing report claimed that the drug is of use in chronic pemphigus.

I saw temporary striking improvement in four patients with ulcerative colitis: prontosil rubrum was injected (5 c.cm. intramuscularly) daily and two tablets given thrice daily by mouth. On the eighth day a sudden improvement in the nature of the stools was seen and persisted to apparent recovery. All four relapsed and failed to respond to the drug again. Two other cases showed no improvement from the start. Its use in ulcerative colitis is not recommended.

Good results and a great reduction in the number and severity of lymphangitic outbreaks in filariasis can be achieved by the use of sulphanilamide. The rationale is that streptococci play the part of secondary invaders and are really responsible for the lymphangitis, rigors and adenitis.

Undulant fever, arthritis deformans and pneumococcal infections have also been alleged on insufficient grounds to succumb to the magic power of sulphanilamide. Experiments on mice suggest that it protects against typhoid and paratyphoid, but it would be unwise at the present juncture to attempt to base any general therapy on as yet incomplete investigations.

TOXIC EFFECTS OF SULPHANILAMIDE

Certain toxic effects, usually but not always the result of prolonged administration, may arise during or soon after sulphanilamide treatment. These are nausea, colicky abdominal pain, morbilliform and maculo-papular rashes, pyrexia, acidosis, anaemia, methaemoglobinemia, sulphaemoglobinemia, and agranulocytosis. The rise of temperature occasioned by the use of the drug though rare is apt to be confusing when it occurs in that it may suggest a relapse of the disease under treatment. I have seen it only after prolonged and large doses and chiefly in the days of prontosil rubrum after repeated injection.

Clinical evidence of acidosis was found in two out of fifty patients treated with sulphanilamide. The CO₂ combining power of the plasma was studied in fifteen further cases. In every instance a consistent though variable fall in this power occurred. The mechanism whereby it was produced is not yet known.

In a series of patients without mishap treated in the course of three weeks there were three examples of haemolytic anaemia possibly resulting from the use of this drug. Two of the patients had streptococcal sore throats, and one had meningococcal meningitis. The dosage of sulphanilamide employed was very large, e.g., 4.8 gm. per os to start with and then 0.9 gm. four-hourly. Recovery occurred after transfusion with

citrated blood. Two of the patients after recovery were tested with small doses of the drug to test for idiosyncrasy. No further hæmolytic, however, occurred.

Methæmoglobinæmia and sulphæmoglobinæmia arise quite often during treatment, and are responsible for the cyanosis which may develop rapidly and to a considerable degree. Methæmoglobin is said to be the true toxic product of sulphanilamide, but sulphæmoglobinæmia arises with frequency if sulphates are being taken as well. It is further stated that:—

(1) Administration of magnesium sulphate simultaneously with, or within two or three days preceding, administration of sulphanilamide gives rise, in most persons, to sulphæmoglobinæmia. The formation of sulphæmoglobin takes place very rapidly even after small doses of the drug.

(2) In the absence of sulphates large doses of the drug are well tolerated, but in a considerable proportion of persons doses of 12 to 24 grammes per diem result in methæmoglobinæmia. Some patients may have an increased susceptibility.

(3) The removal of sulphæmoglobin from the blood is much slower than removal of methæmoglobin. The former has been detected six weeks after administration of sulphanilamide ceased. The latter disappears in approximately twenty-four hours.

(4) Spectroscopic examination of the blood is a more delicate means of detecting sulphæmoglobinæmia than clinical observation of cyanosis.

(5) Oxygen is of little value in treatment of severe cases of sulphæmoglobinæmia. If the patient's life is in danger blood transfusion is indicated. In methæmoglobinæmia oxygen appears to be of value.

Regarding the mechanism of the production of sulphæmoglobin it has been pointed out that the majority of cases formerly spoken of as enterogenous cyanosis, i.e., that form which is due to met- or sulphæmoglobin were associated with prolonged or excessive ingestion of drugs derived from aniline or nitrobenzene, e.g., phenacetin, acetanilide, methyl acetanilide, sulphanilamide and nitrobenzene. Nevertheless, there have been some cases of true enterogenous cyanosis for which drugs cannot be incriminated. Exactly how methæmoglobin is formed is not known. Sulphæmoglobin is derived from the sulphide absorbed from the bowel. Thus phenacetin given to dogs may produce methæmoglobin: if given with sulphur, sulphæmoglobinæmia results. H_2S can react with hæmoglobin in the presence of oxygen and the combination is accelerated or catalysed by simple derivatives of aniline or hydrazine. In human beings either a gross excess of sulphide absorption from the bowel or a normal amount in the presence of a catalyst will cause sulphæmoglobinæmia. Experiments *in vitro* have proved that sulphanilamide has such a catalytic action. By taking sulphur and sulphanilamide together, sulphæmoglobinæmia was caused. It is thought that the group C_6H_5N in any drug will facilitate the formation of methæmoglobinæmia.

Saline cathartics particularly should be avoided as a purgative for sulphanilamide-treated patients. For years it has been taught that to produce watery evacuations is to increase microbial growth and unabsorbed food in the colon, and thus toxic absorption from the gut. The saline purgatives are the worst in this respect and thus favour H_2S formation, and indirectly sulphæmoglobinæmia. The sulphur in the sulphate plays no part in this production. The authors advise that during treatment the patient should be on a low residue diet with low ration of eggs (because of high sulphur content). Paraffin may be used as a lubricant, and a simple enema if needed. No phenacetin may be given during sulphanilamide medication. In general it may be accepted that the cyanosis caused by these blood changes suggests much more danger than really exists. Sulphæmoglobinæmia is the least desirable of the two products, and according to some may be of danger to anæmic patients.

Agranulocytosis.—Most of the reports to the effect that sulphanilamide can cause agranulocytosis are

unconvincing, because it is not clear that other potentially noxious drugs had not been taken for many weeks previously. Apart from these there are a few instances which appear to establish the possibility of this dangerous sequel of sulphanilamide therapy.

It has been pointed out that amidopyrine, phenacetin, certain gold salts and arsphenamine could produce agranulocytosis, and had in common the benzene ring with an attached amine group (NH_2), which increases the ease of oxidation. Sulphanilamide qualifies for inclusion

NH_2

SO_2NH_2

A man of 53 years with acute rheumatism failed to respond to salicylates. He was then given prontosil album 0.3 gm. daily for eighteen days. The pyrexia was higher than ever. Treatment was stopped. Four days later agranulocytosis developed. Blood culture which previously gave no growth at this stage produced hæmolytic *Staph. aureus* and *Strept. viridans*. Between 3rd and 21st May, 54 gm. of drug were given. Agranulocytosis, with no warning from successive counts, developed between 20th and 25th May. No salicylates had been given within twenty-four days of the onset. Death resulted.

Only further experience will determine whether in fact sulphanilamide can kill in this manner. At the worst, such an effect will be one of extreme rarity and, in comparison with the thousands of lives this drug will save, sinks into a position of negligible importance.

Sclerosis

By F. E. SAXBY WILLIS, M.C., M.D. (Lond.),
M.R.C.P. (Lond.)

(Abstracted from the *Medical Press and Circular*,
Vol. CXCVI, 1st June, 1938, p. 463)

In 1904, Marchand suggested that the term atherosclerosis should be used to include all the various types of arterial degeneration. Ludwig Aschoff more recently has put forward the idea that all the types are the result of essentially the same process, but that different forms of stress determine the incidence of the degeneration on different groups of vessels. According to these groups, four main types of sclerosis are recognized; these are:—

1. Nodular (atherosclerosis).
2. Senile sclerosis (decreased or involutionary).
3. Arterio-capillary sclerosis (the diffuse hyperplastic sclerosis of Jores).
4. Medial calcosis (Monckeberg type).

Aschoff in his introduction to *Arteriosclerosis*, edited by Cowdrey, summarizes the changes that take place in the degeneration and ageing of arteries and arterioles as a disturbance which manifests itself by deposits of the most varied kinds in the walls of vessels which have been impaired by the process of ageing with resulting deformation of the lumen and brittleness of the walls. He compares these changes with those in senile arthritis and attaches particular importance to the changes in the cementing matrix, both in joints and arteries, that go on during life and increase with advancing age. He points out, however, that mere ageing of vessels does not constitute sclerosis. The latter is characterized by fatty degeneration and calcification, and to produce these other factors are necessary. What these other factors may be is a problem which is exceedingly complex, as many different factors, in addition to the natural ageing of tissues, have been shown to play a part in its production. Recent biochemical research on fat metabolism in its relation to lipoidal degeneration of arterial

walls, the production of the latter by cholesterol feeding in animals, and most recently by other sterole bodies (benzyl esters) obtained from ovarian secretion seems significant.

The adrenal glands are a storehouse of cholesterol and in conditions of endocrine enbalance presumably the latter may flood the circulation and play a considerable part in the production of sclerosis.

ÆTIOLOGICAL FACTORS

Age.—The ancient dictum that a man is as old as his arteries is probably an inversion of the truth. Sclerotic changes in arteries are found in most bodies over the age of 45, and these changes are more and more marked as age advances; they do occur, however, in younger people, and Monckeberg's figures quoted by Aschoff and Dungal are of interest in this connection. In autopsies on fallen soldiers, all cases over the age of 40 showed atherosclerosis, and under the age of 20, 36 per cent. Dungal finds only very slight sclerotic changes in most post-mortem bodies in Iceland, even up to 70 years of age. It would seem therefore that the process of ageing of tissues, which is essential to the production of sclerosis, has a different age incidence, according to the conditions under which a person lives. Geoffrey Evans states that arteriosclerosis is common after the age of 45 and that there is a familial liability to the arteriosclerotic disease in particular arteries, *e.g.*, coronaries, and that the disease may determine death at approximately the same age in many members of a family. He states that sclerosis is uncommon in young people unless associated with kidney disease.

Heredity seems to play a big part in the ætiology of sclerosis, as it does in longevity.

Sex.—The statistics as regards sex incidence are unsatisfactory to such a degree as to warrant very limited conclusions'. (Sydenstricker.) It would appear that *marked* arterial thickening is more common in males than in females and that clinical impairment of function as a result of sclerosis is also more common in men. The ratio varies at different ages and is given thus by Sydenstricker:—

Age	20-30	30-40	40-50	50-60	60
Ratio	2.0 : 1	1.3 : 1	1.1 : 1	0.94 : 1	1.0 : 1

(Male : Female)

It will be noted that there is a rise in female incidence after the menopause.

Race and climate.—Racial and climatic conditions seem to have a considerable effect on the incidence of sclerosis; it is said to be frequent and early in onset amongst Jews, it is relatively uncommon amongst the Chinese and Japanese, the white and coloured population of the United States show little difference in the incidence of cerebral and nephritic types of arteriosclerosis, but heart disease is only three-quarters as common in the blacks as it is in the whites. Climatic conditions are discussed by Dungal and he states that both atheromatosis (lipoid infiltration) and atherosclerosis (lipoid infiltration plus calcification) are rare in Iceland as compared with the figures given for the rest of Europe and America. He associates this with the fact that the iodine content of the food and soil of Iceland is high and that the diet of the Icelanders is chiefly fish. The average weight of the thyroid gland in Icelanders is about half that in U. S. A. and Germany, and this also he considers is a result of the high iodine intake.

Occupation.—Hard physical work does not of itself produce sclerosis; it may, however, determine the incidence of the latter in various parts of the body, as for instance in the coronary arteries of athletes and the arteries of the limbs in manual labourers. Marked arteriosclerosis is nearly twice as common in metal workers, cloth cutters, plumbers, tailors and carpenters as in business (office) workers and domestic employment.

Diet.—The relationship of diet to arteriosclerosis is one which has attracted the attention of clinicians for

many years, chiefly on the assumption that excess of animal food leads to degenerative arterial change. Investigations in animals, however, show that vegetarian diets may be associated with vascular reaction and calcification. This is true in birds, but it is noteworthy that the parrot family, which are both seed and meat eaters, have a marked longevity but tend to reproduce the human type of sclerosis. The work of Anitschkow and others on the production of sclerosis by feeding with cholesterol is significant. This and the association of gall bladder disease and cardiovascular degeneration in human beings suggest that excess of fats, rather than of proteins, is the chief factor in the dietetic production of sclerosis. It would seem that diets relatively high in protein have little effect on the production of sclerosis of the nodular or the decrescent type. In the presence of renal arteriosclerosis excessive nitrogenous intake is obviously likely to aggravate the condition. Alcohol in moderation appears to have little effect on the development of sclerosis, and this gives some justification for the cynic's assertion that 'more people die from overeating than overdrinking'. Dufour suggests that alcohol may have some beneficial effect as being a solvent of cholesterol. The inclusion of fish in the dietary of sclerotics seems to be indicated owing to its high iodine content. Cereals have never been shown to produce sclerosis apart from those with a high starch content which tends to produce adiposity. Eggs, on the other hand, have a high cholesterol content and in common with other substances rich in vitamin D, were shown by Kreitmair to produce sclerotic changes in animals. Wilton suggests that deficiency in vitamin C may cause the characteristic changes of sclerosis. The experimental work in this connection seems to point to sclerosis being in some cases a deficiency disease.

ENDOCRINE FACTORS

Thyroid.—The work of Dungal on the relative weight of thyroid glands in Icelanders in whom sclerosis is uncommon, as compared with the average weight of those in Germany, America and other countries in which sclerosis is frequent, suggests that there is some definite relationship between the activity of the thyroid gland and the incidence of sclerosis clinically. It may be noted that the administration of small doses of thyroid extract to sclerotics of the hypertensive group often has a beneficial effect both on their symptoms, their weight and blood pressure.

Adrenals.—The adrenal cortex by raising blood pressure may produce sclerosis; it has also been proved that adrenaline injection in animals produces mediocalciosis even when the blood pressure is controlled by nitrites. There is experimental evidence that the adrenal cortex is an important depository of cholesterol over which it may have a regulating function.

Pituitary.—Relationship of the pituitary gland to sclerosis has been described in acromegaly (Zondek). In view of the blood-pressure-raising properties of the posterior lobe and the complexity of the pituitary secretion, it seems likely that there may be important, if indirect, associations.

Male sex glands.—The hormone, testosterone, belongs to the sterole group and can be derived synthetically from cholesterol (Dodds). It is probable that it may have some bearing on the development of senile sclerosis (with which prostatic enlargement is so often associated), but this question has not been fully explored.

Ovarian.—The occurrence of raised blood pressure, so frequent at the climacteric and the increased incidence of sclerosis in females from this time onwards, suggests that the ovarian secretion has a relationship to sclerosis. Recent work by Dodds and others on sterole metabolism is suggestive, particularly as the steroles have a chemical relationship to cholesterol, which is one of the most complex members of the group, which also includes the ovarian hormones.

Pancreas.—The relationship of sclerosis to diabetes and the incidence of the former on the pancreatic

vessels suggests an association, particularly in the elderly stout type of diabetic with a raised blood pressure and evidence of cardiovascular degeneration. Coronary disease is said to be present in 50 per cent of diabetics over 50 years of age.

Clinical features.—It will be obvious that with so many variations in distribution of sclerosis the clinical picture will vary, not only with the type of degenerative change, but with the anatomical incidence. In a short review such as this, it is obviously only possible to give the briefest of sketches of the symptoms and signs that may be found in the four types which have been described.

Taking the senile or decreascent type first, this may be present for years without symptoms other than those of premature ageing, such as wrinkling of the skin, greying of the hair, development of the arcus senilis, and vague 'rheumatic' pains and muscle cramps. On examination, little more than thickening and tortuosity of the brachial, radial and tibial arteries may be detected and there may be no increase in blood pressure. The muscle cramps may be severe and amount to intermittent claudication, with resulting muscle weakness and inability to walk more than a short distance. Where the smaller branches of the peripheral arteries are affected coldness and numbness of the toes and feet may be warning of the approach of senile gangrene. The latter is more apt to occur if there is coincident diabetes, which is found in about half the cases of gangrene, according to the statistics of Eliason and Wright.

Nodular sclerosis is particularly liable to affect the aorta and its branches, giving rise to spasmodic attacks of thoracic or abdominal pain, although it is remarkable how few symptoms may result from most extensive atherosclerosis of the aorta. The latter has been seen by the author in the bodies of men as young as 35.

In the heart, sclerosis of either the senile or the nodular type is prone to affect the coronary arteries, giving rise to angina of effort, coronary thrombosis and arrhythmia due to myocardial degeneration, presenting itself as ventricular extrasystoles, auricular fibrillation or various grades of heart block. The heart as a rule shows hypertrophy of the left ventricle (shown by x-ray examination to be of the 'boot-shaped' type associated with coronary disease). Electrocardiography helps in the diagnosis of ventricular preponderance and in defining cardiac irregularity and coronary disease.

Cardiac asthma may result from atherosclerosis of the coronary or pulmonary arteries, and will cause dyspnoea, orthopnoea, bronchitis and hæmoptysis, particularly in the presence of congestive pulmonary oedema. The symptoms that arise from sclerosis of the arterioles of the kidneys, brain, pancreas, spleen and gastro-intestinal tract vary according to the disturbance of function in the organ concerned. In the kidney shrinkage and fibrosis result with impairment of function, hypertension and hæmaturia. The symptomatology simulates that of chronic interstitial nephritis. Hæmaturia may be a distinguishing feature in sclerosis.

Sclerosis of the cerebral vessels causes such symptoms as headache, giddiness, sleeplessness, confusion of memory or temporary muscular weakness or sensory loss or paraesthesia. No doubt these transient pareses or paraesthesiæ are due to angiospasm as a rule, but thrombosis in narrowed arterioles or hæmorrhages may also result from sclerosis with resulting paralysis. Mental deterioration and 'senile decay' often result.

Retinal arteriosclerosis is commonly associated with these cerebral manifestations; as seen by the ophthalmoscope the retinal arteries are of the 'silver wire' type, indenting the veins and resulting in a patchy retinal atrophy.

Hæmorrhages are often seen. Aural symptoms such as tinnitus and deafness are often associated.

Sclerosis of the gastro-intestinal circulation may give rise to abdominal pain suggestive of gastric or duodenal ulcer (particularly when accompanied by hæmatemesis or colic and melaena). Pancreatic sclerosis may cause

diabetes, or in hæmorrhage crises may simulate acute pancreatitis.

In a case recently under the author's care, admitted to hospital with acute abdominal pain and collapse, a pulsating swelling in the left inguinal region could be traced up into the abdomen. The subsequent autopsy showed a dissecting aneurism of the common iliac artery which had ruptured and caused a large retro-peritoneal hæmatoma. Atherosclerosis was limited to the iliac artery. There was no history of antecedent illness referable to the lesion found.

It will be realized from this brief account of the symptomatology of sclerosis how widely divergent the latter may be in its results. The symptoms of its causation or development may be equally varied. Take, for example, the association of arteriosclerosis, cardiovascular degeneration and gall bladder disease, the literature of which is quoted by Laird. This clearly indicates the importance of investigating the condition of the cardiovascular system before any surgical operation is performed. It also gives clinical verification of the association between sclerosis and abnormal cholesterol metabolism.

Treatment.—Sclerosis of itself is a pathological condition rather than a clinical entity, and many cases do not require treatment and are not likely to be benefited thereby. When one so often sees patients in the seventies and eighties who have evidence of well-marked arterial thickening and have gone through life with very little illness, it makes one hesitate before putting restrictions on their life. As Sir Clifford Allbutt advised, temperance rather than abstinence should be observed, and in cases of this kind it is particularly applicable. What is really needed is treatment of the symptoms which may result from the thickening of arteries and the effects it has on the organs and limbs which they supply.

Treatment of sclerosis can therefore be divided into three kinds:—

1. Preventive.
2. Treatment of the arterial disease itself.
3. Treatment of symptoms referable to the various parts of the body affected.

1. *Preventive.*—We have so little exact knowledge as to the cause of sclerosis that anything in the nature of prophylaxis must be largely experimental, at the same time in families in which sclerosis and vascular calamities have been common care in diet and exercise should be enjoined, and a periodical examination of such patients over the age of 40 is advisable. Where any signs of commencing sclerosis are detected certain alterations in diet are indicated, particularly starchy foods such as pastry and potatoes, and foods rich in vitamin D and cholesterol content should be restricted, regular exercise encouraged and in some cases periodical visits to a spa may be very helpful. The regime at Vichy, for instance, includes opportunities for practically every sort of exercise, according to the capabilities of the patient, and the same is more or less true of our own spas in the British Isles. Inclusion in the diet of vitamin C in the form of fruit, salads, etc., should be advised and iodine in some form should be given; more fish in the diet may meet this requirement, and of the spas, those where the water is rich in iodine are preferable.

2. *Treatment of the arterial disease itself.*—In hypertensive sclerosis we are dealing with a separate group calling for special diet and other measures directed to keeping the blood pressure within safety limits. Sedatives such as bromide, chloral and that useful compound of caffeine and barbiturate, theominal, are helpful. Small doses of thyroid are indicated where there is any tendency to subhypothyroidism. Iodine of potash or iodine also are indicated, particularly in bronchitic subjects. Balneological treatment, as carried out in spas, is useful in reducing weight. Diuresis should be promoted, particularly where there is any tendency to oedema, by spa waters or in more advanced cases by diuretin or mercurials, such as Guy's pill, or where there is oedema with a normal renal function intramuscular mercury such as Salyrgan is helpful.

Regular bowel action should be promoted by an occasional dose of mercury and a daily saline in the morning. Inclination as regards diet may be followed provided that no gastric symptoms are present and that protein intake is limited in nephritic cases and carbohydrate intake in diabetic cases and obesity. Alcohol is allowed in strict moderation, but where hypertension is marked it must be forbidden. Regular sleep is essential and sedatives may be necessary, such as bromides and luminal, and where signs of commencing heart failure are present digitalis is indicated in most cases.

3. *Treatment of symptoms referable to the various parts of the body affected.*—Symptomatic treatment divides itself into, the treatment of pain, whether cardiac, peripheral, cephalic or abdominal, the treatment of hæmorrhage, whether epistaxis, hæmoptysis, hæmatemesis, melæna or cerebral, or of failure of function of affected organs.

For cardiac pain in hypertensive cases, nitrites, of which amyl nitrite and liq. trinitrini are the most useful, are indicated. In coronary thrombosis morphia is not to be spared. In peripheral pain, such as intermittent claudication, pancreatic extracts such as Padutin and acetylcholine have their advocates. For cephalic pain and restlessness, barbiturates such as the sodium salt combination with caffeine are useful. For hæmorrhage, when associated with hypertension, venesection may help. Failure of function, as in the pancreas or kidneys, calls for appropriate treatment by correct dieting, reduced carbohydrate intake, with or without insulin in the former, and reduced protein and saline intake in the latter. Diuretin assists excretion. For intestinal symptoms, regular attention to bowel action by salines, vegetable laxatives and occasional calomel are necessary, with appropriate dieting. For the headache and other symptoms of hypertensive encephalopathy, occasional venesection or even lumbar puncture may be indicated. Injection of 20 per cent solution of magnesium sulphate intramuscularly is recommended by Fishberg in such cases. For cardiac failure, as after a coronary thrombosis, digitalis is helpful in restoring function.

Summary.—To sum up, sclerosis is a degenerative process, the ageing of arterial tissue which is induced, by metabolic enbalance, of which the chief manifestation is lipoidal infiltration and calcium deposition in arterial walls. These changes vary in different organs of the body, according to the size and character of the artery involved and its distribution. There is reason to think that the chief cause of the metabolic disturbance which is responsible for these changes is in the fat metabolism of the body, as evidenced by abnormal cholesterol deposition and consequent lipoidal deposits in the arteries and arterioles. Such disturbance may be produced by endocrine disturbance or dietetic errors. Its clinical manifestations and treatment depend on the type of degeneration, of which there are four main classes, and on its anatomical distribution.

Two Years' Observation on the Use of Atebrin as a Prophylactic Agent in Malaria

By ROY A. HILL

and

MELVIN H. GOODWIN

(Abstracted from the *American Journal of Tropical Medicine*, Vol. XVIII, July 1938, p. 339)

It was shown in a previous article that atebrin and quinine were effective in reducing the number of active cases of malaria on a 16,000 acre plantation. As stated in the preliminary report, the inhabitants were permanently situated in the area and for the most part were engaged in agricultural activities. For various reasons aopheline control was out of the question.

The general plan of the programme was to obtain a blood parasite index at the beginning and close of each malarial season, and to observe by periodic blood

examinations the incidence of malaria in the prophylactic group as contrasted with that of a control group not under medication. The time at which the initial and final blood parasite surveys of the prophylactic period were made was determined by seasonal climatic conditions. Examinations between these two surveys were made upon the evidence of clinical symptoms, and if plasmodia could be demonstrated the patient was treated. In 1936 and 1937 the initial smears were made during the first week in May. In 1936 the survey was concluded and specimens collected the last week in September. In 1937 the last smears were collected between 13th and 20th December. The positive cases disclosed by the mass sample at the close of the season were not included in the percentage of infections for the season since this sample was taken with complete disregard of clinical symptoms. It was necessary that an initial smear be obtained from every person in the survey, and at the close of the season an attempt was made to examine the blood of every person. Often this was not practical, but a large random sample was collected. Table I indicates the size of the sample and the results of the examination of each group of smears.

In the programme for 1936, 337 of the 350 persons (table 1) were included in the project. These were divided into three intermingled groups, the first composed of 109 persons was given 1½ grains of atebrin, three times weekly, the second group of 108 persons received 10 grains of quinine daily, and the third group of 120 was used as a control and received bicarbonate of soda capsules only. The doses given above are for adults. Children were given appropriately smaller doses. All individuals showing plasmodia in the peripheral blood at the beginning of the survey were treated, thus rendering them parasite free before they were assigned to any group. Weekly visits were made by a competent registered nurse and upon evidence of any symptoms, a thick blood smear was obtained.

TABLE 1

Blood parasite indices, including individuals under prophylactic regime and untreated control

Year	SPRING		AUTUMN	
	Number examined	Per cent positive	Number examined	Per cent positive
1936	350	16.9	190	8.4
1937	374	1.1	239	0.3

The marked reduction in malarial incidence after the season of greatest malarial transmission in each year can only be due to the use of prophylactic drugs during the summer season.

Table 2 gives the infections in the various groups during the season of 1936; table 3 gives the percentage of infections in the various groups for 1936 and 1937.

The writers are aware of the fact that the control group, in such proximity to the prophylactic groups, could not give a fair indication of the malarial infection since, granting that the prophylactic measures were effective, infection normally obtained from the persons in the prophylactic areas would not be available. For this reason at the outset of the 1937 season all persons residing in the entire area used in 1936 were placed on prophylaxis. There was an increase of 37 persons in the prophylactic group due to a few new families that had been transferred to this area. A control area was selected, approximately twenty miles removed from the prophylactic area, which contained 339 persons. It was impossible to make as thorough an examination as was desired of persons residing in this area; however, the conditions in the control area simulated closely those in the prophylactic area. The exposed water area was

about the same and the anopheline density paralleled very closely that of the prophylactic area.

area, and, so far as is known, there has been nothing else that would have influenced the malarial morbidity. It is also interesting to note that the infections occurring during 1937 were in the months of August, September, and October, with a peak in October; while in 1936 the majority of infections occurred in June,

July, and August, with a peak in June. The writers do not believe that the slight geographical separation of these two areas could have accounted for this difference. Another locality under observation, however, which appears to be topographically similar, but distant about 75 miles to the north-west, showed a parasite index of 14 per cent in the control group; while an area in the same vicinity on atebrin prophylaxis, containing 933 persons, showed a parasite index of less than 0.1 per cent.

In malarial prophylaxis the ideal objective is, of course, to remove the source of the infection for the vectors. In consideration of the fact that most of the malaria in this locality is caused by *Plasmodium falciparum*, plasmochin was given at the close of each season at the time when the final blood smears were collected. Plasmochin was also made available to those upon whom no final blood examination was made. The adult dose was 1/6 grain three times a day for seven days. Infant dosage was reduced appropriately. Table 5 shows the number of patients infected with gametocytes and schizonts during the past two years of this study.

It is worthy of note that in May 1936 there were five persons who exhibited only gametocytes and nine who exhibited both gametocytes and schizonts in the peripheral blood. At the close of the season the sample indicated that there were no persons with gametocytes only and only three persons whose blood showed both gametocytes and schizonts. In May 1937 57.3 per cent of persons treated with quinine subsequently showed parasites in the peripheral blood while only 14.8 per cent of those treated with atebrin again became positive.

TABLE 5
The relative frequency of schizonts and gametocytes in all examinations (1936 and 1937)

Date	Number of persons examined	FORM OF PLASMODIA			
		Schizonts	Gametocytes	Schizonts and gametocytes	Total positive
May 1936 ..	350	45	5	9	59
September 1936 ..	190	14	0	3	17
May 1937 ..	374	4	0	0	4
December 1937 ..	239	1	0	1	2

Among the total of 82 persons with parasites at one examination or another, there were 18 gametocyte carriers (22 per cent).

TABLE 6

July ..	6	0	6	7
August ..	5	0	0	2
September ..	3	2	0	2
TOTAL AND PER CENT.	17 (45)	2 (14.8)	21 (55)	12 (57.3)

We have no way of determining whether these secondary cases were due to relapse of the first infection or to reinfection.

No gametocytes were observed in the first examination. At the close of the work in 1937 only one person was found whose blood contained both gametocytes and schizonts.

No effort was made to distinguish in the tabulation between the two species of malaria observed in this experiment since 92 per cent of all positive cases were *Plasmodium falciparum* and only 8 per cent *Plasmodium vivax*.

As positive cases were discovered in the control group they were treated by one of two methods, the short course, quinine method as outlined by Bass, or with atabrin, 1½ grains three times daily for five days. Table 6 gives the number of cases treated by each method and the reinfections or relapses following treatment with each. The authors propose to draw no conclusion from these data, but the length of time that infection occurred after treatment with atabrin is worthy of note.

DISCUSSION AND SUMMARY

In the present report 1,646 persons were under observation to determine whether or not a suitable method of drug prophylaxis was available for use in a highly malarious section of Georgia and Florida. In the area where these studies were conducted mosquito control measures were objectionable and in many cases impossible due to the topography. Initial blood smears in the first area indicated a blood parasite index of 19.6 per cent. This has been reduced to 0.3 per cent over a period of two years. Atabrin proved to be the most successful prophylactic agent, although quinine seemed to exert a helpful influence in reducing the malarial incidence. The co-operation of patients taking quinine was difficult to obtain and in a few cases it was necessary to discontinue medication because of idiosyncrasies and toxic reactions. No toxic reactions to atabrin were observed. After the administration of both atabrin and plasmochin to persons residing in the prophylactic areas, the number of malarial carriers and cases exhibiting both gametocytes and schizonts was materially reduced. Due to the natural variations of malarial intensities caused by fluctuations in climatic conditions these prophylactic experiments should always be continued over a period of several years to furnish the maximum amount of reliable information.

The Trade in Secret Remedies

(From the *British Medical Journal*, Vol. I,
4th June, 1938, p. 1213)

THE author and publishers have done a notable service in issuing a sixpenny monograph on *Patent Medicines* for the ordinary reader. Those who know anything of the matter realize, as Professor A. J. Clark does, the reluctance of the Press to deal with it. For the first time, if we except the *Secret Remedies* and *More Secret Remedies* of the British Medical Association—now long out of print and in any case coming from a source suspect in many eyes—the public has the opportunity of learning the facts about this trade. It can also learn why Parliament and the Press have been inactive in dealing with a subject which might be thought to offer both of them a fine opportunity for that service to the public which they presumably exist to give. As Professor Clark says, 'Politicians who depend on popular votes simply dare not offend the Press, and still less dare the Press offend the advertiser upon whom it is entirely dependent for its existence'. For this statement facts and figures are given which deserve careful attention. The trenchant report of the 1914 Select Committee of the House of Commons on Patent and Proprietary Medicines is effectively quoted, and Professor Clark has some mordant remarks on the extraordinary 'luck' that has favoured the Press and

the trade in avoiding Parliamentary action. He does full justice to the ingenuity of the manufacturers and advertisers of secret remedies and to their astuteness in changing their methods with changing times and fashions. He notes and condemns the present fashion which often takes the form of an appeal to fear as well as to ignorance. He realizes, however, that there is a legitimate field for some of these remedies, and that the best of our newspapers now exclude the worst forms of advertisement. In spite of progress in this direction (in which the British Medical Association and its *Journal* have been active if unobtrusive factors) he was able to find in one recent Sunday paper 'a cure for epilepsy, a drug that had cured mitral disease of the heart, varicose veins, piles, eczema, rheumatism, and neuritis, and, finally, a drug recommended for hay fever, asthma, malaria, influenza, and insomnia, in addition to the relief of most forms of pain'. Evidently the appeal to 'the invincible credulity of the public' pays.

Professor Clark welcomes the growing practice of publishing a formula, but it is doubtful whether this change, which avoids payment of stamp duty, protects anybody. To the average man a chemical formula means nothing. There is, however, one change in the situation not mentioned by Professor Clark which seems likely to do something to eliminate the more glaring abuses of patent medicine advertising. The association which includes the proprietors of many of the most advertised remedies has adopted the criteria included in the mild Medical and Surgical Appliances (Advertisement) Bill of 1936, which was 'talked out' in the House of Commons. The advertisements of all members of the association must conform to these criteria. This is welcome, if belated, evidence of the desire of the trade to reform itself. Professor Clark is rightly severe on the law, which, as he states and proves, shows a remarkable leniency towards the vendors of quack medicines, in strong contrast with the severe penalties to which those who misrepresent the character of ordinary foods and drugs are liable. In his opinion the medical profession cannot be held blameless in this matter. He points out among other things that reputable drug firms, by adopting some of the methods of the baser members of the patent medicine trade, have proved that doctors can be induced to use and prescribe expensive proprietaries, though exactly the same drugs can be bought for less than a quarter of the price.

The Select Committee of 1914 found what the medical profession knew only too well—that there was a large and increasing sale in this country of patent and proprietary remedies and appliances, and of medicated wines. It grouped these widely differing remedies into '(a) genuine scientific preparations; (b) unobjectionable remedies for simple ailments; and (c) many secret remedies making grossly exaggerated claims of efficacy, causing injury by leading sick persons to delay in securing medical treatment, containing in disguise large proportions of alcohol, sold for improper purposes, professing to cure diseases incurable by medication, or essentially and deliberately fraudulent'. The third class of nostrums, said the Committee, constituted a grave and widespread public evil calling for new legislation rather than amendment of the existing law. In August 1920, when the Ministry of Health was a new thing and Lord Addison was Minister, a Proprietary Medicines Bill was introduced into the House of Lords 'to regulate the manufacture and sale of certain medicines and surgical appliances, and for purposes connected therewith'. The object of this Bill, introduced by Lord Astor, then Parliamentary Secretary to the Ministry of Health, was to give effect to the recommendations of the Select Committee; but it struck at powerful vested interests and came to nothing. Professor Clark's little book may be strongly recommended. We shall be interested to see whether it has any better luck in the lay press than other attempts to open the eyes of the public have had. It deals with a matter which gravely affects the health of the public—not to mention the public's belief in its own intelligence.

Emergency Treatment in Asthma (Asthmatic Crisis)

By G. L. WALDBOTT, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CX, 30th April, 1938, p. 1423)

IN the treatment of allergic asthma one is occasionally confronted with a serious emergency which has received little attention in recent textbooks. Its clinical picture is characterized by severe collapse with constant extreme dyspnoea to the point of exhaustion. Some authors refer to this condition in speaking of 'status asthmaticus'. Others have termed it 'intractable asthma', thus indicating the inadequacy of the generally recognized methods of treatment. One has recently called this condition 'asthmatic crisis'. This probably is the most appropriate term. It implies that this condition results either in death or in at least a temporary amelioration of the asthmatic condition.

Concerning its onset, Clarke states that the asthmatic crisis usually climaxes a chronic state of asthma; but it may also occur during a series of acute asthmatic attacks. On the basis of its occurrence in an individual who has previously had asthma, it is possible to draw a distinction between it from allergic shock. The latter condition would in every other respect be identical with the asthmatic crisis were it not possible to arise in any type of other sensitization besides asthma.

MECHANISM

Because of this close relationship, certain data obtained on the origin of allergic shock will aid in the understanding of the asthmatic crisis. The syndrome of allergic shock, it should be borne in mind, results, firstly, from extreme sensitivity, secondly, from an excessive amount of an antigen or the simultaneous absorption of several antigens to which sensitivity exists or, thirdly, from too sudden absorption (intravenous) of a dose of antigen which ordinarily would not produce shock. The manifestations of allergic shock depend largely on what organs have previously been affected. In the most common instance of allergic shock, namely, the 'constitutional reaction' in a hay fever patient after an injection of an excessive dose of pollen extract, the skin and the upper respiratory tract are primarily subject to the allergic lesion, namely, the wheal; but practically any other organ may also be affected. In patients with chronic asthma, however, the sudden influx of an excessive amount of injected antigen affects, primarily, the pulmonary tissue, causing severe asthma without the association of urticaria, nasal and conjunctival symptoms which are otherwise common. The same is true if the routes of entry of the antigen are other than by injection. Thus the asthmatic crisis can be considered as allergic shock in a patient whose 'shock organ' has previously been the lungs, because he had been suffering from asthma.

Concerning the sources and the clinical manifestations of allergic shock induced by means other than injections, data on thirty-nine cases were collected through an inquiry among allergists by Ascher and myself. Some of the correspondents hesitated to differentiate between the asthmatic crisis and allergic shock and therefore included instances of both conditions. Asthma was present in all but two cases. In six, no other manifestations were noted; asthma and urticaria occurred in eighteen; asthma and gastro-intestinal symptoms such as vomiting and diarrhoea in three; asthma with urticaria and gastro-intestinal symptoms in eight; asthma and convulsions in two. In fifteen patients, ingestion of food was responsible, egg and sea-food being the most common antigens. In five cases the ingestion of drugs (acetylsalicylic acid in four of them) caused allergic shock. In nine cases the inhalation of animal emanations and foods were responsible. In two instances contact of the skin with food was the causative factor, and in five cases contact

with other substances was responsible. Sensitization to cold produced shock in two patients, and heat affected one person. In this group there were thirteen females and twenty-six males; ten persons were above the age of 15 and twenty-nine were below.

PATHOLOGY

Before I discuss treatment I shall refer briefly to the mode of death in these cases. It is generally agreed that death in allergic asthma is due to obstruction of the bronchi by thick tenacious mucus that is formed during the course of an attack. This obstruction results in asphyxiation. The earlier writers on the pathology of asthma have referred to the marked bronchospasm which may or may not, in itself, be sufficient to accomplish complete bronchial obstruction by narrowing the bronchial lumen. Relatively less common is death due to the formation of oedema in the alveolar spaces, which was described as a characteristic lesion in allergic shock and which was also the outstanding finding in asthma of short duration.

Another less frequent mode of death in asthma is the development of areas of bronchopneumonia. They may result from infection of atelectatic lesions induced by the obstruction of small bronchi or they may represent a secondary infection of oedematous areas. Concerning the possibility of cardiac death as the result of asthma, there has been considerable discussion in the literature. Most authors agree that the heart plays a minor, if any, rôle in the production of death in allergic asthma.

TREATMENT

Recent publications on the therapy of the asthmatic crisis deal primarily with the utter hopelessness of our therapeutic efforts. Certain measures are proposed by which the authors induced cessation of seizures. One advocates the rectal administration of ether and oil. Another suggests that tribromethanol in amylene hydrate be given rectally. Others recommend the inhalation of carbon dioxide, and that of helium and oxygen. Very little is said as to how the general management of such cases should be conducted. A discussion of this problem, however, is of great importance because, in the opinion of many, death in asthma can often be directly attributed to certain therapeutic measures.

In accordance with the mechanism and the pathology of the asthmatic crisis, four principles are outlined which can be regarded as the key for successful treatment: (1) extreme caution in introducing into the system any substance that may be harmful to the patient; (2) elimination of substances which may have harmed him regardless of whether or not positive skin reactions to these substances have been obtained; (3) symptomatic relief to counteract existing cyanosis, to allay cough, to support the nutritional state and to afford rest and relaxation; (4) support of the patient's specific resistance against those antigens to which he is sensitive (hyposensitization).

1. *Avoidance of harmful antigens.*—The results of our inquiry indicate the danger of the introduction of foods and drugs which may aggravate the situation. Foods that have not been eaten for a long time were found to be particularly harmful, especially if taken in large quantities. The danger of acetylsalicylic acid has been sufficiently stressed in the literature. Quinine, phenolphthalein and acetanilid deserve, in my experience, second consideration among drugs. The intricacy of this problem is illustrated by pointing out that the same drugs, especially acetylsalicylic acid, are likely to give relief in certain patients. On the other hand, the most severe attacks of asthma that I have had occasion to observe occurred shortly after the taking of acetylsalicylic acid. Indeed, this has been so striking an experience that the fact that an attack was extremely severe has led me, on two occasions, to the correct conclusion that this drug had brought on the attacks.

A similar situation exists with other drugs and antigenic treatments which are recommended for asthma. The simple application of procaine hydrochloride on the mucous membranes of the nose has

produced severe attacks of asthma. Such substances as peptone, tuberculin, milk or typhoid and other bacterial vaccines may at times give relief, especially if they are administered in highly diluted doses; yet often they constitute a source of marked aggravation of asthma, sometimes even of death.

The use of morphine in asthma has been condemned by many experienced in the treatment of asthma, mainly for two reasons: 1. Morphine depresses the respiratory centre and the cough reflex, thus interfering with a vital protective process; namely, the expectoration of mucus plugs from the bronchi. 2. Patients are often sensitive to morphine. This is indicated by the relatively frequent occurrence of general pruritus and urticaria and the formation of a local weal following its administration. As will be shown later, relaxation of the patient in this condition is a therapeutic consideration of paramount importance. This drug, however, can well be replaced by less harmful ones.

2. *Elimination.*—In every case of severe asthma, elimination of all possible antigens should be attempted, regardless of whether or not sensitivity to such substances is evident. The stuffing of a mattress or a pillow is apt to cause a great deal of irritation in the upper air passages because of its close proximity to the asthmatic patient. Inhalation of such harmful substances should be prevented by covering the bedding with air-tight rubberized materials. Unquestionably the greatest assistance in eliminating harmful environmental factors is afforded through hospitalization. There is reason to believe that an asthmatic patient, particularly if symptoms have been present for some time, acquires many sensitizations arising from his immediate surroundings, such as house dust, certain types of upholstery in furniture and possibly certain fungi present in his home; in short, substances which cannot easily be eliminated. The patient's removal into a hospital induces, in most instances, a dramatic abatement of symptoms, especially if it is a fireproof and air-conditioned structure and, therefore, contains less dust and mould-producing substances.

One of the measures on admission to the hospital should be a thorough cleansing of the bowels by means of a large saline or dextrose enema. Its purpose is to eliminate digested and undigested food particles, absorption of which may have been instrumental in the production of the attack. Retention of water and of some of the dextrose and salt from these enemas may take place and assist the patient in his defence. Soaps should not be added, as untoward reactions, such as severe diarrhoea or increase of dyspnoea, may result if sensitization to soaps or some of the constituents (orris root) exists. For the same reason vegetable cathartics should be avoided.

The discontinuance of epinephrine is unquestionably one of the most important procedures. Most of these patients have been treated with this drug for some time. Epinephrine exhibits certain peculiarities that have not been sufficiently stressed in the literature. An asthmatic person very rarely requires more than from 0.3 to 0.5 c.c. subcutaneously of epinephrine in order to obtain its full therapeutic effect. Only in the most acute types of allergic reactions are larger doses necessary. After a patient has taken epinephrine for some time, his tolerance to this drug increases. By increasing the doses and shortening the intervals between injections, the patient soon reaches a stage at which even much larger amounts are of little or no benefit. In such instances discontinuance of the drug for a few days will re-establish the previous efficacy of the smaller doses. That such discontinuance can be carried out very abruptly without any marked difficulties whatever was demonstrated by observations on two patients who had taken as much as 1 ounce and 1½ ounces (30 and 37.5 c.c.) respectively of epinephrine a day for many months. In both patients severe asthma of long duration promptly subsided on withdrawal of the drug and the subsequent management thus became much less difficult. Whether or not the drug itself has the tendency to keep up the asthmatic state it is difficult

to say. The numerous small areas of infection of the skin which are often encountered as the result of improper sterilization of the hypodermic needles may aid in lowering the 'allergic balance'. If one recalls the clinical appearance of those in the habit of using epinephrine, their striking pallor, frailness, tremor and tachycardia, one cannot help but feel that the withdrawal of this drug constitutes a major therapeutic procedure in meeting the emergency of the asthmatic crisis. The same, to a lesser extent, may be said about ephedrine, because of its pharmacologic similarity to epinephrine; there is also the added chance that sensitization to ephedrine may be established by its too frequent use.

Among other eliminative procedures may be mentioned the puncture and irrigation of sinuses when considerable amounts of purulent secretion are present in the sinuses. In rare instances this may check the emergency state.

3. *Symptomatic treatment.*—Practically every asthmatic patient encounters an aggravation of symptoms on exertion. Insistence that the patient secures sufficient relaxation and sleep is of the utmost importance. This may be a most difficult task, because sensitization to the drug to be employed may be encountered. I found barbiturates advantageous for inducing rest. Some are inclined to administer from 5 to 7 ounces (150 to 210 c.c.) of ether dissolved in equal parts of oil by rectum. Others may follow, rectal instillation by either a syringe or a male catheter of tribromethanol in amylene hydrate. The dose recommended is 60 mg. per kilogram of body weight. While both measures are highly commendable, it should be borne in mind that sensitization to ether as well as death following the administration of tribromethanol in amylene hydrate has been encountered. Opinions may differ as to which is the most preferable means of sedation. Whatever one's choice may be, it is best to insist on employing only one hypnotic because of the increased risk of sensitivity when several hypnotics are used. Drugs that have been taken before without ill effect should be given preference. The first dose should be very small and its effect carefully watched.

If the hypnotic should not be sufficient to produce the desired degree of relaxation, the extreme exhaustion of the patient may require a narcotic. When this necessity arises pantopon (hydrochlorides of the alkaloids of opium, principally morphine) may be resorted to. The chief advantage of this drug over morphine is said to lie in its lesser action as a depressant on the respiratory centre, since some of the alkaloids which it contains are respiratory stimulants and thus counteract the paralyzing effect of morphine. Clinically, one is impressed by the slight degree or absence of cyanosis when this drug is used.

Cough is a source of a great deal of discomfort. It is practically always followed by increased dyspnoea. Simple cough syrups containing ammonium chloride and potassium iodide may be of some assistance. Compound cough mixtures should be avoided because of the increased chance of sensitization to some of the drugs employed.

Cyanosis, which is often in evidence, may be combated by oxygen and carbon dioxide and, whenever available, by a mixture of 79 per cent helium and 21 per cent oxygen. The greater diffusibility of helium accounts for a more complete displacement of residual air than by other gases. In evaluating this treatment, however, one should bear in mind that, even in severe allergic asthma, cyanosis and anoxemia are not always present; that is, if no other complications such as heart disease or bronchiectasis exist and no narcotics have been given before. The dramatic results from the inhalation of helium gas may in some instances be explained by the displacement from the alveoli of air which is laden with harmful inhaled antigens and by its replacement with the dust-free gas. Therefore, its use is indicated even when no cyanosis is present.

In order to maintain the patient's nutritional state, intravenous injections of from 25 to 50 per cent solution of dextrose may be given. In addition to its

caloric value, the osmotic effect of this hypertonic solution may aid in the removal of oedematous fluid from the affected lungs. Mainly for the latter purpose, the intravenous administration of 100 c.c. of 50 per cent sucrose to which 0.5 c.c. of 1 : 1,000 epinephrine solution has been admixed was suggested. Instant cessation of extreme attacks in six asthmatic patients has been observed. Some of the patients had previously failed to respond when intravenous injections of dextrose and epinephrine were given individually.

We have for several years used blood transfusions from either non-allergic persons or treated symptom-free asthmatic patients. The principal purpose of these transfusions is their nutritional value. We considered it possible also that a certain immune effect might be established which could be compared to that of transfusions in certain infectious diseases. This conception is made more plausible through the recent experiments showing the presence of protective or immune substances against specific antigens in allergic patients who had become symptom-free. Whether or not these substances also exist in normal individuals is not indicated. Our own experiments along these lines have not as yet been conclusive. Clinically, however, transfusions from both normal and symptom-free asthmatic patients were found very valuable. An intradermal skin test with the donor's blood and a preliminary small intravenous injection is first given in order to minimize the risk of untoward allergic reactions. (These might occur if the patient is sensitive to antigenic substances present in the blood of the donors.) Between 200 and 400 c.c. of blood is then given in the usual manner. The patient's exhausted and debilitated state nearly always responds. With the precautions outlined I have not had any allergic reaction in more than forty transfusions given in cases of this type and in other cases of allergy.

4. *Hyposensitization*.—Specific therapy has received very little attention in the literature on severe asthma. In my experience it is as indispensable in this emergency as in any other type of allergy. The method of rapid hyposensitization is based on the observation that a patient with hay fever may obtain instant relief during the hay fever season following one or several injections of specific extract, provided the dose is large enough to produce a moderately-sized local weal and not too large to cause generalized reaction. Guided by this principle of giving a sufficiently large amount and, at the same time, avoiding an overdose, this treatment can be made both effective and safe. The antigens chosen should be those which were found to be the main causative agents of this attack, on the basis either of skin tests or of clinical experience. During the summer months, the respective pollen in the air at the time of the attack should always be considered as a potential cause. A scratch test should first be performed in order to gauge the patient's tolerance. In case of a strongly positive skin reaction no injections should be given, since repeated scratch tests with this antigen may accomplish a desensitizing effect. If the test is negative or slightly positive, an initial dose of a highly diluted extract (as low as from 1 : 10,000 to 1 : 1,000,000) is administered, preferably intracutaneously, and its effect carefully watched. If the injection does not produce a weal, the dose can be worked up rapidly at intervals of one half to one hour until a local weal appears at the site of the injection. From now on, future injections should be cautiously gauged and the intervals between them lengthened until the effect of the previous injection has well subsided. This may require from two to twelve hours and more. If properly gauged, the asthmatic attacks begin to clear up simultaneously with the development of a weal, sometimes as dramatically as after an injection of epinephrine. If improvement does not ensue, other antigens should be chosen, because the one administered previously may not be one of the dominant agents in the production of this attack. During the course of the treatment one should constantly be watchful for an excessive local reaction at the site of injection and of an aggravation of the attack by the treatment. The

injections should then be discontinued for several hours or for days until the flare-up is thoroughly controlled. When the injections are started again, considerably smaller doses should be employed. If carried out with these precautions, rapid hyposensitization treatment constitutes the method of choice in this emergency.

BRONCHOSCOPIC TREATMENT

In addition to these methods of treatment, another means of therapy should be available to all those treating a patient with severe asthma; namely, bronchoscopy. It should be held in readiness in case the other measures fail. This treatment is often too indiscriminately used in asthma, especially if advocated for the administration of iodized oil. In the asthmatic crisis, however, especially when the emergency is extreme, the introduction of a bronchoscope into the lungs should be regarded as a life-saving measure. Its purpose is to remove the thick, tenacious mucus, which is such a grave source of danger to the asthmatic patient, and to dilate spastic bronchi.

In a review of the records of 1,431 allergic asthmatic patients, it was found that there were seventy-six who had been hospitalized on one or more occasions because of unusually severe attacks. In only eight cases did bronchoscopic treatment have to be resorted to. Extremely severe and 'intractable' attacks promptly subsided on the removal of mucus from the bronchi in all but one case.

Among these seventy-six cases, death occurred in only one case.

It may be of statistical interest that only three others out of the 1,431 patients with allergic asthma died while under my care and that drugs seemed to be responsible in every single instance. One patient (J. H.) died during a moderately severe attack a few seconds after he had administered to himself 1 c.c. of epinephrine. There was blood at the site of injection and the typical blanching effect on the skin was not present, indicating that a vein may have been punctured and the drug thus had been injected intravenously. Another chronic asthmatic patient (J. T.) was said to have taken a 'patent medicine' containing coal-tar products for a headache at a time when he had been entirely free from asthma. Within a few minutes severe shock, dyspnoea, cyanosis and convulsions developed, followed immediately by death. The third patient died in some unexplained manner, after having taken a hypnotic during the course of a light attack of asthma. She appeared to be in a natural sleep, which gradually turned into a comatose state from which she could not be aroused. Death occurred two hours after she took the hypnotic. No wheezing had been noticeable before her death.

SUMMARY

1. The 'asthmatic crisis' represents either a sudden aggravation or the climax of a progressive state of asthma. It constitutes a grave emergency.

2. The following therapeutic principles are suggested:

(a) Extreme caution should be used in the introduction into the system of antigens that might aggravate the condition, particularly drugs.

(b) Such measures of elimination as are usually emphasized in the treatment of allergic disease should be carried out. Hospitalization is of great assistance in accomplishing this. In addition, withdrawal of epinephrine and similar drugs that have been given before is advisable.

(c) Symptomatic relief can be accomplished by measures which secure rest and relaxation, allay cough, control existing cyanosis and aid in the maintenance of the patient's nutritional state.

(d) Specific hyposensitization with antigenic extracts that are considered the chief source of the attack should be employed as the method of choice.

3. Among seventy-six cases thus treated, one death occurred and eight patients were not benefited until bronchoscopy was resorted to. In seven of the eight cases, the removal of thick tenacious mucus from the

bronchial tree and an attempt at mechanical dilation of the bronchi resulted in prompt cessation of the emergency.

The Dangers of Bacteriophage Therapy

(From the *Journal of the American Medical Association*, Vol. CXI, 6th August, 1938, p. 536)

THE danger of producing bacteriophage-resistant variants with heightened virulence and tissue invasiveness would seem to contra-indicate local bacteriophage therapy in streptococcal infections. This conclusion by Dr. R. R. Madison of Stanford University School of Medicine is based on his study of the *in vitro* effects of bacteriophage on hæmolytic streptococci. As a test of this effect, 100 cubic centimetre flasks of veal-infusion broth plus 1 c.c. of bacteriophage (phage-lysed homologous streptococcus filtrate) were inoculated with 0.1 cubic centimetre of a twenty-four hour broth culture of *Streptococcus hæmolyticus*. The rates of population increase and fibrinolysin products were plotted for each flask; control flasks contained the same broth minus bacteriophage. During the first six hours the population of each flask increased to nearly 100 million streptococci per cubic centimetre. Lysis then occurred in the bacteriophage-containing flasks, the count falling to about 100 thousand per cubic centimetre as determined by the Petroff-Hauser counting chamber. (On gross appearance the flasks were then transparent, suggesting complete lysis.) This

lytic fall in bacterial count was followed by a secondary overgrowth, the count increasing to nearly 10 million per cubic centimetre by the end of twenty-four hours. This bacteriophage-resistant overgrowth formed or secreted fibrinolysin at a faster rate than in the control flasks. By the end of twenty-four hours there was ten times the concentration of the fibrinolysin present in the bacteriophage medium that was present in the bacteriophage-free controls. In previous work Dr. Madison had shown that there is a close correlation between fibrinolysin production and the virulence or tissue invasiveness of hæmolytic streptococci. He concludes from his two studies that, although bacteriophage therapy might temporarily reduce the number of streptococci in a local lesion, such therapy would practically never completely sterilize these tissues and would invariably transform all residual streptococci into bacteriophage-resistant variants with presumably increased pathogenicity. This conclusion is in accord with the experimental evidence reported about two years ago by Bronfenbrenner and Sulkin in their study of local bacteriophage therapy in staphylococcal infections. Such local bacteriophage therapy invariably increased the size and severity of the staphylococcal lesion. The extravagant clinical hopes stimulated by the discovery of the Twort 'transmissible lysin' ('bacteriophage') seem at present of little more than historical interest. Nevertheless, commercialization of bacteriophage, unaccompanied by warning of possible clinical dangers, still continues in certain parts of the country.

Reviews

THE BRITISH ENCYCLOPÆDIA OF MEDICAL PRACTICE.—Under the General Editorship of Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., D.Sc., D.C.L., LL.D. 1938. Butterworth and Company, Limited, London. (To be completed in 11 volumes.) Sold in complete sets only. Cash price, Rs. 25 per volume. Also available on the instalment system at Rs. 10 per month. Price, Rs. 26-8 per volume. Only available from Messrs. Butterworth and Company (India), Limited, Calcutta. Volume V. Pp. xxiii plus 632 plus 51

THE first chapter in this volume is on 'Endoscopy' and the last on 'Goitre'. The forty-six chapters are on a varied assortment of subjects which the chances of nomenclature have brought into one volume, from enemas to epistaxis, from food to filariasis, and from gall-bladder disease to gas (poison) in war. The names of the writers are all well known and have most of them appeared in earlier volumes.

The chapter on filariasis is written by Dr. Manson-Bahr. This important subject is dealt with concisely and on the whole satisfactorily, though recent work in this country is entirely neglected and the information on '*Filaria*' malayi is not up to date, as a patchy but probably wide distribution has been recognized in India for some time. The writer was unable to resist the temptation of including an illustration of elephantiasis of the scrotum.

The chapter on food by Drs. McCance and Widdowson is excellent as far as it goes, but one feels that a little more space might have been allowed in view of the importance of this subject, and, for the sake of readers in the Empire outside Great Britain, some reference made to food requirements in other countries. The chapter appears particularly short in that it follows a long one on foetus diseases and monstrosities, which covers fifty-four pages, in contrast to the twelve devoted to food. The chapter on the foetus is an important contribution, but its interest is largely academic.

The chapter on enteric fevers is disappointing; it is a purely textbook account of the disease and seems to

lack character. The most important point in the treatment, diet, is given the barest mention and a diet of only about 2,000 calories seems to be advocated. Even if the writer disapproves of the higher-calorie diet in this disease, he should say so; in view of the successes claimed by its advocates, it cannot be ignored.

An important subject included in this volume is etiquette and ethics in medical practice. The first paragraph should receive a wider publicity than it can ever hope to get here, as it will be read mainly by doctors, whereas it is the general public that would derive most benefit from it. The writer contradicts a common fallacy, namely, that there is a strict code of rules and regulations to which the doctor has to comply and which are framed to maintain the status and dignity of the profession regardless of the interests of the patient and the public.

Amongst the other contributions of importance there is a good account of glandular fever by Dr. Letheby Tidy, and a chapter on goitre and other diseases of the thyroid by Professor F. R. Fraser and Sir Thomas Dunhill, which is of the high standard that we would expect from these two eminent writers.

LECTURE NOTES ON LEPROSY.—By John Lowe, M.B., Ch.B. (Birmingham). 1938. Published by the British Empire Leprosy Relief Association, Indian Council, Taikotara Road, New Delhi. Pp. vii plus 56. Illustrated. Price, 8 annas

'THE following notes are not intended to be a full and complete description of leprosy, its diagnosis, treatment and prevention. For such a description larger publications should be consulted (e.g., *Leprosy, Diagnosis, Treatment and Prevention* by E. Muir). Such publications should be in the hands of all leprosy workers.

There is, however, a need for a publication on leprosy which is smaller, more concise and cheaper, and these notes aim at meeting this need.

These printed lecture notes are based on the cyclostyled lecture notes which the author has used for

several years as the basis of the series of six lecture-demonstrations delivered each year as part of the course for the D.T.M. Calcutta and D.P.H. Calcutta.

It is hoped that these notes may be of use in two chief ways. First they should be of use to medical practitioners and medical students who are not, and do not intend to become, specialists in the subject, but who wish in a short time to get a grasp of the most important points regarding the diagnosis, treatment and prevention of leprosy. Secondly, they should be of use to those who have to teach others about leprosy, that is to teachers in medical colleges and schools, or to leprosy workers giving short courses of lectures on leprosy to general practitioners or to medical students. Such teachers might use these notes as the basis of their lectures and demonstrations, illustrating the various points by demonstrations of numerous patients, by lantern slides, microscopic specimens and so on.

The above paragraphs are taken from the preface of this very valuable little book. We are quite satisfied that this book will meet the needs, and be useful in the ways, that the author hopes. The author is an experienced teacher and has presented his subject clearly and concisely. The illustrations are numerous; they are excellently reproduced photographs which show exactly what they are intended to show, even the photomicrographs. The printing and paper are good, and altogether the brochure is extraordinarily good value for its exceptionally low price.

THE PRINCIPLES AND PRACTICE OF MEDICINE. DESIGNED FOR THE USE OF PRACTITIONERS AND STUDENTS OF MEDICINE.—By the late Sir William Osler, Bart., M.D., F.R.C.P., F.R.S. Revised by H. A. Christlan, M.D., LL.D., S.D., F.R.C.P. Thirteenth Edition. 1938. D. Appleton-Century Company, Incorporated, London, and New York. Pp. xxv plus 1424. Price, 35s.

No one can fail to admire the courage of an editor of a textbook of medicine who concludes his preface with the words 'In preparing this revision, wisely or unwisely, I have had the assistance or criticism of no one', but whether this admiration will be extended to other features in his character does not seem so certain.

As one cannot hit a man who puts his hands behind his back, we must content ourselves with remarks on the general arrangement, which has not been changed to any great extent and is a rational one, and on the format, which is excellent. Nearly three hundred pages have been added in this edition but the book does not seem to be uncomfortably bulky or heavy, and the type is particularly easy to read. Almost two generations of students and physicians have confidently relied upon their 'Osler' as a textbook of the first order, and we see no reason why another generation should not do so.

A SHORT PRACTICE OF SURGERY.—By Hamilton Bailey, F.R.C.S. (Eng.), and R. J. McNeill Love, M.S. (Lond.), F.R.C.S. (Eng.). Fourth Edition. 1938. H. K. Lewis and Company, Limited, London. Pp. viii plus 996, with 818 illustrations of which 109 are coloured. Price, 28s.

The first edition of this book in 1932 was accorded an enthusiastic reception. The progress of the subsequent editions has been no less remarkable. The call for four editions and two reprints in the brief space of six years bears eloquent testimony to this fact. Surgery progresses with such rapid strides that it is difficult for a textbook to maintain the pace. The whole of the text of the present edition has been reset, but it rebounds to the credit of the authors that in spite of thorough revision and the inclusion of 55 additional figures the bulk of the book has not been increased. A new feature of this edition which deserves special mention is the inclusion of brief historical data in the form of foot-notes.

Ever since the first appearance of this book we have recommended it to each succeeding batch of medical students as the best textbook of surgery. We have nothing more to add to this encomium. The names

of the joint authors have come to be identified with an excellence of illustration and a lucidity of description which are almost unrivalled. Thus it appears that the ancient Chinese proverb 'one picture is worth a million words' is no exaggeration.

The printing, get-up and illustrations are all first rate and are in keeping with the reputation of the publishers.

P. N. R.

DISEASES OF THE EYE.—By Sir John H. Parsons, C.B.E., D.Sc., F.R.C.S., F.R.S. Ninth Edition. 1938. J. and A. Churchill, Limited, London. Pp. viii plus 705, with 21 plates and 360 text-figures. Price, 18s.

THIS is the ninth edition of this world-famous textbook of ophthalmology and the appearance of a new edition after a lapse of only two years is sufficient proof of its popularity.

The book is divided into eight sections which consist of the anatomy and physiology, the examination of the eye, diseases of the eye, errors of refraction and anomalies of accommodation, disorders of motility of the eye, symptomatic diseases of the eye, diseases of the adnexa of the eye, preventive ophthalmology and finally three appendices on the preliminary investigation of the patient, therapeutic notes, and the requirements of candidates for admission into the public services.

The book is well illustrated with 21 plates and 360 text-figures. It is still kept within reasonable proportions and differs very slightly from the previous edition. The author has added some new drugs and new methods of treatment.

We know of no textbook which can be so strongly recommended for students and medical men who are interested in the study of ophthalmology.

E. O'G. K.

OPHTHALMIC NURSING.—By D. E. Grand. 1938. E. and S. Livingstone, Edinburgh. Pp. ix plus 111. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 3-12

THE object of this manual is to deal with the main points in ophthalmic nursing and to provide a brief summary of the signs and symptoms of the common eye diseases which most frequently occur.

The first portion deals with the anatomy and physiology of the eye, the common types of refractive errors and general ophthalmic nursing. The author lays special stress on the fact that the eye is a part and parcel of the body and thereby, in the treatment of the eye condition, the body should be looked after carefully. Attention has also been drawn towards the peculiarities in temperament of ophthalmic patients; their individual likes and dislikes are to be studied to a greater degree than those of surgical or medical patients.

Section II comprises a brief survey of the common eye conditions and their treatment. The various methods of nursing in different eye diseases have been described in detail. It is a pity that nothing has been mentioned about general anaesthesia which is sometimes required in ophthalmic practice.

In section III the common eye operations are described briefly and a list of instruments required in each operation is given. The instruments are all illustrated in an excellent way.

An extract from the foreword by Mr. A. C. Hudson is well worthy of publication:—

'There is perhaps no branch of nursing in which the responsibility of the nurse is greater than the supervision and treatment of diseases of the eye, and a realization of the disastrous consequences liable to ensue from lack of meticulous care in all manipulations, and in supervision in the ward and operating theatre, cannot be too strongly inculcated in those engaged in such duties.'

The book, which is the outcome of an extensive experience in ophthalmic nursing, will doubtless prove

to be very useful for nurses and those interested in ophthalmic nursing in India.

E. O'G. K.

A HANDBOOK OF TROPICAL DISEASES WITH TREATMENT AND PRESCRIPTIONS.—By P. B. Bhattacharya. Second Edition by J. C. Banerjee and P. B. Bhattacharya. 1938. Published by U. N. Dhur and Company, 15, College Square, Calcutta. Pp. x plus 413. Illustrated. Price, Rs. 7-8

THE reviewer did not know the first edition of this book, a fact that he regrets, as, judged from this edition, it is a book that has been compiled with a considerable amount of care and with frequent reference to the best authorities.

Most of the important diseases and infections that occur in India and that are usually classified as tropical diseases are included; notable exceptions are yaws, dracontiasis, Weil's disease and pellagra. They are arranged in groups, diseases caused by protozoa, by bacteria, by filterable viruses, by helminths, by spirochaetes, and by venomous animals, diseases due to vitamin deficiency and to physical agents, and diseases of unknown origin.

Each disease is described thoroughly from the point of view of the physician, under the headings aetiology, pathology, clinical manifestations, clinical and laboratory diagnosis, differential diagnosis, treatment, and prevention. In nearly every section facts are summarized in phrases or sentences which are numbered; this will appeal to the student, particularly when he is revising a subject with which he is already familiar.

Naturally, one has a few criticisms; the first is that the book bears the stamp of the pedagogue rather than that of the physician. It is a good thing to have one's facts nicely summarized and classified, but the classification habit can be carried too far and false differentiations manufactured. For example, in the section on post-kala-azar dermal leishmaniasis, under the heading 'Predisposing causes' the following classification is given:—

1. Residence in areas where kala-azar is endemic.
2. History of kala-azar about 1 to 3 years previously
 - (a) with antimony treatment resulting in
 - (i) complete cure or
 - (ii) incomplete cure associated with presence of flagellates in a culture of peripheral blood.
 - (b) without antimony treatment.

The facts are that this condition is a sequel to generalized leishmania infection and that it appears 1 to 3 years after the visceral infection has been cured, either spontaneously or after treatment.

Another criticism is that the title is misleading; only tropical diseases that occur in India are included. Further, the charge cannot be limited to nationalism, as the book has a distinct air of provincialism; for example, under the heading of 'Differential diagnosis' a phrase such as 'does not occur in Bengal' or 'rare in Bengal' appears more than once.

Finally, the index is no index but a sort of rearranged contents list.

However, we consider it a book that the undergraduate medical student will find very valuable as a supplement to his ordinary textbooks of medicine, in which the subject of tropical diseases is so often badly neglected. The post-graduate student studying for the licence or the diploma of tropical medicine will also find it useful.

We cannot close this review without a word of praise for the publishers. They have done their work excellently and produced a book that compares well with medical books published in Great Britain and the United States. The paper is good, the print clear, and the binding satisfactory, and above all there are few type-setting errors.

L. E. N.

PHYSIOLOGICAL AND CLINICAL CHEMISTRY.—By William A. Pearson, Ph.C., M.D., Ph.D., Ph.D., Sc.D., LL.D., and Joseph S. Hepburn, A.M., B.S. In Chem., M.S., M.D., Ph.D. Second Edition. 1938. Henry Kimpton, London. Pp. 467. Illustrated with 46 engravings. Price, 25s.

THIS book has been written with a view to imparting a broad general knowledge of biological chemistry to the student of medicine as is essential for a thorough understanding of such subjects as physiology, bacteriology, immunology and other allied subjects.

For the convenience of the student the book has been divided into three main parts. The first portion of the book begins with pure physiological chemistry and includes chapters dealing with the physico-chemical principles (such as the composition of matter, molecular weight, hydrogen-ion concentration, etc.), and various methods of quantitative analysis (such as gravimetric, volumetric, colorimetric, electrometric, gasometric, etc.). Thereafter the author proceeds to give a brief survey of organic chemistry and includes fairly comprehensive chapters on lipins, carbohydrates, proteins, enzymes, and the composition of tissues, which will help to give an average student more than superficial knowledge in these subjects.

The second portion of the book deals with the important subject of food and metabolism and within a limit of 56 pages the author has very ably dealt with such subjects as the chemical composition and the specific dynamic action of food, basal metabolism, vitamins, digestion and absorption of the different food-stuffs and food poisoning. Chapter IX which deals with this important subject is an interesting study and will repay perusal.

The last part of the book deals with clinical chemistry. This portion, which covers more than one-third of the whole book, deals with such important subjects as salivary, gastric and intestinal digestion, chemical and microscopical examination of faeces, composition of blood, lymph and cerebrospinal fluid, biochemical analysis of blood—clinical and medico-legal tests for blood, chemical examination of urine, qualitative and quantitative, kidney function test, etc.

The last part of this section deals with the composition and analysis of milk and water.

The laboratory work described at the end of each chapter appears to us to be of value and students are advised to carry out the experiments to make themselves thoroughly acquainted with the subject-matter described in the chapter.

This book is well written and the perusal of the book would be of help to the student in getting a clear insight into the subject of physiological and clinical chemistry.

J. P. B.

BIOCHEMISTRY FOR MEDICAL STUDENTS.—By W. V. Thorpe, M.A. (Cantab.), Ph.D. (Lond.). 1938. J. and A. Churchill, Limited, London. Pp. viii plus 457, with 37 illustrations. Price, 12s. 6d.

THE word 'biochemistry' has only come into general use during the last twenty years, and according to the *Oxford English Dictionary* only came into the English language at the beginning of this century, though the word 'biochemical' appeared some thirty years earlier. It can be defined as the 'study of the chemical and physio-chemical reactions of the human and animal body'; it is in fact a link between chemistry, particularly organic chemistry, and physiology.

A number of books on biochemical methods in medical practice have been published; these are suited to the needs of the physician and surgeon, but this book is meant for the student, and it may be looked upon as a book on physiology which has specialized in the physio-chemical aspects of the subject that have an important application in medical diagnosis and treatment, without going as far as actually applying them.

It is a book that should be used by the student of physiology in conjunction with his textbook on the subject and not instead of it. Much more emphasis is laid on chemical processes than is usual in textbooks on physiology and many formulæ are given. These may alarm the medical or dental student whose chemical sense is not highly developed. He will however find them helpful in demonstrating the chemical affinities between different substances and he will seldom find it necessary to memorize them.

As one would expect, the chemistry of food and the principles of nutrition are given an important place in the book. The chapters on these subjects are concise and comprehensive; they will be useful to the student and teacher as an introduction to lectures on nutrition.

We have few criticisms, and these are mostly matters of individual opinion; for example, we should like to have seen a chart showing the normal acid secretion of the stomach.

It is a book that should serve its purpose well and we strongly recommend it to teachers in this country, as well as to physicians and students for higher degrees.

LABORATORY MANUAL OF HEMATOLOGIC TECHNIC—INCLUDING INTERPRETATIONS.—
By R. C. Beck, M.A., M.D. 1938. W. B. Saunders Company, Philadelphia and London. Pp. 389. Illustrated. Price, 18s.

THE laboratory attendant—the laboratory technician of America and the 'lab. boy' (who must in many instances be a grandfather by now) of the British medical laboratories—is coming into his own and his true value and importance are being recognized. Perhaps the singular pronoun should have been avoided as it is nowadays so often, and very suitably, 'she'.

Perhaps one of the most important developments in medical science to lead indirectly to this recognition has been the advance in hæmatology and the development of hæmatological technique. Much of this is very laborious and very time absorbing, and, though labour can be reduced considerably by using suitable laboratory apparatus, the amount of work that one pair of hands, and eyes, can perform in the day is limited. Again, though in blood work great care, accuracy, and patience is required in the case of many examinations, after the technique is standardized and the necessary manual dexterity acquired it becomes mechanical and does not need any deep understanding of the subject. Further, the highly trained pathologist or research worker will naturally feel that he is wasting his time, is liable to become impatient, and is therefore temperamentally not so well suited to the work as the trained 'technician'.

This book has been written for laboratory technicians and is admirably suited to their requirements, but it is a book that every laboratory worker, however highly qualified and however experienced, will find useful. There is an immense amount of detailed information on the subject which the book claims to cover, and there are few methods that have received any sort of recognition that are not included.

The book is a little more than a record of technique; the reason for the examination and the significance of the result, as well as the rationale of the method advocated, is usually given. There are innumerable illustrations and diagrams, and some very useful conversion tables, e.g., grammes to percentages of hæmoglobin. The source of the diagrams is seldom acknowledged, though many of them, if not true copies, are very free adoptions from the papers of other workers.

It is very surprising that no books on technique give the degree of error that may be expected with each particular method; one so often sees clinicians, confidently quoting results that are so obviously 'cooked', or referring to small differences as matters of great significance, when the two readings are well within the normal range of technical error.

This is a book that we can strongly recommend as a guide to hæmatological technique for the use of any laboratory worker.

MODERN ANÆSTHETIC PRACTICE.—Edited by Sir H. Rolleston, Bt., G.C.V.O., K.C.B., M.D., F.R.C.P., and A. A. Moncrieff, M.D., F.R.C.P. 1938. Published on behalf of the 'Practitioner' by Eyre and Spottiswoode (Publishers), Limited, 6, Great New Street, E.C.4, London. Pp. 213. Price, 10s. 6d.

THIS, the third book of this important series of practical handbooks edited by Sir Humphry Rolleston, is a symposium of articles on modern anæsthetic practice that have appeared recently in our invaluable contemporary *The Practitioner*.

Advances in anesthesia have been in two directions, one mechanical and the other chemical, each equally important in its own different way. Invaluable as they are, chloroform and ether are poisons, and both these modern trends are leading to the relegation of these two drugs to the medical history books of the future, so to speak. The mechanical advances are not an unmixed blessing. They have enabled operations to be performed with safety that could not have been undertaken before, or, if so, only with the greatest risk to the patient, so that the surgeon naturally demands the best anæsthetic available, even for his less difficult cases. The result of this is that the student does not get the same practical experience, as did his counterpart of 25 years ago, in the methods of anesthesia on which he will in nine cases out of ten have to depend in the future. This is particularly true in India; one cannot deny the right of the surgeon and anæsthetist to take advantage of recent advances in the large hospitals and teaching institutions, but in this vast and comparatively poor country the 'nine cases out of ten' becomes ninety-nine out of a hundred.

On the other hand, the 'chemical' advances have been of considerable importance in this country, and the introduction of the avertin and the barbiturate groups of drugs has been of the very greatest assistance to the isolated medical officer, and to the obstetrician.

Each chapter in this book deals with a different aspect of the subject; some of the titles are, nitrous oxide anesthesia in surgery, basal anesthesia, endotracheal anesthesia, anesthesia and analgesia in midwifery, spinal anesthesia, local anesthesia and analgesia, and anesthesia in dentistry.

One writer uses the word *whcal* when he means *weal*. Isn't it time that some authoritative medical writer took a firm line on the spelling of this word, and who is in a better position to do this than the editor of this series? The word *whcal* is an English word of long standing meaning a pimple or pustule; the alternate spellings given in the *O. E. D.* include *wheel*, *wecll* and *whelle*; but it is a word that has recently fallen into disuse. *Weal* is a variant of *wale*; it is a word of equally long standing and means 'the mark or ridge raised on the flesh by the blow of a rod'. To take the present instance, an intradermal injection obviously produces something much more like a *weal* than a *whcal*, but the writer spells it *whcal*. The English language is not static; new words come into use, others drop out, and the meaning of words is continually changing. About fifty per cent of English writers use the spelling *weal* and the other fifty per cent write *whcal*; but uniformity is desirable, so why should not the correct spelling be adopted by all English writers.

To return to the book under review, space will not now allow us to say more than that it is an ideal book for the practitioner who wishes to extend his knowledge of modern anæsthetic methods.

A B C OF THE VITAMINS: A SURVEY IN CHARTS.—By J. Gregory, M.S. 1938. Baillière, Tindall and Cox, London. Pp. xii plus 93, with 56 charts. Price, 13s. 6d.

THE idea of publishing an A B C for the use of the student and physician is a good one, but as a means of conveying knowledge the diagrammatic method has its limitations; precision has too often to be sacrificed. For obtaining superficial knowledge in the shortest possible time no method could be better; on this framework a sounder knowledge can easily be built. There

is however a danger that the indolent student and the slovenly practitioner will be satisfied with this very superficial knowledge and not go further into the subject. In this particular instance there is perhaps an added justification for the employment of the method, as, except in the case of a few vitamin deficiencies, all that the student and practitioner needs is an outline of the subject.

Whilst there are a number of very useful diagrams which give one an immediate visual picture of the disease, *e.g.*, pellagra and rickets, there are others in which the facts do not really lend themselves to this method of demonstration; for example, the experiment in vitamin-E deficiency and sterility is explained in nine short sentences, each put into a separate compartment and spread out over two large pages (and incidentally arranged in such a way that the reviewer at first read them in the wrong order) which are decorated with a few line drawings of rats; this could have been told as a consecutive story in less than half a column of this journal, with almost greater clarity.

On the credit side again there are the maps showing the world distribution of certain diseases; the one on rickets is particularly good, though osteomalacia is shown as very common in the whole of tropical India, whereas really its highest incidence is in certain parts of northern sub-tropical India.

It is a book that we can strongly recommend to teachers in medical colleges and schools in India, as well as to sanitarians, practitioners and health workers.

THE HISTORY OF BACTERIOLOGY.—By W. Bulloch, M.D., F.R.S. 1938. Oxford University Press, London, and New York. Pp. xii plus 422. Illustrated. Price, 10s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THE history of bacteriology is in a way the history of modern medicine. In the days of ancient Greek medicine, the suspicion obviously lurked in the minds of such writers as Hippocrates and Herodotus that there was something in the disease-causing 'miasmas' which the human eye could not see, though, if they thought more deeply than that, they probably endowed it with a chemical rather than an animate nature. It was not until the medical renaissance of the 16th century that this suspicion took a more concrete form—for example, in the writings of Fracastorius—to become a theoretical proposition in the 17th and 18th, with the evolution of the microscope, and a proven fact in the 19th century.

It is impossible to give the date of the birth of bacteriology or to fix its paternity. History is not a simple matter of names and dates, and, though there must be few more fascinating pastimes than historical research, the boundary line between the results achieved and just honest fiction is extremely narrow. It is seldom possible to apportion the credit for any discovery or any idea—the brilliant but indolent theorist, the perspicacious opportunist, and the dull but industrious worker each play their part and it is a matter of chance whose name is remembered.

Athanasius Kircher (1602–1680) seems to have been a theorist, though not an indolent one, who wrote on many subjects, including the microbe origin of contagious disease, in words that would entitle him to claim priority if he were alive to-day. However, historians do not approve of him; they consider that none of his works constitute a scientific advance, and Dobell, three hundred years later, feels justified in referring to him as 'a man possessed of neither scientific acumen nor medical instinct', strong words to use about a fellow medical writer on so distant an acquaintance. We hope that future historians will be kinder, and if they remember Clifford Dobell, F.R.S., at all they will remember him as more than van Leeuwenhoek's biographer.

A sense of humour, or a sense of proportion which is much the same thing, is essential in a historian and this Professor Bulloch certainly possesses; added to this is

his personal acquaintance of many of the great bacteriologists of the last half century—perhaps the most important period in the evolution of bacteriological science—a combination that makes his work the most readable and most important contribution to the subject at present available.

The extensive bibliography and the short biographical notes on some three hundred bacteriologists complete it as a valuable book of reference.

A TEXTBOOK OF BACTERIOLOGY FOR DENTAL STUDENTS.—By Arthur Bulleid, L.R.C.P. (Lond.), M.R.C.S., L.D.S. (Eng.). Second Edition. 1938. William Heinemann (Medical Books), Limited, London. Pp. xvii plus 207, with 60 illustrations. Price, 15s.

THIS is the second edition of a useful little book which is essentially a practical book with the necessary amount of theoretical matter. The book is designed to meet the needs of dental students and practitioners, and deals in a practical way with the laboratory investigations that can be carried out in diseases of the mouth. There is much in this book that will be of interest to bacteriologists in general.

MUIR'S BACTERIOLOGICAL ATLAS.—By C. E. Van Rooyen, M.D. (Edin.). Second Edition. 1937. E. and S. Livingstone, Edinburgh. Pp. xvi plus 90. Price, 15s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 10

For ten years Muir's Bacteriological Atlas has been used by many students of bacteriology and has been of great help to the teachers of bacteriology in conveying to students the outstanding morphological features of pathogenic micro-organisms which neither a description nor a photograph can convey as forcibly as a well-drawn diagram. The slight exaggeration, in proportion to their surroundings, of important diagnostic features which is possible in diagrams is of value in the recognition of their presence. In this second edition the text has been thoroughly revised and twenty-six new coloured plates have been added. When used in conjunction with a textbook of bacteriology the student will find this atlas of immense value in studying microscopic preparations of different micro-organisms.

C. L. P.

ELEMENTARY ANATOMY AND PHYSIOLOGY.—By J. Whillits, M.D., M.S., F.R.C.S. 1938. J. and A. Churchill, Limited, London. Pp. ix plus 342, with 87 illustrations. Price, 12s. 6d.

THERE is such a very close connection between anatomy and physiology that it is a matter of regret that, although the subjects are taught simultaneously in the medical course, there is not more liaison between them. A combined textbook dealing with the two subjects fully is of course out of the question, but the idea of writing a book introducing anatomy and physiology side by side is a good one.

In the volume under review the author has carried out this idea very satisfactorily and has produced a book which the student commencing his medical course could read with considerable advantage, as it simplifies and clarifies the two subjects, and at the same time shows where lie the connecting links which are not always obvious in the standard textbooks.

It is a book that is particularly suited to the student studying in the smaller medical schools in India and proposing to take one of the lower qualifying degrees, and we recommend this book to teachers in such schools, as a class textbook to form a grounding on which they can build. It should also be useful to nurses and others who are not required to go very deeply into the subject.

The publishers have done their work excellently, the type is easy to read and the illustrations are numerous and clear.

Abstracts from Reports

PROCEEDINGS OF THE INTERNATIONAL UNION AGAINST TUBERCULOSIS, LISBON, SEPTEMBER 1937. By E. BRIEGER. AFTER-CARE AND REHABILITATION, PRINCIPLES AND PRACTICE. (ALSO PUBLISHED AS A SPECIAL SUPPLEMENT TO THE OCTOBER 1937 NUMBER OF THE *BRITISH JOURNAL OF TUBERCULOSIS*)

THIS remarkable memorandum prepared by Dr. Brieger and edited by Sir Pendril Varrier-Jones, Dr. E. Bachmann and Dr. W. Bronkhorst with the co-operation of various European organizations, was presented to the 1937 session of the International Union against Tuberculosis. It presents evidence of much laborious investigation and statistical analysis and may be considered as the *vade mecum* on the subject. All the available evidence has been critically sifted and unbiased conclusions arrived at. The compiler and the editors must be congratulated on the publication of such a timely monograph on a subject which is now occupying the attention of workers in all parts of the world. It will repay perusal by all tuberculosis workers, state and local authorities and anti-tuberculosis organizations, particularly in India where an all-India anti-tuberculosis association is to be inaugurated in the near future (*vide* Correspondence, page 774 this journal).

The monograph is divided into three parts, with sub-sections, appendices and graphs. Part I deals with prognosis and after-care, part II with social rehabilitation and part III with the multiple unit for institutional care and after-care. The material utilized for the investigation has been drawn from European and American institutions.

In the initial stages of anti-tuberculosis work in these countries, treatment in sanatoria was considered to be the chief factor in the relief of the problem, but experience soon showed that although treatment was an extremely important factor it was not in itself sufficient. The establishment and growth of dispensaries, with their many-sided activities, followed as a matter of course. 'But in spite of this and of constant improvement in therapeutic methods, the ultimate results, except for what may be called the minimal cases, remained unsatisfactory'.

The immediate results of combined intensive treatment in sanatoria, as demonstrated by Christensen, show that under routine sanatorium treatment 30 per cent of tubercle-positive cases on admission become tubercle-negative, when this is combined with pneumothorax treatment the figure rises to 50 per cent and with the triple combination of sanatorium treatment, pneumothorax and gold therapy the figure reaches 65 per cent. But the ultimate success of the treatment has been found to depend largely upon environment and after-care. The after-care material may be divided into four categories, *viz*, (1) those who, after treatment of varying length, are completely healed, (2) those who regain their full earning capacity through temporary after-care; (3) those who retain it through permanent after-care and (4) those who cannot regain their earning capacity because their illness takes an unfavourable and unstable course. The relapses in the improved cases may be due to premature resumption of work, to unsuitable work or to an inadequate standard of living. Early detection, sufficiently long sanatorium treatment, the guarantee of adequate economic conditions and regular hours of work have been shown to have a definite influence upon the prognosis in tuberculosis.

After-care is an essential part of sanatorium and hospital organization. It enters into direct relation with therapy and furnishes the auxiliary organization which alone can ensure the final success of treatment. It has been pointed out, and we agree with the view, that

therapy with temporary after-care will perceptibly raise the number of effective cases. The sociological function of ensuring a livelihood to the permanently disabled cases, which fail to respond to treatment and after-care, is not yet a duty imposed on sanatoria in the West. In the Papworth scheme the provision of an industrial settlement, ensuring a livelihood for semi-healed and permanently disabled cases, is combined with efficient therapeutic treatment. The problem of the livelihood of the chronic tuberculous needs a stable solution. After-care work should be directed towards (1) the provision of work carefully selected to maintain the physical improvement achieved by sanatorium treatment, (2) the maintenance of the recovered health, under suitable working conditions and environment, of those who have regained full working capacity and (3) the provision of an environment suited to their sub-standard life of those whose working capacity is permanently reduced, either in the open labour market or as settlers in a work-colony. The restoration of working capacity for the tuberculous is undoubtedly the ultimate object of all measures for care and treatment. 'The tuberculous working man who survives from year to year must work in order to exist, although it is known that certain stress and strain may seriously impair the benefits of treatment. The tuberculous members of the population must be regarded as a real factor in the economic system of the nation'.

Broadly speaking, there are two aspects of rehabilitation: (1) removing the physical disability if possible (physical rehabilitation) and (2) making the disabled person a functioning economic unit (vocational rehabilitation). It is estimated that 50 per cent of patients discharged from sanatoria find their way back to some occupation. Therefore their rehabilitation and incorporation in the industrial economy of the nation constitutes a special problem, inasmuch as it demands the application of clinical, physiological and psychological tests for estimating the working capacity of the sub-standard worker in relation to individual physical condition and actual working conditions, followed by continuous medical care throughout the life of the individual. The period of rehabilitation should begin as 'industrial convalescence' and is followed by re-employment, under conditions where the benefits of therapy are consolidated rather than tested by strain. We agree with Dr. Brieger when he states that 'the re-employment of the tuberculous depends upon the degree of stabilization in general physical condition that can be attained by treatment. The recovered case may be able to achieve a degree of stabilization which will allow return to work in normal life. The invalid, however, must be cared for, either in hospitals or homes where the risk of infection is minimized. Those most in need of sheltered conditions of employment are those who constitute the group known as 'middle cases'. From their condition they are unemployable in normal industry. For such persons industrial settlements have developed as a combination of treatment and employment'. Sheltered industries are most satisfactory for the re-employment of the tuberculous where an industrial plant is set up under hygienic conditions and fully mechanized.

Dr. Brieger thinks that it is possible to build up a scheme like the above at no greater cost than relief by public assistance and that the cost to the community becomes considerably less in infection as well as in money.

The care of the tuberculous is inevitably a heavy charge but the highest measure of success is likely to be attained when the three fundamental aspects of the work—care (dispensary including prophylaxis), treatment (hospitals and sanatoria) and after-care—are so organized that harmonious co-operation between them is assured. At the present moment, this is far from being achieved. It is hoped that this timely publication will help to stimulate measures in this direction. The writer and the editors are to be congratulated in focusing attention on the movement of after-care and rehabilitation.

THE ROCKEFELLER FOUNDATION, NEW YORK: ANNUAL REPORT FOR 1937

Trusting the future

ON 23rd May, 1937, John Davison Rockefeller, the founder of The Rockefeller Foundation, died in his ninety-eighth year. Mr. Rockefeller's gifts for philanthropic purposes were roughly \$530,000,000. He gave a total of \$446,000,000 to establish four funds: The Rockefeller Institute for Medical Research, the General Education Board, The Rockefeller Foundation, and The Laura Spelman Rockefeller Memorial. In addition, Mr. Rockefeller made individual contributions of approximately \$84,000,000 for educational, religious, and charitable purposes. Since their foundation, the four funds established by Mr. Rockefeller have expended a total of \$645,000,000 in 88 different countries.

Mr. Rockefeller always made his gifts after thorough study and careful planning.

In the first place, he trusted the future. He did not think that benevolence and wisdom were confined to his generation. He was not under the illusion that what seems important to-day will necessarily be important to-morrow. He did not believe in tying up foundations to rigid and unchangeable purposes. When The Rockefeller Foundation was incorporated, the sole purpose stated in his charter was 'to promote the well-being of mankind throughout the world'. It was characteristic of Mr. Rockefeller's developing point of view that in 1920 he wrote to the trustees of the General Education Board as follows:—

If in any gifts heretofore made to you by me there are any restrictions or limitations as to the specific purpose for which they are to be used, I hereby revoke such restrictions.

In the second place, Mr. Rockefeller did not believe that it was wise to attempt to maintain foundations in perpetuity. 'Perpetuity is a pretty long time', he remarked. It is perhaps not generally known that under their characters both The Rockefeller Foundation and the General Education Board are authorized to expend principal as well as income. In addition to income, the Foundation has thus far spent \$87,000,000 from its principal fund, while the General Education Board has spent \$140,000,000. Two Rockefeller boards have already terminated their activities: The Laura Spelman Rockefeller Memorial, founded by Mr. Rockefeller, was merged with the Foundation in 1929 after having spent \$27,500,000 of its principal fund; the International Education Board, established by Mr. Rockefeller, Junior, was completely liquidated in 1937. The General Education Board is now approaching liquidation. How long The Rockefeller Foundation may continue depends upon the opportunities for expenditure which lie ahead.

These ideas of Mr. Rockefeller have had great influence in shaping the policies of the boards which he established. The temptation to visualize the future in terms of the present—to think of the needs and methods of to-day as having a sure claim to immortality—is one which confronts trustees as well as founders of philanthropic foundations. For example, to establish under a permanent endowment in some university or research centre a department or chair of psychiatry or organic chemistry may seem, with such light as we have at the moment, a rational and socially desirable step. But what wisdom have we to-day to determine that a century or more hence psychiatry and organic chemistry will represent the pressing needs or the practicable techniques of that time? In endowing what they thought was of permanent importance, earlier generations made wrong guesses which embarrass us to-day. How can we assume that our guesses have any greater validity or are made with any clearer foresight?

This question led the trustees of The Rockefeller Foundation and of the General Education Board to adopt a principle by which recipients of gifts to endowment funds, for whatever purpose given, have wide discretion in the uses to which those funds may be

put. Specifically, under a resolution passed by both boards in 1937, notification is sent to each recipient that it is the desire of the boards that the gift, 'whether the income only is spent or the principal as well, shall always be regarded as available for use in the broadcast way, so as best to promote the general purpose for which it was made'. The notification contains the provisions outlined in general terms in the three succeeding paragraphs:—

(1) Ten years after the date of the gift, the income from it may be used in whole or in part for some purpose other than that for which the gift was made, such purpose to be as reasonably related to the original purpose, as may be found practicable at the time, having regard to intervening changing conditions.

(2) Beginning five years after the date of the gift, 5 per cent of the principal of the fund may be used each year for any purpose for which income may then be used.

(3) After the expiration of twenty-five years, any part or the whole of the principal may be used for some other purpose, the new purpose—as in point 1—to be as reasonably related to the original purpose as may be found practicable at the time, having regard to intervening changing conditions.

These liberalizing provisions represent an attempt to free the future from frozen funds and 'tired' endowments, in the belief that the wisdom of this generation cannot be substituted for the wisdom of the next in the solution of problems hidden from our eyes. The endowments affected by these provisions amount to \$51,000,000 given to date by The Rockefeller Foundation, and \$148,000,000 given by the General Education Board.

The year in brief

During 1937 The Rockefeller Foundation appropriated a total sum in excess of \$9,500,000. Of this amount, \$2,400,000 was given to the medical sciences, \$2,200,000 to public health, \$2,000,000 to the social sciences, \$1,100,000 to the natural sciences, \$800,000 to the humanities, and \$400,000 to rural reconstruction in China.

In carrying out its 1937 programme the Foundation operated in 52 different countries, from Norway to the Fiji Islands. Twenty-three of these countries were in Europe, four in Asia, three in Africa, six in South America, eleven in North and Central America and the West Indies, and five in other parts of the world. Forty-five per cent of the money given went to foreign countries, and the remainder, 55 per cent, was for work in the United States.

New international barriers

From the beginning of its activities twenty-five years ago the Foundation has been guided by the objective written into its charter: 'The well-being of mankind throughout the world'. In accordance with this purpose the aim of the trustees has been to maintain the work of the Foundation on an international plane without consideration of flags or political doctrines or creeds or sects. Particularly in a programme based on the advancement of knowledge it is imperative to disregard the geographical boundaries which arbitrarily and often unhappily divide the earth into a patchwork of senseless antagonisms. For in the last analysis knowledge cannot be nationalized. No successful embargoes can be maintained against the export or import of ideas. Whether new conceptions in atomic physics come from Copenhagen or from Cambridge, England; whether the cure for cancer is developed in New Haven or in Berlin; whether it is a Russian or an Italian or an American who takes the next step forward in mankind's struggle with virus diseases—we are all of us, under whatever flag, the joint beneficiaries of the intellectual property of the race. In all the clash of competing nationalisms there is here an underlying principle of unity: the single aim and language of science in the discovery of truth. It is this principle which challenges the twentieth century with the conception of civilization as a co-operative achievement and with the ideal of intellectual capital as an international possession.

A foundation, therefore, whose aim is to assist in pushing out the boundaries of knowledge must necessarily work wherever the best tools are to be found. In its search for high talent and promising opportunities it must assume that frontiers are not the forbidding barriers they pretend to be.

This ideal, which for more than two decades The Rockefeller Foundation has consistently attempted to follow, has in recent years encountered serious difficulties. And these difficulties are increasing. Objective scholarship is possible only where thought is free—and freedom can exist only where there is tolerance, only where there are no 'Keep Out' signs against the inquisitive and questioning mind. Disinterested research cannot survive in an atmosphere of compulsion and repression. It withers under the efforts of governments to impose uniform ideologies and to circumscribe in the interests of a dominant regime the area of intellectual liberty. Particularly in the broad range of subjects covered by the social sciences, and in the humanities as well, the world has recently witnessed in several countries the progressive disintegration of creative scholarship.

This phenomenon has naturally affected the programme of the Foundation. In some fields it is now profitless to go where we formerly went. We find ourselves stopped at some frontiers—not because the frontiers have any greater geographical significance than they had a few years ago, but because behind them the search for truth by eager and sceptical minds has been made impossible.

Some twenty years ago in a Central American city a revolution developed while the Foundation was engaged in a study of yellow fever control measures. Dr. Emmett Vaughn, who was in charge of the work, determined to continue his research. Every morning with a flag of truce he crawled through the barricades to collect his mosquitoes on one side of the fighting line, and in the afternoon he crawled back again to gather up his specimens on the other side. He was molested by neither army. Both sides thought him somewhat crazy—a man who, when great issues of human destiny were being fought out, spent his time catching mosquitoes. To-day in that Central American country the revolution has been largely forgotten, but Dr. Vaughn is remembered as the man who helped to stamp out an age-long pestilence.

The Rockefeller Foundation likes to think of this incident as an example of what its approach to the welfare of mankind should be. But occasionally aggressive action by the fighting lines makes impossible even the gathering of mosquitoes.

Public health: a world problem

Laboratory techniques have been brought to the assistance of field work all over the world in influenza, scarlet fever, tuberculosis, yaws, syphilis, rabies, and the common cold. Schools have been established for the training of public health personnel; and governmental agencies, national and local, have been assisted in building up more adequate health departments. Altogether, the Foundation has operated in 77 different countries and colonies and has expended approximately \$63,000,000 on public health work.

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1936

VOLUME II

THE HEALTH OF THE ARMY IN INDIA

Malaria.—It was predicted that 1936 would be a bad year for malaria in India, but, in so far as the Army was concerned, expectations were not fulfilled and except for Northern Command and Burma District there was a general decrease.

The increase of malaria in the Northern Command was an aftermath of the Mohmand operations of 1935. During these operations 'delay-action' quinine was

given to the men in camps which were notoriously malarious. While this had the effect of keeping men at duty it reacted later by producing an increased number of relapse cases and latent fresh infections during the following spring. In addition in the Rawalpindi District the breeding season extended into late November with many admissions during that month.

The reason for Multan being now the most malarious military station is considered to be due to the change in climatic conditions, with increased humidity and rainfall, which has become apparent in the areas affected by new irrigation from the river Indus. Increased malaria in Hyderabad is attributable to the same cause. The results already noted caused by 'delay-action' quinine in the Mohmand operations account for the increased incidence in Peshawar and Landikotal.

Routine treatment has been by (1) atebirin 0.3 gramme daily for seven days followed after an interval of three days by plasmochin 0.03 gramme daily for five days. In some hospitals quinine is given for the first 48 hours after admission, and prior to the administration of atebirin, or (2) quinine 20 grains with plasmochin 0.03 gramme daily for 21 days.

The relapse rate for all-India still remains at almost half that prevailing in 1932, e.g., 18.7 per 1,000 as compared with 34.9 per 1,000 in 1932.

Dengue.—The incidence of this disease shows a still further decrease this year, there having been 244 cases compared with 262 in 1935.

The complete absence of dengue among troops in Karachi last year has not been sustained. Although there were 18 cases among British troops in the station, there was only one case among Indian troops.

Sandfly fever.—There has been a reduction in the incidence of this disease but it still ranks third in the causes of sickness among British troops in India being, with the exception of minor septic diseases, next in importance to malaria.

The Northern Command bears the greater part of the brunt of this disease as in former years, Landikotal and Peshawar being the stations particularly affected.

Pyrexia of uncertain origin.—There has been a steady decrease of these cases in the last five years.

The following figures illustrate the decrease in the use of the term P. U. O.:—

1932	106
1933	61
1934	46
1935	37
1936	10

Oriental sore.—At the end of 1935, the number of cases of oriental sore in Quetta, where the disease is endemic, was found to be increasing and early in 1936 the disease began to assume epidemic proportions among the local population in city and cantonment.

Although conditions prevailing after the earthquake in May 1935 might be considered favourable for increased breeding of sandflies in the piles of debris, no such evidence was forthcoming and the irregularity of infection among units in relation to proximity to the ruined city did not suggest infection from sandflies breeding in the ruins. The chief predisposing factor was probably that during July, August and September 1935, when infection probably occurred, the majority of the population were living under abnormal conditions and the risk of infection was greater.

Over 600 cases of all classes were treated at Quetta. Included in this number were 34 cases among British troops in Quetta. In addition there were 26 cases in a battalion of British troops in Secunderabad which had left Quetta at the end of 1935.

Treatment found eventually to give the best results consisted of curettage under gas followed by application of pure carbolic acid; the wound then being covered with elastoplast and left for two weeks. A modification of the above was used latterly in the Indian Military Hospital. After curettage, tannic acid was dusted on the wound to minimize bleeding and,

for the sake of economy, sterile vaseline was used instead of elastoplast with equally successful results.

In very extensive cases, especially those with multiple sores on the face, sodium antimony tartrate was given intravenously starting with $\frac{1}{2}$ grain and increasing on alternate days by $\frac{1}{2}$ to $1\frac{1}{2}$ grains up to 10 to 15 grains. Trivalent antimony compounds were found to be more effective than the pentavalent.

Fevers of the typhus group.—Forty-four cases occurred among British troops as compared with 19 in 1935. In addition 47 cases were diagnosed among Indian other ranks. Owing to the difficulty in the differential diagnosis of certain of the mild cases without any trace of a characteristic rash the above may be understatements. As in previous years the cases fall into three main groups on their agglutination reactions. Of 108 cases (including other categories than British other ranks and Indian other ranks) only 13 could not be classified owing to approximate rises in agglutination titres of two or more members of the *Proteus* OX group—e.g., *Proteus* OXK British—29, Indian—9, *Proteus* OX19 British—9, Indian—32; *Proteus* OX2 British—9, Indian—7; unclassified British—6, Indian—7.

A possible significant point which might affect any conclusions based on the distribution of the disease in commands and stations and also in seasonal incidence is the curious manner in which the majority of the cases occur in stations in which district or brigade laboratories are located. In 1936 only 9 cases seemed to occur in stations at any distance from a military laboratory. The very few cases reported among the civil population in India annually is probably similarly due to the lack of laboratory facilities for fever cases among the mass of the population. In a large number of the milder cases in the military population diagnosis without repeated agglutination tests would not have been possible.

Enteric group of fevers.—In 1934 the incidence was the lowest ever recorded, but again this record has been broken by the even greater reduction in 1936, which is particularly striking among Indian troops. It is possible that a portion of the reduction among enteric group cases is due to increasing knowledge of the mild typhus group cases, but this would not apply to the great reduction in both typhoid and para-typhoid A group (Indian) which occurred during the year and the ratio per 1,000 for typhus fever (Indian) is identical with that in 1934. The numbers of deaths in both British and Indian troops from enteric fever are also greatly reduced. There has been no corresponding reduction among the civil population but rather an increase, and although strict attention to the general hygiene of military areas is very much to the fore, there have been no dramatic changes in this respect. Increasing interest is being taken by all Indian units as regards child welfare among their families and numbers of enteric group cases who previously would have escaped notice are now being brought to light and properly treated. It is possible therefore that another focus of infection is being eliminated. The main answer however appears to be in the improvement in the T. A. B. vaccine both from the R. A. M. College, and the Central Research Institute, Kasauli, which has taken place during the past few years.

Dysentery, diarrhoea, colitis and amoebic hepatitis.—During 1936 the admission ratio for dysentery decreased by 4.6 per 1,000 as compared with 1935 and is the lowest for some years. This is however offset by an increase in admissions for diarrhoea and colitis leaving a decrease of 1.4 per 1,000 for the whole group of diseases. Reduction also occurred in admissions for amoebic hepatitis, and only two cases of liver abscess were admitted during the year.

Cases were as usual sporadic and no epidemics occurred.

The fly season corresponded as usual with the greatest incidence of the cases and in Northern Command it was noticed that units arriving recently in stations after train journeys produced small crops of cases. The fact that this group of disease is under peace conditions

largely passed on from the insanitary conditions prevailing among the civil community was stressed in the 1935 report.

The striking range of the fly and the absence of any reliable method of producing active immunity against the numerous varieties of dysentery bacilli prevalent among the population of India account mainly for the fact that the admission rate to hospital among British troops is in the year 1936 still as high as 42.1 per 1,000 as compared with an admission rate of 1.5 per 1,000 for the enteric group of fevers.

The extent of the infection among the local population may be gauged by the fact that during the routine examination of menials prior to employment the majority of pathogenic bacilli discovered are mainly of the Flexner and Shiga group.

The percentage of dysentery cases diagnosed bacillary, bacillary exudate, protozoal and clinical dysentery throughout India during any one year now varies very little.

Cysticercosis.—One case occurred at Trimulgherry and was invalided to England. The man was a pork butcher in England before joining the Army. On reporting sick for a minor injury of the hand he was found to have subcutaneous nodules in various parts of his body and he stated that these had been present for seven months. Subsequently he had an epileptiform fit.

In addition to this case of cysticercosis 17 cases of epilepsy were invalided home during the year without any association with cysticercosis being discovered.

There were 17 cases of *Taenia solium* infestation treated during the year, compared with 24 during the previous year.

Venereal diseases.—Owing mainly to a reduction in Burma the admissions for venereal disease are lower than last year and slightly lower than the average of the last five years.

Cerebro-spinal fever.—One case occurred among British troops in Rawalpindi. This case was severe and resulted in death in spite of energetic treatment with group I antimeningococcus serum given intravenously, intrathecally and intramuscularly. There were 16 cases with 4 deaths among Indian other ranks and 4 cases with 3 deaths among Indian followers.

Of 14 strains of meningococci cultured 11 were found to belong to group I (type I or III). The remaining 3 strains were not typed.

Smallpox.—There were seven cases of smallpox during 1936, compared with eight in 1935. Four of the cases were among British other ranks, one was a British officer and the remaining two were children of British soldiers. One child aged $4\frac{1}{2}$ years had been vaccinated eight times but always unsuccessfully. The other, aged 11 months, had not been vaccinated, as the mother refused. Both of the children and one of the British other ranks, who had been revaccinated in 1933, died.

Respiratory diseases.—The number of admissions for respiratory diseases, other than pulmonary tuberculosis, was 1,210 or 23.2 per 1,000, being practically the same as in 1935.

There were 132 cases of lobar pneumonia with 14 deaths compared with 164 cases and 19 deaths in 1935. Out of 51 cases of broncho-pneumonia there were six deaths. There were 834 admissions for bronchitis and 90 for pleurisy.

Tuberculosis.—There were three more cases and two less deaths but 28 more invalids for pulmonary tuberculosis than in 1935. The cases were distributed throughout India, although Southern Command gives a somewhat higher ratio of infection than the other Commands. There was also no higher incidence in any one unit.

Effects of heat.—There were 13 cases of heat-stroke with three deaths, and 39 cases of heat-exhaustion with one death. The number of cases of heat-stroke is two more than in 1935 but there were only half the number of cases of heat-exhaustion.

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1936. BY LIEUTENANT-COLONEL A. C. CHATTERJI, M.B., D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH

The statement below shows the comparative birth and the death rates and the natural increase in 1935 and 1936:—

	1935.	1936.
Birth rate ..	32.7 per mille	33.5
Death rate ..	22.7 " "	24.5
Natural increase ..	10.0 " "	9.0

Compared with the preceeding year, death rates were higher from all principal causes, cholera by 25 per cent, smallpox by 800 per cent, fevers by 1.4 per cent, dysentery and diarrhoea by 10 per cent, respiratory diseases by 11.8 per cent, injuries by 25 per cent and all other causes by 5 per cent. In plague only there was a reduction of 50 per cent inasmuch as there was one death in the year under review against two in the preceeding year. The infantile death rate also increased by 7.8 per cent. Thus, it will appear that the health of the province during the year under review was comparatively worse than that of the previous year.

Calcutta alone accounting for 20 deaths from it. The provincial death rate from this cause was 0.01 per mille. The figures for the previous year being unavailable, no comparative statement could be furnished.

ANNUAL REPORT ON THE MEDICAL INSPECTION OF SCHOOL CHILDREN IN THE FIVE MUNICIPAL TOWNS OF PESHAWAR, BANNU, DERA ISMAIL KHAN, KOHAT AND ABBOTTABAD OF THE NORTH-WEST FRONTIER PROVINCE DURING THE YEAR JULY 1935 TO JUNE 1936. By K. C. UPPAL, M.B. (P.B.), D.P.H. (LOND.), OFFICIATING ASSISTANT DIRECTOR OF PUBLIC HEALTH

The total number of boys medically examined during the year under report was 16,315.

Uncleanliness.—Fourteen per cent of children were found unclean during the year as compared with 13 per cent during the year before. There is a small increase in the number of unclean boys in Peshawar, where 17 boys out of 17,684 were found unclean as compared

ANALYSIS OF FEVER DEATHS IN 1935 AND 1936

Causes	Number		Death rates per mille		Percentage of increase + or decrease — in 1936	Percentage to total fever mortality	
	1935	1936	1935	1936		1935	1936
Malaria fever ..	342,955	337,647	6.9	6.8	— 1.5	48.6	47.1
Enteric fever ..	8,709	8,359	0.17	0.17	± 0.0	1.2	1.2
Measles ..	3,326	4,549	0.07	0.09	+28.6	0.5	0.6
Relapsing fever (spirochaetal).	8	7	0.0001	0.0001	± 0.0	0.001	0.001
Kala-azar ..	17,469	21,161	0.35	0.42	+20.0	2.5	2.9
Influenza ..	3,616	2,502	0.07	0.05	—28.6	0.5	0.3
Cerebrospinal fever ..	Not recorded separately.	910	Not recorded separately.	0.02	0.1
Typhus fever ..		1,551		0.03	0.2
Blackwater fever ..		115		0.002	0.02
Other fevers ..	329,545	339,341	6.6	6.80	+ 3.0	46.7	47.4

6,007.3 lb. of quinine were sold through post offices in 1936 against 7,781.1 lb. in 1935 and 8,589.1 lb. in 1934. Compared with the previous year twenty-two districts showed a reduction in the sale of quinine in 1936. Calcutta and two other districts (24-Parganas and Dinajpur) in which there were reduction in the consumption of quinine showed an increase in fever indices. Chittagong once more headed the list in the average sale of quinine per head of population.

Pneumonia.—Since 1923, this disease has been steadily on an increase taking larger tolls of lives every year. During the year under report, there was an increase of mortality from it both in the rural and the urban areas including Calcutta. In the whole province, the death rate from it increased by 16.7 per cent, in the rural areas by 18 per cent, in the urban areas by 13.4 per cent and in Calcutta by 16.8 per cent.

Pulmonary tuberculosis.—Pulmonary tuberculosis took a toll of 15,266 lives from Bengal with a death rate of 0.31 per mille in 1936 against 16,524 with a death rate of 0.33 per mille in 1935. Compared with the previous year, there was thus a decrease of 1,258 deaths or 6 per cent in death from this cause in the whole province. The variation in the death rates in the rural and the urban areas was too slight to deserve mention. As in the previous year 68.8 per cent of the total deaths from this cause in all towns occurred in Calcutta alone.

Leprosy.—During the year 1936, 494 deaths from leprosy were reported in the province, of which 459 were from the rural and 35 from the urban areas,

with two out of a total of 18,723 during the last year. This is being due to large number of fresh admissions in the new session. Cleanliness surveys are regularly held twice a week in all the schools in Peshawar. The number of boys found unclean in Bannu is on the decrease. Out of a total of 9,531 examinations, 2,536 or 26 per cent were found unclean as compared with 2,846 out of a total of 9,072 or 31 per cent. Intensified educative health propaganda is required to be carried out among the parents there.

Skin diseases.—8.6 per thousand of children were found suffering from skin diseases as compared with 8 per thousand during the previous year. The small increase does not call for any comment.

Dental diseases.—Eight per cent of children were found suffering from dental diseases as compared with 7 per cent during the year before. There is a negligible increase in the number of dental cases in Peshawar. In Bannu and Abbottabad the number has decreased, while Dera Ismail Khan returns the same number as last year and Kohat again shows an increase. This increase is only apparent because children in the infant classes were more thoroughly examined this year in Kohat.

Affections of ear, nose and throat.—Two per cent of children were found suffering from these troubles as compared with the same number during the previous year.

Enlarged tonsils and adenoids.—Five per cent of children were found suffering from these ailments

during the year as compared with 7 per cent during the previous year.

External eye diseases.—The percentage of this disease found in the schools of Peshawar, Bannu, Dera Ismail Khan, Kohat and Abbottabad during the year under report as compared with the previous year is given below:—

Name of town	1934-35		1935-36	
	Per cent		Per cent	
Peshawar	9		13	
Bannu	9		8	
Dera Ismail Khan ..	14		11	
Kohat	2		1	
Abbottabad	6		5	

Trachoma accounts for the small increase in the number of external eye diseases in Peshawar. In all the other towns the disease is decreasing gradually.

Defective vision.—2.4 per cent of students were suffering from defective vision against 3 per cent during the previous year.

Malaria, enlarged spleen and anaemia.—Out of a total of 46,308 examinations made during the year 444 or about 1 per cent cases of malaria, 1,682 or about 4 per cent cases of enlarged spleen and 941 or about 2 per cent cases of anaemia were recorded as compared with 1, 2, 3 and 2 per cent respectively during the previous year.

Smallpox and other infectious diseases.—There were no cases of smallpox amongst the school students during the year under report. However 103 students were revaccinated.

Cholera broke out in Bannu city and its suburbs in the last week of August 1935. Three thousand cholera inoculations were performed by the Medical Inspector of Schools in the city and its suburbs. Owing to the prompt action taken by the Civil Surgeon, Bannu, the epidemic subsided soon after.

Tuberculosis.—The following table shows the number of school children found suffering from tuberculosis of various types during the year as compared with the last year:—

		1934-35	1935-36
Lungs	10	10
Glands, neck	35	26
Glands, axillary	1	2
Ankle joint	2	3
Spine	3	3
Bones	1
		<hr/>	<hr/>
TOTAL	51	45

REPORT ON THE WORKING OF THE PUNJAB MENTAL HOSPITAL, LAHORE, FOR THE YEAR 1937

THE year 1937 opened with 991 patients in the hospital; 162 patients (139 males and 23 females) were admitted during the year, 143 were discharged and 29 died leaving 981 patients under treatment at the close of the year. The total number of patients admitted was larger during the year under report than that in the previous year, viz, 162 against 149. The number of admissions would have been still higher but for the strict control maintained in selecting curable cases.

There were only 29 deaths during the year under report as compared with 37 during 1936 and 44 during 1935. Out of the total number of 29 deaths, 8 were due to tuberculosis of lungs, 4 each to dysentery and debility and the remaining 17 to various other causes. The death rate in 1937 was lowest since the inception of the hospital, viz, 2.97 as against 3.58 and 3.96 in the two preceding years. The daily average sick was also very low, being 49.45 during the year under report.

The new accommodation for 300 patients on the male side is nearing completion and it is hoped that it will be brought into use very shortly. The question of providing funds for additional accommodation on the female side is still under consideration. The problem here is becoming difficult as it has been impossible to reduce the overcrowding among the females and a number of criminal as well as non-criminal women have had to be refused admission.

Of the 162 patients admitted, 56 were suffering from manic depressive insanity, 37 from schizophrenia including dementia præcox, 20 from mania and 49 from various other causes.

The net saving on account of the value of vegetables, fruits and manufactures, which are mainly used in the institution, amounted to Rs. 20,000-11-3 during the year 1937 as against Rs. 22,704-0-3 during the previous year. In the year under report, however, the cost of articles was worked out at the rates prevailing in the market, whereas it had been the practice in the past to estimate the cost more liberally.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR FOR THE YEAR 1936. BY LIEUTENANT-COLONEL S. L. MITRA, D.P.H., I.M.S., DIRECTOR

Comparative incidence of the chief diseases.—The undermentioned statement compares the ratios under the chief heads of mortality in 1936 with the average ratio of the previous ten years:—

				URBAN		RURAL		COMBINED	
				Ten years' average	1936	Ten years' average	1936	Ten years' average	1936
Cholera	0.9	0.1	1.6	0.2	1.6	0.2
Smallpox	0.6	0.7	0.5	0.7	0.5	0.7
Plague	0.08	0.1	0.2	0.03	0.2	0.04
Fevers	7.1	5.5	17.2	17.4	16.8	16.9
Dysentery and diarrhoea			..	0.6	0.5	0.1	0.08	0.1	0.1
Respiratory diseases		0.5	0.6	0.07	0.07	0.09	0.1
Injuries	0.5	0.5	0.3	0.3	0.3	0.3
All other causes		4.4	4.7	3.4	3.2	3.5	3.3
TOTAL				14.7	13.7	23.4	22.0	23.0	21.7

The death rate has decreased from 24.3 in 1935 to 21.7 per mille of population in 1936. The decrease in the number of deaths was due chiefly to the fewer deaths from cholera and fevers, the death rates being 0.2 and 16.9 as against 1.8 and 18.2 of the previous year.

REPORT OF THE RAMAKRISHNA MATH CHARITABLE DISPENSARY, MYLAPORE, MADRAS, FOR 1937

THE dispensary has been fulfilling a long-felt want of the poorer section of the locality. Its record of work for the last eleven years, i.e., from the year of its commencement till the year under review, has been one of steady rise and progress. The enormous rise in the number of patients from about 5,000 in 1926 to over 82,000 in 1937 bears ample testimony not only to the utility of the institution and the growth of its work, but also to the increasing responsibilities of the management.

The executive appeal to the generous public to continue their active sympathy and co-operation, and to come forward with liberal contributions for fulfilling the immediate needs of the institution. Donors wishing to perpetuate the memory of their friends or relatives may do so by creating memorial endowments for the maintenance of the charitable dispensary. A tablet bearing the names of the persons whose memory is to be perpetuated will be fixed in a suitable part of the building.

ANNUAL REPORT OF THE CHEMICAL EXAMINER'S DEPARTMENT, MADRAS, FOR THE YEAR 1937

ANALYTICAL NOTES

Datura.—The examination of the urine appears to be more valuable than the examination of the stomach wash in cases of *datura* poisoning. In three out of fourteen cases a mydriatic alkaloid was present in the urine though absent in the stomach washes.

Ganja (Indian hemp).—We found that the resin of *ganja* which yields Beam's test with alcoholic hydrochloric acid gives also a characteristic purple colour in chloroform solution with acetic anhydride and a drop of sulphuric acid. The latter reaction may therefore be used as an additional test to Beam's test.

The principle which gives the above test is a resin and dissolves not only in sodium hydroxide solution but also in barium hydroxide solution. Its solubility in barium hydroxide solution may be used to detect small quantities of *ganja* in viscera.

Oduvan leaf.—The poisonous principle of *oduvan* leaf was obtained in this laboratory in a purer condition than before by substituting alkaline ether extraction for the usual acid ether extraction. In the absence of alkaloids, glucosides are obtained in a purer condition in this manner, as tannins and other impurities appear to be retained by the alkaline aqueous solution. The ether extract obtained in this manner from the leaves is highly poisonous to frogs and gives with sulphuric acid a blue colour gradually changing to a permanganate tint. It does not give a green colour with concentrated hydrochloric acid.

Nerium odorum.—This plant known as *Kaner* (Hindustani), *Alari* (Tamil), is very common in South India and its leaves are often used as a poison, either as a paste or as a decoction. This poison has been a subject of study for several years in this laboratory.

The pure white crystalline glucoside has been isolated from this plant and its chemical and physiological properties have been studied.

One-fiftieth of a milligramme was found to be about the average minimum lethal dose to frogs weighing about 10 grammes, paralysis and death being the symptoms noted.

The formula $C_{22}H_{30}O_{10}$ and the name 'Nerin' are tentatively suggested for the substance.

ANNUAL REPORT OF THE NATIONAL ASSOCIATION FOR SUPPLYING MEDICAL AID BY WOMEN TO THE WOMEN OF INDIA (COUNTESS OF DUFFERIN'S FUND INCLUDING THE WOMEN'S MEDICAL SERVICE) FOR THE YEAR 1937

HER EXCELLENCY THE MARCHIONESS OF LINLITHGOW, during her visit to England in the summer of 1937, had an opportunity of speaking to Their Majesties The Queen-Empress and Queen Mary regarding the Association and its record of 52 years' invaluable service to women and children in India. Her Majesty Queen Elizabeth was graciously pleased to signify her interest and appreciation by agreeing to become a Royal Patron of the Association and Her Majesty Queen Mary consented to continue Her Royal Patronage. The interest and sympathy of Queen Elizabeth have been further shown by her presenting a beautiful portrait of herself to be hung in the Countess of Dufferin's Fund office, in New Delhi. Her Majesty also gave her consent to a reproduction of the photograph being made for the present report.

The year 1937 has seen a definite expansion of the work of the Association as two new branches of the Countess of Dufferin's Fund have been formed, one in the new Province of Orissa and a second in the Province of Sind. In both provinces medical aid to women is in a backward state and it is hoped these new branches will give an impetus to the work of medical relief for women and children in their respective provinces. Short reports on their inauguration and progress will be found on pages 57 and 98.

Another event of considerable importance has been the closing down of the United Kingdom Branch of the Dufferin Fund. This step was taken on the recommendation of the Executive Committee of the United Kingdom Branch and with the concurrence of the Central Council, as it was realized that the work formerly entrusted to the United Kingdom Branch had greatly diminished during recent years.

Dr. A. C. Scott who has been Medical Adviser in the United Kingdom since 1934 has been responsible for the reception and assistance of officers on leave and has given invaluable advice and help on all matters relating to their post-graduate studies and general welfare. The executive committee have decided to continue this appointment which has been proved to be of great value and will be still more necessary now that the United Kingdom Branch has been closed.

The Central Council have been appointed Trustees of the Capital Funds formerly invested in the name of the United Kingdom Branch of the Dufferin Fund and all funds in that account have been transferred to the account of the Central Council.

In April 1937 the Government of India undertook the full financial responsibility for the Maternity and Child Welfare Section of the All-India Institute of Hygiene and Public Health, Calcutta. The services of Dr. Neal-Edwards, W. M. S., who has been Professor of Midwifery at the Institute since 1935, have been lent to the Institute, at the request of the Government of India, until she proceeds on leave in February 1938. It is hoped her successor will be appointed shortly.

The re-building of the Dufferin Hospital, Calcutta, has made considerable progress. It is hoped that this new hospital, when completed, will be one of our best equipped and most up-to-date institutions which will be a centre not only for first class surgical and medical treatment for women and children, but a modern training school for nurses, a post-graduate training school for medical women and a centre for research.

The new hospitals at Shillong and Khamgaon are making excellent progress and are fulfilling a great need in their respective districts.

The council have been deeply impressed by the great need there is in India for a better educated and better trained nursing service and have realized this can only be attained by attracting to the nursing profession Indian girls of better class who will enter the profession with a vocation for nursing and with ideals of service.

This cannot be brought about until the living conditions and facilities for training in our hospitals are greatly improved. With this object in view the executive committee of the Dufferin Fund have earmarked the unspent balance of the Silver Jubilee money amounting to Rs. 71,300 for grants for re-building and improving nurses' quarters, for increasing teaching equipment in training schools for nurses and for providing teaching allowances for sister tutors and salaries for additional staff nurses. It is also proposed to award scholarships to trained nurses to enable them to take courses in administration in large hospitals to fit them for administrative posts.

ANNUAL REPORT OF THE HEALTH DEPARTMENT, MUNICIPALITY OF SINGAPORE, FOR THE YEAR 1937

The most remarkable thing in this report is that since 1928 there has not been a single case of cholera reported, there has been only one case of plague since 1930, which case occurred in 1933, and the year under report has also been free from smallpox.

ANNUAL PUBLIC HEALTH REPORT OF THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1936

The death rate during the year 1936 was 34.89 per thousand of the population, or 2.79 higher than the average during the preceding five years and was the highest in British India. The Director of Public Health has been asked to submit considered proposals for a properly organized public health service, manned by adequate and trained personnel, on which emphasis has been laid by the Central Advisory Board of Health at its inaugural meeting.

Malaria took the heaviest toll of human life, accounting for 61 per cent of the total mortality from all causes. Any radical engineering and other works to mitigate the danger from malaria are at present impracticable owing to their prohibitive cost. Government desires, however, that the only remedial measure available at present, namely, quinine, should be made accessible to the greatest possible extent and will sympathetically consider proposals for its cheaper and more widespread distribution through non-official and other agencies. Local bodies have a special responsibility in this matter and adequate funds should be set aside by them for the increased and more extensive supply of quinine.

Mortality from plague has been steadily declining. Many endemic foci of infection, however, still persist, pointing to the necessity of the continuance of vigorous anti-plague measures, particularly the destruction of rats. Mortality from cholera was also half of that in 1935 and was lower than the quinquennial average by 0.13 per mille. Other infectious bowel diseases (typhoid and dysentery) caused mortality which, although not so sudden and acute, was quantitatively as serious as that from cholera. Combined with diarrhoea, they were responsible for a death rate of nearly 3 per mille or $4\frac{1}{2}$ times more than that caused by cholera. The main causes of this avoidable mortality are bad water-supply, unsatisfactory conservancy and inefficient drainage. Government is anxious to see that improvement in urban and rural water-supply is accelerated and every effort is made to secure better protection of water used for drinking and domestic purposes.

There has been a fall amounting to about 90,000 in the number of vaccinations performed. The lower mortality reported from smallpox is not necessarily an indication of improvement, as there is reason to suspect that deaths from smallpox are often attributed wrongly to chickenpox.

Although the number of deaths among infants under one year of age was slightly less than during the preceding year, the rate of infant mortality continued to be appallingly high, viz, 234.98 per thousand births. The maternity and child welfare movement continued

to make progress. The number of child welfare centres increased from 7 to 71, while the total attendances increased from 43,508 to 559,282. If any appreciable improvement is to be brought about, local bodies must associate themselves more and more actively and directly with welfare work and the public generally and more especially those who are in affluent circumstances must evince greater interest in this movement.

The year marked further progress in anti-leprosy work. Two more clinics were opened bringing the total to 32. The attendance at these clinics rose by 5,350 and the treatment is being increasingly appreciated. Government considers that the spread of this disease can be effectively checked if public opinion insists on the segregation of lepers and would like to see greater propaganda carried on in this direction.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ORISSA FOR THE YEAR 1936

Incidence of the chief diseases.—The statement below shows the ratios per 1,000 of population under the chief heads of mortality in 1936.

	Rural	Urban	Combined
Cholera	1.2	0.8	1.1
Smallpox	0.6	0.2	0.5
Fevers	14.3	7.0	14.0
Dysentery and diarrhoea	2.3	2.8	2.3
Respiratory diseases ..	0.7	1.7	0.7
Injuries	0.4	0.4	0.4
All other causes	8.6	8.4	8.6
TOTAL	28.1	21.3	27.8

The highest death rate, 14.0, was recorded from fevers, but in the absence of correct diagnosis it is not possible to say what percentage of deaths under fevers is definitely due to malaria.

ANNUAL REPORT OF THE LEAGUE OF NATIONS HEALTH ORGANIZATION, EASTERN BUREAU, SINGAPORE, FOR THE YEAR 1937

This report is a valuable record of the history of epidemic and infectious diseases for the area over which it operates. It does not lend itself to abstraction because the information given in it has already been condensed from longer reports, but it should be in the hands of all public health and port medical officers throughout that portion of the world with which it deals.

Correspondence

EFFECT OF LARGE DOSES OF PRONTOSIL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—On the 21st of September at about 5-30 p.m. I was called in to see two young girls, aged 4 and 5 years, who had eaten 8 and 3 tablets of Prontosil red respectively at 12 noon. At 3 p.m. the former was a bit dull and at times unsteady in gait. The temperature was 99°F., pulse 120, and respiration 30 per minute. The urine was reddish. 'Fruit salts', two teaspoonfuls, was ordered. During the night the girl passed three reddish watery motions. The next morning the colour had almost disappeared.

The elder girl had no more symptoms than a slight discoloration of the skin.

Yours, etc.,

BALKRISHNA N. MEHTA, M.B., B.S.,
Medical Officer.

JUNANSINHJI DISPENSARY,
BEAVNAGAR,
14th October, 1938.

CARE AND AFTER-CARE OF THE TUBERCULOUS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—A copy of the *Indian Medical Gazette's* Special Tuberculosis Number has just come to hand. May I send you my very hearty congratulations on this excellent number? For a long time it has been felt in this country that there should be a forum where the question of tuberculosis in India could be brought forward in a complete comprehensive picture. I feel that your Special Tuberculosis Number goes far to fulfil this need.

May I express the hope that the *Indian Medical Gazette* will give consideration to a suggestion recently made to me that a more frequent Special Tuberculosis Number would receive a very sincere welcome in India?

To mark this September issue which contains a reprinted report on the International Union's Committee for After-Care and Rehabilitation, I will be glad to offer 50 copies of this Report to readers of the *Indian Medical Gazette* who will write to me for them.

Yours, etc.,

P. FRASER,

Secretary, Empire Conference on the Care and After-Care of the Tuberculous.

OVER-SEAS HOUSE,
ST. JAMES'S,
LONDON, S.W.1,
12th October, 1938.

SIPHUNCULINA FUNICOLA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the *Indian Medical Gazette* of (i) January 1938, page 17, (ii) April 1938, page 254, (iii) August 1938, page 468, you published articles and letters on the subject of the breeding places of *Siphunculina funicola*.

Since 24th March, 1937, I have been carrying out an investigation to try and find out the natural breeding places of the *Siphunculina funicola* fly in this area.

I can now report definitely that the *Siphunculina funicola* in this area breeds naturally in thatch grass, and that in this area it has never been found to breed in ammoniacal soil or decaying vegetation.

In this investigation we have examined nearly 800 collections (boxes or bottles) of material, running into thousands of separate microscopical examinations.

Up to this hot weather season of 1938, though we had bred the *Siphunculina funicola* in thatch grass, we never succeeded in breeding it out in numbers. During the present year, however, with a slight alteration in our technique we have bred many *Siphunculina funicola* flies in the thatch grass in which eggs, larvæ and pupæ were found; in these experiments no media was used except the original thatch grass in which the *Siphunculina funicola* in its young forms were found. In all, on 27 occasions, flies have been hatched out in different batches, giving a total of fifty-five of these flies hatched, from and in thatch. One specimen produced twenty flies; seventeen of these were actually examined alive and three found dead. This piece of thatch was collected on 8th August, 1938, and on it eggs and larvæ were found, batches of flies hatched out on 14th, 15th and 29th August, 1938.

Some of these actual flies were sent to Professor P. A. Buxton of the London School of Hygiene and Tropical Medicine, and he identified them as the *Siphunculina funicola* fly, further he forwarded the specimen on to Dr. Curtis W. Sabrosky in the U. S. A., who critically examined the flies and pronounced them to be the *Siphunculina funicola*.

One interesting fact in connection with this last experiment is that, on the same date as a batch of

these flies hatched out, we hatched a batch of flies from a specimen of ammoniacal soil, and sent these flies also to Professor Buxton, who states that—'those bred from soil are not *Siphunculina funicola*, but belong to the family of *Borboridæ*'—'the other tube you sent me (i.e., the tube of thatch flies) contains *Siphunculina funicola*'.

Some other specimens of flies which bred from thatch have also been examined in the School of Tropical Medicine, Calcutta, and pronounced to be the *Siphunculina funicola* by Dr. D. N. Roy, assistant professor of entomology.

A further fact of great interest is that on 30th April, 1938, thatch containing *Siphunculina funicola* eggs was collected (8 pieces of thatch averaging $\frac{3}{4}$ inch by $2\frac{1}{2}$ inches long); from this thatch three adult *Siphunculina funicola* flies were hatched out on 31st May, two on 11th June, and from that date to 1st November no further flies were hatched out, but on 1st November two further flies hatched out (I think actually the flies must have hatched out on the night of 31st October, as we examined the tube on the morning of 1st November when we found flies). This means that fly eggs in thatch are viable for a very long period, in this case six months already. In the funnel tube in which we are carrying out this experiment we also found, on 1st November, pieces of pupal skin, one dried up dead larva and several eggs, some dried up and some looked quite healthy.

I am compiling a complete report of this investigation, and will publish it together with photographs of specimens. However, as so much has been written of late concerning this fly, I think it is time that these results were published.

Yours, etc.,

C. S. P. HAMILTON, D.S.O.,

M.R.C.S., L.R.C.P.,

Chief Medical Officer, Juri Valley Medical Association.

KAPNAPAHAR TEA ESTATE,

JURI P. O.,

SYLHET,

4th November, 1938.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL N. M. WILSON, O.B.E., K.H.S., is permitted to resume his duties as Surgeon-General with the Government of Madras, with effect from 21st September, 1938, forenoon, on the termination of his appointment as Director-General, Indian Medical Service.

Colonel A. C. Munro to be Officiating D. D. M. S., Northern Command, in addition to his other duties. Dated 21st September, 1938.

Lieutenant-Colonel B. Prasad to be Officiating A. D. M. S., Presidency and Assam District. Dated 9th September, 1938.

Lieutenant-Colonel R. F. D. MacGregor, M.C., an Agency Surgeon, on return from leave, is employed as Residency Surgeon, Hyderabad, with effect from the afternoon of the 15th October, 1938.

Lieutenant-Colonel G. R. McRoberts to resume his appointment of Senior Specialist in Medicine, Madras, with the duties of Professor of Medicine, Medical College, and Physician, General Hospital, Madras, with effect from the date of taking charge.

Major M. K. Kelavkar on expiry of his leave resumed charge of the Medical Store Depot, Lahore Cantonment, on the forenoon of 3rd September, 1938.

Major R. Linton, on the expiry of his leave, ex-India, is re-appointed to be Civil Surgeon, Dacca, vice Major E. G. Montgomery granted leave.

Captain E. Parry to be Surgical Specialist, Army in Burma. Dated 28th August, 1938.

Captain J. L. Mewton to be Specialist in Gynaecology, Peshawar District. Dated 1st September, 1938.

Transferred to Civil Employment

Captain F. W. Whiteman, on 8th September, 1938, to Bihar.

Captain J. W. D. Goodall, on 8th September, 1938, to Bengal.

Captain F. V. Stonham, on 27th September, 1938, to the Punjab.

Captain J. W. D. Goodall, on arrival in Bengal, is posted to Midnapore as Civil Surgeon, *vice* Dr. Rash Behari Datta.

Captain G. B. W. Fisher, on return from leave, is appointed as Civil Surgeon, Bakarganj, *vice* Dr. W. A. Browne.

The Secretary of State for India has appointed Lieutenant R. Passmore, to the Civil Branch of the Indian Medical Service, with effect from the 2nd March, 1938. He will continue to be employed in the Medical Research Department as Assistant Director, Nutrition Research, Coonoor.

The undermentioned officers are restored to the establishment:—

16th August, 1938

Lieutenant (on probation) R. D. D. Birdwood.

1st September, 1938

Lieutenant (on probation) H. C. Rogers, with seniority from 1st September, 1937.

Lieutenant (on probation) E. L. Wilson.

Lieutenant (on probation) J. E. Ennis.

LEAVE

Lieutenant-Colonel H. S. G. Haji, M.C., Officer Commanding, Indian Military Hospital, Secunderabad, proceeded on 6 months and 20 days' combined leave *ex-India* on the 12th September, 1938.

Captain R. D. MacRae, an Officiating Agency Surgeon, is granted leave on average pay for 4 months combined with study leave for 6 months and leave on half-average pay for 2 months, under the Fundamental Rules, with effect from the afternoon of the 15th October, 1938.

Captain C. J. H. Brink, Residency Surgeon, Kashmir, is granted leave on average pay for 26 days, with effect from the 1st November, 1938, or any subsequent date from which he may avail himself of it. His services are replaced at the disposal of the Defence Department on the expiry of the leave.

PROMOTION

The undermentioned Indian Medical Service officers were advanced to the List of Specially Selected Lieutenant-Colonels with effect from the dates mentioned against each:—

Lieutenant-Colonel (now Colonel) R. S. Townsend, M.C. Dated 1st April, 1937.

Lieutenant-Colonel (now Colonel) G. G. Jolly, C.I.E., V.H.S. Dated 16th September, 1937.

Lieutenant-Colonel (now Colonel) E. S. Phipson, C.I.E., D.S.O. Dated 16th November, 1937.

Lieutenant-Colonel F. A. Barker, O.B.E. Dated 1st April, 1937.

Brevet-Colonel R. N. Chopra, C.I.E., K.H.P. Dated 1st April, 1937.

Lieutenant-Colonel T. C. Boyd. Dated 1st December, 1937.

Majors to be Lieutenant-Colonels

G. D. Malhoutra. Dated 16th October, 1938.

J. Carrey. Dated 24th October, 1938.

Captains to be Majors

V. E. M. Lee. Dated 1st August, 1938.

E. P. N. M. Early. Dated 6th August, 1938.

G. F. Condon. Dated 15th August, 1938.

D. P. Mitra. Dated 1st September, 1938.

N. J. U. Mather. Dated 18th September, 1938.

T. D. Ahmad. Dated 6th October, 1938.

M. Jafar. Dated 9th October, 1938.

Lieutenant (on probation) to be Captain (on probation)

W. Laurie. Dated 8th June, 1938, with seniority from 10th September, 1937.

RETIREMENTS

Lieutenant-Colonel H. K. Rowntree, M.C. Dated 22nd September, 1938.

Lieutenant-Colonel E. S. Goss, M.C. Dated 25th September, 1938.

RELINQUISHMENT

Lieutenant G. K. Beatty relinquished his probationary appointment in the Indian Medical Service, with effect from the 2nd August, 1938.

Notes

HISTORY OF THE RUTHIN CASTLE CLINIC

IN 1912 Dr. David Lawson suggested to Dr. E. I. Spriggs that he should become the head of a sanatorium for gastric disease. He consented, but desired that the work should embrace all internal medicine. Dr. (now Sir Edmund) Spriggs was recovering from a long illness and had been advised not to return to London, where he was a physician on the staff of St. George's Hospital. Dr. Lawson then formed a small limited company with himself as chairman. Duff House, Banff, was acquired and equipped. Dr. Edmund Spriggs was appointed senior physician.

The new features in an institution for private patients were that, in addition to a nursing staff, it was provided with whole-time doctors and trained workers in chemistry, bacteriology and x-rays laboratories, a special dietetic staff, dispensary, and apparatus with skilled attendants for massage, baths and physical treatment, all under one roof.

Duff House was well supported by the profession from the first. The War depleted institutions and practices and in those years it was run, as regards the men, with a changing staff of those who were physically not sound or over age. The work was, as elsewhere, overcome with difficulty. Free beds were provided for a number of officers, and duty was also done in the hospital for soldiers at Banff.

After the War there was a demand to be nearer the centres of population. The work also increased and it became necessary to enlarge. The directors were unable to buy Duff House and it was decided to move to Ruthin Castle, which, with 500 acres of land around, was bought. Large additions to the Castle were made, and the clinic was opened there on 11th April, 1923.

The principle of inclusive charges for all services has been followed throughout. The patient knows then what the charges will be. The doctor in charge can also pay as many visits as he likes or order any test or treatment, without increasing the cost to the patient.

The clinical workers have practised throughout as consulting physicians, co-operating with the family doctor of the patient, and with other consultants. Full technical reports are sent to the patient's medical attendants.

In the twenty-five years there have been over 12,000 admissions, including many patients who have been admitted several times, suffering from all kinds of illness except infectious and mental diseases. Nearly 3,000 have suffered from disorder of the heart and arteries, about the same number from diseases of the alimentary canal and nutritional disorders, many from nervous diseases and rheumatism, the rest from all manner of illnesses.

Over 100 papers have been published from time to time, not counting addresses by members of the staff to medical societies.

Among the subjects upon which research at the clinic has perhaps been most fruitful are medical diagnosis as a whole and the treatment of cardiovascular, alimentary, and nutritional disorders.

DISTRICT DISPENSARY OPERATION TABLE FOR INDIA

In the small district dispensaries of India, the doctor is provided with a very limited space and also with a

very limited equipment, but in those areas where the population is very scattered, he has opportunities of doing a great deal of work of all sorts, provided he is keen.

I found the difficulty was to provide him with a table on which he could do his dressings and on which also he could do those operations which he is most commonly called upon to perform, piles, fistulae, amputations, and minor eye operations. It may be said that it is undesirable to perform such operations in the same room in which earlier in the day septic cases have been treated, but unless there is another room, which usually there is not, he has no choice. For this type of dispensary I did not find any suitable table advertised and after much discussion with various doctors who use them I was able to design the table illustrated above, the more important features of which are the following:—

It has a head plate which raises and lowers, the advantages of which need no mention, but which is also fitted with a douche tray as in the Kilkelly table, designed by my predecessor here, which prevents a patient being drowned when his eyes are washed, as no kidney-shaped tray is ever satisfactorily applied in district work. The whole table then slopes towards the centre pipe so that a patient with a septic arm can sit beside the table and have it irrigated, the washings also going into the bucket. At the opposite end, septic foot wounds can be irrigated while the patient sits or lies on the table. Both the feet at the lower end are adjustable; this enables one to overcome the usual type of floors. Nearly all the parts are easily removable for cleaning.

I have had a number of these tables in use for 5 or 6 years and they have been found most satisfactory. They have been made for me by Messrs. Down Bros., London.

E. W. HAYWARD,
Principal Medical Officer,
Jodhpur.

SALUTAN FOR BURNS AND ABRASIONS

SALUTAN is a tannic acid preparation put up in a convenient 'dredger' by C. J. Hewlett and Sons, Limited, 35-42, Charlotte Road, London, E.C.2.

The burn or abrasion is washed with some mild antiseptic solution, and the powder is dusted on; it is then covered with cotton-wool. Next day all the loose cotton-wool is removed and more powder dusted on the adherent wool and fresh wool placed over this.

Eventually, the outer dressing is removed and the adherent wool allowed to separate naturally.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
